The acute diseases of the middle ear are not numerous and for our present consideration we may confine ourselves to the acute inflammations of the tympanum, together with the disturbances which usually accompany them. The different varieties of inflammation of the tympanum usually given by writers, such as simple catarrhal, purulent, suppurative, etc. are really only a difference in intensity and not in type, so that for convenience we may confine ourselves to the simple term "Acute Inflammation."

A question of interest to us here, is, are there serious results liable to develop from acute otitis media if left to run its course unmolested? I might, with equal propriety, ask if there is danger of serious results in a case of ophthalmia neonatorum if neglected? What would you think of a doctor who

[1] Read before the Michigan State Medical Society, June, 1891.

would say in such a case, "Well, suppuration is bound to come any way it and will get better after that," and not use the remedies which are known to be of great benefit in those cases, or who even failed to make use of one of nature's greatest remedies—warm water for cleansing purposes? We would even hold parents responsible in such a case for, at least, keeping the eyes cleansed, if they had no directions from a physician at all.

But how is it in the case of otitis media? The child, if old enough, complains of earache. This symptom alone in 90 per cent. of cases is an indication of inflammation and should receive attention. But the parent thinks it is only an earache and it will get well in a day or so, and even doctors are sometimes guilty of looking at it in the same light; perhaps some sweet oil and laudanum is dropped in the ear or a little tobacco smoke blown in and no investigation is made of the drum head, which in a great majority of cases would give positive evidence of the condition of the tympanum. Could we consider our duty done in the supposed case of ophthalmia, if we failed to expose the cornea and ascertain its condition? Just so, I hold, we are responsible if we fail to investigate the condition of the ear with equal care. It is just as easily done, and if it were ten times as difficult that would not excuse us from the duty.

In the former case, the danger is that of impairment or loss of function or possibly of the globe itself. In the latter case we have these same dangers and added to them, that of danger to life itself. It is unnecessary for me to consume your time with a description of the anatomical relations of the middle ear. It will suffice to mention some of the important structures in close proximity to this organ; viz., brain and meninges, internal carotid artery, vestibule and cochler, seventh nerve and mastoid cells. A consideration of these parts led Prof. Politzer to remark that, "The tympanum is bounded on the outside by the drum head and on the inside by death." What are the results that may follow acute inflammation of the tympanic cavity? It is true that many cases go on to an apparent spontaneous recovery without suppuration or rupture of the membrana tympani. It is also true that many of them do suppurate and perforate and may then recover without much impairment of function, but, on the other hand, many of them terminate in chronic suppuration with constant danger of acute attacks, which may involve important surrounding structures, to say nothing of the constant annoyance the patient has to bear. But let us go back to those milder cases, which we say have terminated in resolution, and see what becomes of some of them. The attack may be very mild, terminating in a few days. Perhaps the little patient has a naso-pharyngeal catarrh, and two or three times a year has an acute attack of rhintis or pharyngitis, which are also neglected as in the chronic trouble, and with each exacerbation of the throat disease there is also a congestion or mild inflammation in the ear, which also in time becomes chronic with obstruction of the Eustachian tubes and we have developed that disease we so frequently see viz., *Dry catarrh of the middle ear.*

One may say how could this have been prevented? I answer by asking how do we prevent trachoma following an acute ophthalmia? Is it not by judicious treatment of the acute affection? Just so in the case of the ear; in the acute stage we can use warm or hot water douches, and general antiphlogistic treatment and in severe leeching of tragus, and sedatives, and as the acute symptoms disappear, use inflation by Politzer's method, or any other good one, and at the same time apply appropriate treatment to the throat and nose.

It is not, however, my design to give details of treatment as this can be readily obtained from books if we are sufficiently interested to look up the subject. How can we bring about an improvement in this branch of our profession? As I intimated in the beginning, it can only be done by education. *First,* we must educate ourselves to look upon the organ of hearing as one worthy of our careful consideration and attention. It is true there may not be opportunities for brilliant results such as are afforded in some other branches. But our aim is not always to achieve great things; but to do well the small duties if we can thereby benefit suffering humanity.

How far and in what way must we proceed in our endeavors in this direction? It is evident that upon the specialist rests the first burden of the work. I believe it is our duty, upon every opportunity to impress upon our brother general practitioners the necessity of giving more attention to this work. They are the ones that come in contact with the families in their homes. They have charge of the little patients during the acute diseases with which inflammation of the middle ear is so likely to occur. They are able to teach parents the necessity and importance of giving attention to the sup-

posed dangerous earache, etc. The greatest stupidity is manifested among some of the lower classes in our large cities. One expression frequently used is, "there is no danger so long as the ear does not bleed."

In a report from eleven institutes, where especial attention is given to ear treatment in the cities of this country and of Europe, only one out of seven of the cases admitted was an acute malady. This shows how little attention is given to this matter by the people themselves. Probably the experience of every practitioner indicates the same heedlessness.

In conclusion let me urge upon each one the importance of doing what he can to bring the laity and profession as well to look upon this subject in its proper light. We have educated the people to take some care of their eyes and are very careful to correct errors of refraction, etc. This shows what can be done in other lines if we will only do our full duty, and labor to advance the science of medicine and its usefulness.

Special Correspondence.

A LETTER FROM BERLIN.

As Berlin has in recent years, developed as a medical centre of considerable importance; and has become conspicuously noteworthy, because of the discoveries of Koch, with the announcement within a few months, that he had found a remedy which exercised a curative action on tuberculosis, a few words in things medical, may not be without interest to the brethren in America.

Berlin is one of the cities, *par excellence*, in which the antiseptic theory was unconditionally accepted. But, alas! for human progress; Listerism, or even orthodox antiseptics, is thoroughly dead as far as Berlin is concerned. And, with the solitary exception of Koch, himself; who has three wards, in which he yet is continuing his investigations, at the Moabit Hospital, nobody here pretends to cure any species of tuberculosis with the lymph!

It appears, that even Von Burguran who was one of the most ardent advocates of the Koch treatment, has now, wholly discarded it, and, from the free manner in which I saw the mercurial oleates employed in these lupus patients, it would seem a question; which was effecting the cure; the mercury or the lymph.

In this connection, I might say, that while in Ireland I saw six cases of lupus, in the service of Dr. James Brown, in the South County Hospital, City of Dundalk. In all cases, the temperature chart showed well marked re-action at the time of inoculation. In all, there were too, well marked local changes in the ulcers. In many, the sores cicatrized over. Yet, in every instance, within two months after apparent cure, the ulcers broke out afresh.

Considering the rather questionable manner in which this mysterious medicament was withheld from the profession, and its elaboration and precise nature kept secret, until it was practically proven a failure, few will have the regrets which they might otherwise experience at the premature demise, of what promised to be, one of the greatest boons ever conferred on suffering humanity.

When one enters an operating room here, and sees the porcelained brick walls, polished and marbleized floors, glass tables, and numerous sterilizing ovens, he naturally asks himself; what has become of antiseptics?

Antiseptics are now seldom employed here, except in fœtid wounds, or where purulent changes are progressing; never in the cavity of the peritoneum.

The word now is vigorous asepsis. But there is danger, even with this, that it may be brought into disrepute, by young, inexperienced, and over enthusiastic operators, in carrying it to an absurd extent.

It, however, is an immense gain, to be able to dispense, at least, in part, to get rid of the slopping and splashing, inseparably connected with antiseptic douching and flushing, not only to the inconvenience of the operator, but to the peril of the patient; who has his body often chilled, in the performance of the tedious time-consuming operation, to which layer after layer of wet towels are spread over his bare integuments. The Berlin Hospitals, large and small, are all constructed on the pavilion plan. This arrangement is most conspicuously carried out at the Moabit Hospital, which covers more than ten acres of ground, consisting of thirty-two pavilions; each containing from thirty to forty patients. They are long, rather wide, with low, tarred paper roofs, and hard, smooth, stony floors. There are no cellars under them. They are well lighted and ventilated, and stand about forty feet apart. The group takes the shape of a horse shoe, with a large shaded yard for an area.

One can conceive many reasons why those isolated structures are not desirable, as serving the purpose of a general hospital, independent of economical grounds. For it is well known, that low-roofed buildings are very warm in summer, and very cold in winter; and are extremely difficult to heat and ventilate.

The ideal hospital is at Frederick's-Hain, a suburb of Berlin, in which the widowed Empress of the late Emperor, is actively interested. The operating theatre is a marvel of beauty. This hospital is U-shaped too. It consists of seven separate buildings, which, with their extensive grounds, are all walled in. A large proportion of the patients are very young children. Here, as in the large Bethanian hospital, they have dispensed with intubation of the larynx altogether, and have gone back to tracheotomy.

I saw three little patients in the diphtheria-pavilion with tubes in their trachæ. Steam is applied to their throats direct from the main supply, being conducted to the little patients in long narrow rubber tubes. This hospital is ventilated by indirect radiation. The air entering from above and passing out again close to the floor. I saw a hospital similarly constructed in Tewksbury, Massachusetts, not long since. This is the only possible effective system of ventilation, in large apartments warmed in winter by transmitted heat. The hospital arrangements here are excellent. The surgeons informed me that they have an abundance of everything in the way of supplies for dressings. The sick are nursed by orderlies and nurses. The latter serve from six months to a year, in learning, and then have to give in return three years after they have completed their novitiate.

The Bethelem hospital, controlled and owned by a Protestant order of nuns, is a fine institution. It occupies an extensive area, within the mural confines of which are nine separate buildings. By Dr. Holl, the chief of the surgical division, I was given a long opportunity to examine patients and make inquiries. I was quite surprised at the number of ununited fractured femora here after treatment. It occurs, I am informed, quite as often in the young and vigorous as with the old and decrepit. It is a favorite custom with them to apply starch-bandages on any sort of flesh wound to the extremities. They claim that it gives firmness and comfort to the parts, until the healing processes are complete. As a rule, they never apply the gypsum bandage until, at least one week has elapsed after the fracture. I was convinced that this is a move in the right direction. They first subdue all congestive and inflammatory action before the plaster-bandage is adjusted.

I saw three of Mikulitz's resection of the astragalus here. One had been in the hospital three years. There was bony anchylosis in none of them, and I was confirmed in my impression of the general uselessness of the operation in scrofulous disease of the ankle-joint, by these cases.

National prejudices die hard. Notwithstanding the generally admitted opinion that ether anæsthesia is the safest, yet they still use chloroform in Berlin, and, very seldom anything else.

No doubt Berlin must continue a great medical centre for some time for Germans and German speaking Americans. But for those in America, unfamiliar with the language, they may stop at the British Isles, at London, Dublin or Edinburgh, cities which have provided members of the medical profession whose names will go into immortality.

THOMAS H. MANLEY, M. D.
Berlin, August 10th, 1891.

SELECTED FORMULÆ.

ACUTE ARTICULAR RHEUMATISM.

Hatfield speaks well of the following liniment as a local sedative to the affected joints:

℞ Ol. gaultheriæ.....f℥ ss.
Spirit. chloroform.....f℥ ss.
Lin. saponis.....f℥ iij.
M. Sig. Apply freely and wrap the joint in cotton batting.—*Dis. of Chil.*

Internally the following may be given:

℞ Sodii bicarb.....℥ ij.
Sodii salicylat.....℥ ij.
Aquæ menth. pip.....f℥ iij.
M. Sig. f℥ij. every three or four hours.

The above formulæ seldom causes any nausea, as the salicylate is apt to do when given in syrup. The soda should be omitted when the urine becomes alkaline.—*Powell, Ess. Dis. Children.*

IRRITATING EYE-WASHES.

Franke (*Deutsche Med. Zeit.*) calls attention to the fact, that the installation of solutions of atropin, eserin and cocaine into the eye frequently gives rise to acute conjunctivitis. The reason of this is that these solutions are not antiseptic and generally contain mould or fungi. If these remedies are added in the desired proportion to a 1 : 10,000 solution of bichloride of mercury, they

will be kept antiseptic for an indefinite period, and not give rise to any irritative symptoms.

INHALATION IN WHOOPING-COUGH.

℞
Thymolis..... gr. xx.
Acid carbolicis.
Ol. sassafragis.
Ol. eucalyptus.
Picis liquidæ.
Ol. terebinthinæ, aa.....f℥ ij.
Ætheris.....f℥ iv.
Alcoholis, q. s. ad.....f℥ iij.

M. Sig. Put about 30 drops upon a pad of such size as to be conveniently hung around the child's neck, renewing the application every two or three hours.

In severe cases the inhalation treatment is supplemented by the internal administration of

℞
Acid carbolicis.....gr. iij.
Sodii bromid.....gr. lx.
Tinct. belladonæ.....gtt. xx.
Glycerinæ.....f℥ iij.
Aquæ, q. s.....f℥ ij.

M. Sig. f℥ij occasionally for a child 3 or 4 years of age.

—Jour. Amer. Med. Assn., from Dr. Beall Daniel's Med. Jour.

ASTHMA.

The following prescription is claimed by Dr. Brubaker to have a greatly beneficial effect in asthma:

℞
Liquor potassii arsenitis.....gtt. ij.
Potassi iodidii.....gtt. x.
Syrup. tolu
Aquæ, aa.....f℥ ss.

M. Sig. This dose t. d.

LUPUS ERYTHEMATOSUS.

℞
Zinci sulphatis.....℥ ss.
Potassi sulphureti.....℥ ss.
Aquæ rosæ.....f℥iij ss.
Alcoholis.....f℥ iij.

M. Sig. Mop on morning and evening for ten or more minutes at a time.

—Courier of Med.

ACUTE GASTRO-ENTERITIS.

℞
Creolin.....gtt. iij.
Cinnamon water.....gtt. lxxv.
Syrup marshmallow.....gtt. xxij.

M. Sig. Teaspoonful every hour for very young children.

—Schwinz.

Morris recommends the following:

℞
Bismuth subnit.....℥ jss.
Salol.....gr. xvj.
Menthol.....gr v.
Aq. destil, q. s. ad.....f℥ ij.

M. Sig. f℥j three or four times a day for child one or two years old. An occasional dose of Dover's powder added to the above when the bowels are too loose.

—Daniel's Med. Jour., June, 1891.

CREOLIN IN ERYSIPELAS AND ECZEMA.

Dr. Rothe has used in the treatment of erysipelas a creolin ointment containing—

℞
Creolin.....1½ parts.
Creta præp., axung. porc., aa...15 "
Ol. menth. pip.....gtt v.

This is spread in the thickness of the blade of a knife over the diseased parts two or three times a day, a thin layer of cotton-wool being applied as a covering. In from twelve to twenty-four hours improvement was always apparent, and the disease was cured in three or four days. The same ointment also did good service in a case of weeping eczema of the face, as also in several cases of eczema in children. A patient suffering from scabies was treated with a thorough washing with soft soap and inunction of this ointment, with such a decided effect that Dr. Rothe considers creolin to be undoubtedly a specific for the disease.—*Brit. and Colo. Drug.*

POWDER FOR ATROPHIC RHINITIS.

Hall recommends the following in the treatment of atrophic rhinitis:

℞
Bicarbonate of sodium
Borate of sodium } of each..... gr. v.
White sugar.....gr. xij.

This is dissolved in two ounces of hot water and snuffed into the nostril thoroughly. After this has been employed to loosen any secretion which may remain, intra-nasal instillations of weak solutions of alum, in the strength of 1 per cent., or in other cases sulphate of zinc, nitrate of silver, or powdered iodoform, or aristol, or salol, or boracic acid, are useful. After these applications it is well to apply to the mucous membrane of the nasal cavity a spray of eucalyptus as follows:

℞
Vaselin.....℥ij.
Essence of eucalyptus.....f℥j.

In other cases it is only necessary to spray the nostrils with liquid vaseline.—*News.*

SYPHILITIC ULCERS.

In *La Semaine Médicale,* the following prescriptions are given for the treatment of syphilitic ulcers:

℞
Salicylate of mercury
Carbonate of potassium } of each....gr. xv.
Distilled water.....f℥ vj.

Apply to the part by means of compresses, or if an ointment is preferred, the following may be used:

℞
Salicylate of mercury.....gr. xv.
Vaseline.....℥ j.

Mix and use externally.

OINTMENT FOR COMEDONES.

The *Canadian Pharmaceutical Jour.* quotes the following prescription, said to be used by Unna in the treatment of comedones:

℞
Solution of hydrogen peroxide.....f℥ij.
Vaselin.....℥ij.
Lanolin.....℥j.
Acetic acid.....f℥j.

Mix and perfume.

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

EDWARD T. REICHERT, M. D.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF PENNA.,
EDITOR AND MANAGER.

Nos. 518-520 MINOR STREET,
P. O. Box 843. Philadelphia, Pa.

THE MEDICAL AND SURGICAL REPORTER.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

At the termination of the period of subscription, we will promptly discontinue sending THE REPORTER unless directed to the contrary by the subscriber.

Remittances should be made by draft, check, postal note, or money order payable to Edward T. Reichert.

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy." Unless this is done, newspapers are not looked at.

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

THE OBSTETRIC FORCEPS AND IDIOCY.

The relation between forceps delivery and idiocy, cerebral palsies, and various brain lesions, is one which has attracted much attention among obstetricians and neurologists. That these conditions do follow instrumental labor is well established, hence it is of interest to examine the subject, in order to draw practical lessons concerning the use of the forceps. Aside from gross lesions produced by pressure or crushing, the damage to the brain is usually brought about by intracranial hæmorrhage, or thrombosis. A great many idiots are the first-born of a family, and the majority are boys. According to Jacobi asphyxia plays an important role in the etiology. I. Langdon Brown showed that forty per cent. of the idiots who were first-born children had a history of asphyxia.

In the *American Journal of Obstetrics*, June 1891, Jacobi, in a very instructive article, points out the anatomical conditions present in a *neonatus* which favor the occurrence of hæmorrhage. The blood has less fibrin, less salt, less hæmaglobulin, less soluble albumen, less specific gravity, and more white corpuscles than the blood of advanced age. Although the proportion of the heart to the rest of the body is largest about the time of birth, the arterial pressure is low, which condition favors venous stasis, hæmorrhage, or thrombosis. The elastic membrane of the arteries of medium and small calibre is thin and simple, especially where actual branches are given off. This arrangement also favors hæmorrhage.

These facts so succinctly stated by Jacobi show the wisdom of the teachings of modern obstetrics concerning the conduct of labor. Prolonged labor is very dangerous for the fœtus. Asphyxia and death, or worse, asphyxia and idiocy, are real dangers. The danger increases with the pressure to which the head is subjected; as when there is a large head in a normal pelvis, or a normal head in a small pelvis. The broad rule that

the second stage of labor should be completed within two hours to insure the safety of mother and child, is not an absolute one, but is a safe guide, only to be disregarded under proper circumstances. When the second stage is tedious, or the head becomes arrested in the pelvis, the forceps should be applied; primarily to save the fœtus from asphyxia, and secondarily to save the mother from fistulæ.

On the other hand the wise obstetrician will ever bear in mind that the forceps is an instrument capable of harm, and that the harm is due largely to the carelessness or lack of skill of him that uses it. Injury or death may result to the fœtus from a faulty application of the forceps, and especially from violent efforts at traction. When the head is high up the advantages of Tarnien's axis-traction forceps should cause its employment. Less force need be used—because well-directed—and less injury will be done. It is to be hoped that stories of obstetricians "pulling with all their might," "bracing their feet against the bed," etc., will cease to be heard. Such methods are unnecessary, can only do harm, and hence are reprehensible.

Agitation of this subject can result only in good; for while it will deter some of small experience from using the forceps, it will prove a healthy correction to those who have been violently abusing them. A careful use of the forceps *secundém artem*, will seldom injure either mother or fœtus. While forceps extraction accomplished by violence, or a failure to resort to the forceps under proper indications will result in many deaths or "spoiled babies" through cerebral traumatism or asphyxia.

Correspondence.

COMMENTS ON DR. J. MADISON TAYLOR'S LETTER.

To the Editor Medical and Surgical Reporter:—It is rather surprising that Dr. J. Madison Taylor in closing his admirable letter in your journal of the 29th inst. should say, in speaking of the warped ideas of the too radical or too conservative physician—"That these matters right themselves if left alone is no more true than that the body rights its functions unassisted." Judging from his comments, in the early part of his letter, on the ancient but rational treatment of maimonides, and his own reputation as a physician he certainly could not have meant what he said in allowing nature to play such an unimportant role in the cure of diseased conditions of the body. All human beings demand some object to worship, to adore; from the savage Hottentot who bows down to his pile of stones, to your civilized enlightened man who reverently recites the Apostle's Creed. This spirit of worshipping the unknown, the uncomprehended is closely allied to the blind confidence human nature reposes in any vaunted remedy for the relief of human ills; and it matters not whether it is composed of charms, incantations, Christian Science or drugs. We can overlook these superstitions in the laity who know little or nothing of the human organism. But why any physician, educated and observing as they all ought to be, can have the self confidence, the audacity to claim that his medicines will cure without nature's potent assistance should be deprived of his title. Of every hundred cases that the doctor "*cures*" ninety-nine would have recovered without seeing a drug with the claims of a quicker convalescence.

It requires no elaborate theorizing to prove this. The fact that homœopathy does not claim a higher mortality, not so high in fact, in some diseases, as when "*medicine*" is given; and the hue and cry that follows the birth of every new drug, each with its coterie of followers as fickle as a Roman populace. "Now this *drug* was (?) incomparable; and the ensuing night made it a fool and beggar," which goes to prove that nature is the great leader even though handicapped by every drug in "The Heavens above or the earth beneath."

Nature may ask our assistance but rarely does she demand our meddling interference with her laws.

J. Newton Hunsberger.

BRASS MOULDERS' DISEASE.

Editor of the Medical and Surgical Reporter:—I should like to submit a short sketch of Brass Moulders' Disease which has come under my notice, and I earnestly request that all who have had any experience on the subject will answer the few brief questions at the end of this article.

H. B——, aged 42, farmer. Until the fall of 1875 perfectly robust and healthy. In the fall of '75 he began brass casting and for the first six months was troubled very much with colic, constipation, chills and fever and became much debilitated.

He suffered much from loss of appetite and indigestion. Chills and fever at intervals until '86, a period of ten years.

Patient continued the work for ten years or up to the above period, 1886. In March 1886, symptoms of numbness set in, beginning in right hand, which grew cold, extending to elbow. Later left arm became affected in same manner.

In July '86, patient quit work. Complained of complete loss of appetite and a peculiar sensation like a tremor running the length of spinal column, also had severe neuralgic pains in the head. For three months lived an out-door life on a farm. Result: much improved in health, symptoms had nearly disappeared.

Resumed work in October. Symptoms almost immediately began to return, accompanied with severe neuralgic pains beginning in the lower limbs, sharp shooting pains passing from heel to calf of leg and knee, sometimes continuing up the limbs by way of spine to head, pains shooting up from back part of head over crown. Constant insomnia. After severe attacks would leave left shoulder and arm numb, which would disappear under rest. Lower limbs affected in the same manner, though left side and right leg affected the most.

All symptoms aggravated by heavy lifting or prolonged exertion, becoming alleviated during rest.

Quit work again January '87, totally unfit for labor. Did but little work in shop for nearly two years. Symptoms again gradually disappeared as general health was improved, though they were never removed entirely. This period of two years, patient spent in travelling all over the continent and Europe, also part of the time working on the farm. In walking, patient constantly complained of a sensation of pulling or drawing from limbs to back which seemed to fetter the gait, and was aggravated by over exertion.

Resumed work October '89, continuing to December 1st, '90, a period of thirteen months, when he quit work with a return of all the symptoms with the addition that his right leg was swollen to the body.

Treatment.—Complete rest. Much of the time in bed, with light exercise.

Resumed work May '91, with improved health but not fully recovered. Since which time to the present, three months, patient has continued at work and is doing so at the present time.

Present condition normal, very little numbness of hands and arms, right hand and elbow being most affected, sleeps well, appetite not quite as good as when he went to work in December.

In conclusion I wish to hear from some of your legion of readers brief answers to the following questions:

1st. What is the prognosis as to the ultimate result if the patient continues his occupation?

2d. The usual life history. Cause of death, etc., if death occurs?

3d. Should the patient continue his occupation or ought he to be encouraged to give it up?

4th. Are there any medicines that will cure or prevent the disease?

Wm. H. Burr, M. D.
Burrville, Conn.

PERISCOPE.

THERAPEUTICS.

HOT INFUSION OF DIGITALIS IN THE TREATMENT OF PNEUMONIA.

Dr. E. P. Hershey, writes in the *Medical News* that during the past three months, excellent opportunity has been afforded him to test the value of the treatment of pneumonia by means of large and frequently-repeated doses of the infusion of digitalis, given early in the attack. The marked benefits resulting in a few cases thus treated last fall suggested its great importance and bolder use. In twenty cases, the treatment was commenced by the administration of ten grains of the mild chloride of mercury, together with a tablespoonful of the infusion of digitalis, given every hour, as hot as the patient could drink it. In from six to ten hours, profuse perspiration occurred in every case, followed in twelve cases by a normal temperature. In three instances, the temperature, without the use of any antipyretic, dropped to 100°, in four, to between 101° and 101.5°, and in one, to between 103° and 105.5°. In no case was the temperature below 103° when first seen, and in all but one, it was ushered in by a distinct rigor. In all the cases the characteristic rusty sputum was

present, but its short duration showed clearly that the inflammatory process had been cut short.

The severest case was that of G. J., a laborer, aged thirty-two, in whom there was violent delirium from the outset. The patient having felt ill for nearly twenty-four hours, had a violent chill at 4.30 P. M., February 25th. At 6 P. M. the thermometer showed a temperature of 105.5°; the pulse was 130. His attendants had him strapped to the bed. Crepitant rales were heard at the base and over the middle lobe of the right lung, anteriorily and posteriorily. The patient was given ten grains of calomel, followed in one hour and a half by a tablespoonful of a hot infusion of digitalis, the latter being repeated every hour, despite the fact that the temperature at 11 P. M. had fallen to 103°, at 5 A. M. to 101°, and the pulse to 115, with a general improvement of all the manifestations of delirium. At 6 A. M. there was profuse expectoration of rusty-colored sputum, that continued for twenty-four hours. On the third day the temperature returned to 105°; after active purging, it fell rapidly. On the morning of the fourth day the pulse had dropped to 50, the temperature to 96°. The infusion of digitalis was discontinued, and a combination of camphor, strychnine, and quinine given. Convalescence was rapid, and just ten days after the beginning of the attack the patient was up and about. The loss of weight in this short attack was remarkable. At the beginning of the attack the man weighed about 168 pounds; on March 7th he weighed 144½—a loss of 23½ pounds.

That the hot infusion of digitalis acts quickly upon the cardiac muscle that forces the blood through the affected area and thus to a marked degree overcomes the dyscrasia, is probably the *rationale* of the action of the drug. The use of a large dose of calomel, by reducing the consistency of the blood, takes the place of the old-time method of bleeding.

Petresco used the remedy still more heroically, making an infusion of ten grains of the powdered leaves instead of seven, to the ounce, and giving a tablespoonful every half hour instead of every hour. There can be no doubt that the results obtained in the cases reported were due to the solution being given hot; Dr. Hershey found that, in the use of drugs intended to act quickly upon the circulation, their diffusion is more rapid if given hot. This method of administration was suggested by Dr. D. D. Stewart, of Philadelphia, who first reported that the administration of sulphonal in hot water gave better and more rapid results than when the drug was given dry or in cold solution. In the twenty cases treated no ill results followed these large doses of digitalis. However, it would be advisable to watch the circulation; in case of a sudden lowering of the pulse-rate, the infusion should at once be stopped, for this is an indication that the desired effect of the remedy has been obtained; should slow pulse and low temperature persist, nothing will stimulate better than camphor, quinine, and strychnine, in quantities suitable to the case. Alcohol was not used until the temperature had subsided. In none of the cases was the so-called standard remedy, carbonate of ammonia, used. Further investigation will be made with this method of treatment, and when a sufficient number of cases have been treated an additional report will be made. At present this method of treatment has yielded Dr. Hershey far better results than any other.

NERVOUS APHONIA OF FOUR WEEKS' DURATION CURED BY SUGGESTION DURING HYPNOTIC SLEEP.

Emile Müller (*Gaz. méd. de Strasburg—Gaz. hebdom. des Sciences Médicales*, April 4th, 1891) relates the following case: Miss R., thirty years of age, was sent to him by her physician to be treated for aphonia, from which she had been suffering for four weeks without interruption. She had had three previous attacks, none of which had lasted for more than a week. Expectorants, inhalations, the continuous current, all had been employed without effect.

Laryngoscopic examination was negative. Dr. Müller tried faradization without result. He then concluded to employ hypnotism. He succeeded in hypnotising her without difficulty, promising her that he could probably restore her voice, if she allowed herself to go to sleep.

While she was in deep sleep, he suggested to her that her voice had returned. He then asked her her name, and she replied in a clear, strong voice. She also answered other questions put to her. Dr. Müller finally raised her from the hypnotic sleep, and she, wishing to apologize for having gone to sleep, perceived that she was speaking in her natural voice. She remained under observation for about a fortnight, and had no further aphonia during that time.—*Jour. Nerv. Ment. Dis.*

IODOFORM IN THE TREATMENT OF BURNS.

Rottenberg (*Therap. Monatshefta*, March, 1891) advocates the following method of treating burns. He is surgeon to large iron-works, and sees many cases of all degrees of severity. The blisters, if present, are pricked, and a silk thread soaked in corrosive sublimate solution run through them, and allowed to remain. The whole surface, no matter what the degree of burning, is coated thoroughly with a thick layer of vaseline containing 10 per cent. iodoform, and then covered with gutta-percha. The ointment is renewed daily. The pain is always very speedily lessened, and healing takes place in an eminently satisfactory manner, and quickly.

THE TREATMENT OF CHRONIC ECZEMA BY CREOLIN.

Dr. R. Glasgow Patteson,in the Dublin *Med. Jour.*, calls attention to the fact that the value of tarry preparations in many forms of skin disease—especially psoriasis and eczema—has long been recognized. "If I were required to name one remedy only for eczema," writes Mr. Jonathan Hutchinson, "I would chose tar; if allowed to chose two, tar and lead; and if three, tar, lead and mercury;" adding his "belief that tar is the specific for all forms of true eczematous inflammations of the skin." The form in which he uses it, is the alkaline solution of coal-tar known as "Liquor Carbonis Detergens"—a teaspoonful to a pint of warm water. The cost of this preparation debars its use in out-patient practice, and it was the cheapness of creolin and its excellent antiseptic properties that induced me a year ago to try its effects in the treatment of chronic eczema. A short experience satisfied Dr. Patteson that the most useful strength was that of one drachm of creolin to eight ounces of water—roughly speaking—a teaspoonful to half a pint of water. In this proportion, from which Dr. Patteson has never varied, it forms a bland and soothing emulsion, milky in appearance, and with a strong tarry odor, which has a marked effect in allaying irritability and itching, prevents the formation of scabs and crusts, and appears in a striking manner to moderate the pus producing activity of certain forms of eczema. The mode of applying it which Dr. Patteson has found most efficacious is the following, which though applicable in the majority of instances, must yet, like every other remedy, be modified to meet individual cases.

The parts affected, having been freed from crusts or other accumulations, by appropriate means, should be freely bathed in the freshly-prepared emulsion for from ten to fifteen minutes. If the disease is in the acute stage, or if there is much secretion, lint soaked in the liquid may be applied over all parts, and retained in place by suitable dressings. But if the eczema is of the squamous type, treatment in the intervals is best carried out by means of ointments—that which has yielded in his hands the best results being one composed of zinc oxide, white precipitate, and the glycerine of the subacetate of lead. Under this treatment recent cases recover with astonishing rapidity, and even cases of long standing soon show signs of improvement which, in the majority of instances, goes on to complete and permanent recovery. In only a few instances has it failed to do more than alleviate the condition.

He has since tried the remedy in cases of scaly eczema and psoriasis with marked relief to the irritability and itching, but it is still too soon to form any judgment as to its curative powers. But in the infective pustular eczema it is an agent that effectually controls the process, and well deserves a trial on a larger scale. If we accept Unna's definition of eczema as "chronic parasitic catarrh of the skin, with desquamation, itching, and the disposition to respond to irritation by exudation and well-marked inflammation," then we have a rational basis on which to ground our treatment by such an active germicide as creolin.

MAGNESIA AS AN INTENSIFIER AND PRESERVATIVE OF PEROXIDE OF HYDROGEN.

It was ascertained some time ago that when calcined magnesia is added to peroxide of hydrogen the bleaching action of the latter upon cotton is greatly intensified.

Prud'homme has recently studied this behavior, and has found that there is produced a peroxide of magnesium which is much more stable than the peroxide of hydrogen, even at a boiling temperature.

If a 6 volume peroxide of hydrogen is diluted with 10 parts of water, and then boiled for half an hour, its strength is reduced in the proportion of 100 to 10.

But if, under the same conditions, there are added 5 Gm. of calcined magnesia for every 100 parts of peroxide present, the half-hour's boiling will reduce the strength in H_2O only by one-tenth (from 100 to 90).

The formation of the peroxide of magne-

sium is rendered evident by proceeding as follows:

Place calcined magnesia [5 parts] in contact with a 3-volume peroxide of hydrogen [100 parts] at the ordinary temperature, and allow them to re-act for some time [the original says "from several hours to several days"]. Then filter, wash the contents of the filter, and dry at 100° to 105° C.

On assaying the product with permanganate of potassium, it will be found to have the composition $3Mg(OH_2).MgO(OH_2)$. This compound loses its active oxygen at a temperature of about 300° C.

The bleaching effect of a mixture of magnesia and peroxide of magnesium is due to both agents acting together. When fatty substances, such as oils, are bleached by these agents at a boiling temperature, there is an abundant escape of carbonic acid gas, due to the oxidation of glycerin.

Peroxide of hydrogen alone, when very slightly acidified, is capable of attacking neutral fats, producing therefrom fatty acids under evolution of carbonic acid gas.—After *Compt. Rend.*, 112, 1374.

[*Note by Ed. Am. Drugg.*—The facts above given may be utilized in surgical practice, in which peroxide of hydrogen is at present playing an important part as an antiseptic and disinfectant. The addition of magnesia will, in many cases, not be objectionable; and when it is desired to have the peroxide act rather slowly and gradually, no better method can be employed.]

SULPHONAL IN THE NIGHT SWEATS OF PHTHISIS.

Dr. Erede, of Genoa, calls attention (*Riforma Medica*, May 22nd, 1891), to what he calls "the marked antidiaphoretic action of sulphonal." He says that if given in the early hours of the evening it almost invariably succeeds in suppressing or greatly diminishing the night sweats of phthisis. A dose of half a gramme, given in the form of pastille or suspended in some gummy vehicle, generally suffices. The largest amount given was 1 gramme; this failed of its effect only in a very few cases in which the disease was extremely advanced. As no untoward effects were ever noticed, even in very debilitated patients, Erede thinks that with proper precautions the drug might be pushed up to 2 grammes, the usual hypnotic dose. In many cases he observed that in discontinuing the sulphonal after a time the sweating did not begin again at once, but only after some days, when it was immediately checked by repeating the medicine. This shows that the organism does not readily adapt itself to the prolonged use of the drug, as it does, for instance, to certain narcotics. Erede is inclined to think that the effect of sulphonal in checking diaphoresis is to be explained by its action on the nervous system.—*Brit. Med. Jour.*

FORMIC ACID IN SURGICAL TUBERCULOSIS.

In a paper read before the German Surgical Congress, Dr. Senger stated that his attention had been drawn to the fact that, in the treatment of surgical affections with iodoform-glycerine emulsions, the effects produced differed greatly, according to quality of glycerine employed. It was found that impure glycerine contained always a certain amount of formic acid, the proportion varying according to its degree of impurity. This led him to infer that the marked irritating properties of the formic acid might have some share in the curative effects of iodoform emulsions in tuberculous processes. The fact that iodoform, when introduced into the body, is converted by the process of oxidation into formic acid and hydriodic acid, explains its varying effects in different cases. When oxidation is sufficiently active to decompose it, iodoform exerts a curative action, which is not manifested when the process of oxidation is feeble. For these reasons the author added formic acid to iodoform emulsions and obtained favorable results, where the latter proved ineffective. In cases of tuberculous affections of the glands, and in a case of tuberculous arthritis of the ankle joint, formic acid was used alone, the formate of soda in solutions being injected. The results were excellent.—*Deut. Medicin. Wochenschr.*, No. 17, 1891.

BULL NETTLE—A NEW ALTERATIVE.

Dr. W. W. Pugh, M. D., states in the *Southern Practitioner* that he has been experimenting for some time, more than two years, with the root of a plant that grows in Texas, known by botanists as *jatrophia stimulosus*, and commonly called "bull nettle." He has found it to be specially adapted to the treatment of syphilis.

It is a stimulant of unusual power, and a most excellent alterative. He has treated quite a number of syphilitic patients, suffering from the worst forms of the disease, and has relieved them in three or four weeks, the

symptoms not having re-appeared in those treated over two years ago.

He makes a tincture of the root, and gives from twenty to thirty drops, three times a day.

MEDICINE.

RESUSCITATION BY OXYGEN.

Lieut. Col. Henry Elsdale's experience with oxygen as a resuscitating agent, related in the May number of the *Nineteenth Century*, is evidently considered by him (and by the editor of the magazine), as something wholly new. While far from being a novel application of oxygen, the case appears to be unique in the extraordinary pressure employed. A man who had been attempting to empty the coal-gas from a balloon was found lying insensible, "having been breathing an atmosphere of coal-gas for an unknown time." "No action of the heart could be felt," there was "no perceptible breathing," and to all appearances the man was dead. Pure oxygen being at hand, under a pressure of 1000 pounds to the square inch, a tube connected with the reservoir was inserted into the man's mouth, and the gas turned on "as delicately as possible." Immediately the body began to exhibit writhings and convulsions, and in about ten minutes the man arose, well.

That wonderful physician who, a century ago, honored the chair of chemistry at Oxford, Thomas Beddoes, the worthy friend and co-laborer of Joseph Priestley, Erasmus Darwin, James Watt and Humphrey Davy, demonstrated, among other things too little remembered by the profession, that kittens and rabbits that had inhaled oxygen for a certain time were more resistant to drowning, freezing or suffocating with irrespirable gases, than similar animals not saturated with oxygen.

Since the time of Beddoes, numerous observations proving the usefulness of oxygen in resuscitating the drowned or those poisoned with narcotic drugs or asphyxiating gases have accumulated. In J. Solis-Cohen's treatise *On Inhalation*, we read that previously to 1847 it had been proposed by Jackson and Richardson that "wherever ether was administered oxygen should be kept in readiness to be inhaled in case of the occurrence of formidable symptoms, and that Mr. Hooper, acting on the suggestion, has supplied his inhaler with the means of furnishing oxygen at pleasure." Ducroy "proposed to make every patient awakening from chloroform-narcosis inhale oxygen, in order to rid him of headache and other inconveniences following the administration of that anæsthetic," and a very remarkable instance of recovery from chloroform-narcosis by the use of oxygen, which occurred at the New York Medical College, was published by Abrahams in 1853.

Notwithstanding all this, and despite the fact that modern commercial enterprise has made it perfectly feasible always and everywhere to have the agent at command, there are many Hospitals in which oxygen is not ready for instant use in emergencies, and it has not yet been recognized as an indispensable part of the outfit of life-saving stations. We believe that, not only in every clinic or private house where ether or chloroform is to be given should oxygen under pressure, be instantly available, but that in hotels where persons are liable to be poisoned with coal-gas, and even in police-stations where persons poisoned by opium are likely to be taken, it should always be possible te find a reservoir of the gas. At seaside resorts, too, it should be part of the rescuing paraphernalia kept at the beach. A single life saved, and there would be many, would more than compensate for the cost. The pressure appears to have been a factor in Elsdale's case, and in any case the administration of oxygen should be accompanied with slow and regular movements of artificial respiration. B. W. Richardson has shown that in artificial respiration the emptying of the lungs is ordinarily as important as the filling of them; and in his simple device of a double hand-bellows for that purpose, artificial expiration by suction plays an equal part with artificial inspiration by pressure.—*Med. News.*

A CASE OF FOUR ATTACKS OF APPENDICITIS IN ONE YEAR—EXCISION OF THE APPENDIX—ABSENCE OF ANY FURTHER SYMPTOMS A YEAR AFTERWARDS.

Dr. A. Ernest Maylard, says the *Lancet*, in view of the recent discussions which have taken place regarding the treatment of this particular class of diseases, the record of the present case may not be without interest. The patient, Mr. G. G——, a strong and healthy young fellow of twenty-one, was under the care of my friend, Dr. Alex Napier, of Crosshill, to whom it had suggested itself that the case was one particularly well suited for the operation of excision of the appendix. He asked me to see the patient with him,

and I concurred both in the diagnosis and in the treatment proposed. The clinical notes of the case, as furnished by Dr. Napier, are briefly as follows:—June 4th, 1889: First attack slight, lasted only a few days, and subdued by rest and a few doses of an opiate. Constipation, pain and tenderness in right iliac fossa, some distension; temperature not much elevated. July 14th: Second attack, after lawn tennis, very severe; temperature ran up to and over 103° F.; pulse rapid; vomiting for several days; constipation; coated tongue; marked distension, universal tenderness, and tympanitic percussion note. Most acute pain in right iliac fossa. Patient very seriously ill for a few days, but gradually recovered, as before, by rest, opiates, poultices, and limited diet. Oct. 7th: Third attack, after some indiscretion in the way of exercise. Again a severe attack, much like the last; overcome in the same way. April 2d, 1890: Fourth attack, less severe than the last two, but marked by exactly the same general symptoms. In all four attacks, as the symptoms passed off, the pulse fell markedly—to 44 on one occasion. On April 8th I saw the patient with Dr. Napier, he was then recovering from his attack. We had him removed to the Training Home for Nurses, where, with the assistance of Dr. Rutherfurd, I excised the appendix on the 16th. Operation: An incision was made in the nipple line, over the cæcum and ascending colon. The presenting bowel was traced downwards until the junction with the ileum was reached. The finger, then inserted beneath the cæcum, felt the appendix distended and fixed. It formed a tense elastic tumor about the size of a little finger. For about half an inch at its cæcal extremity it was normal in calibre, but from that point onwards the appendix was dilated. Around this narrow normal part of the appendix a double ligature was passed, and the neck divided between. In the first attempt to detach the appendix from its connexion it burst, and some mucus-like material escaped. The adhesions were in some places intimate, but at others recent and very vascular. After complete severance the oozing was so free that pressure had to be applied for some short time. The wound was dressed once after the operation, and healed by primary union. The patient's temperature was normal throughout his recovery, and no untoward symptoms of any kind showed themselves. He was kept rigidly on his back for a month to allow of firm union in the parietal wound. State of the appendix: On slitting up the viscus it was found to be empty, and on everting it the lining of its walls had the appearance of pulpy granulation tissue. No canal could be made out at its cæcal extremity.

It is now a year since the operation. The patient has enjoyed perfect health, and is quite free from any feeling of weakness in the region of the cicatrix. The diagnosis of catarrhal appendicitis proved correct, and so, also, would seem the treatment. Whether this patient would, by conservative measures, have reached a period when no further repetition of his troubles would have taken place, or whether the time might have come for opening an abscess in the region of the appendix, or even graver measures, it is impossible to say. The operation can hardly be said to have carried any risks with it, and its result was and has been to relieve him completely of his trouble.

PYOGENIC COCCI IN THE SWEAT IN PYÆMIA.

Dr. Anton Freiherr von Eiselsberg, Assistant in Professor Billroth's clinic in Vienna, reports (*Berl. klin. Wochenschrift*, June 8th, 1891) the dicovery of pyogenic cocci in the sweat of a man aged 31, the subject of pyæmia, following osteomyelitis of the femur. The patient was somewhat relieved by operative procedures, and these were followed by excessive sweating, but he ultimately died with multiple pyæmic abscesses. Both in the pus from the original seat of disease and in that from the metastatic abscesses and also in the patient's blood, a large quantity of staphylococcus pyogenes aureus was discovered. In order to examine the sweat, the patient's forehead was very carefully cleansed and disinfected, and specimens of sweat were taken from various parts of the skin so cleansed directly they appeared. Inoculations into cultivation tubes were made, and it was found that in agar and gelatine no result took place, but in two agar tubes a growth ensued, which on further inoculation was proved to consist of staphylococcus aureus. Cultivation on plates and frequent repetition of the experiments were followed by similar results. The presence of the identical micro-organism in the pus and in the blood and in the sweat, after the most elaborate precautions had been taken to prevent contamination of the skin, would seem to warrant the conclusion that the coccus is actually present in the sweat and is excreted from the body with it. The improvement so commonly noted after excessive sweating may perhaps be directly

dependent upon this excretion, and at any rate should direct attention to the treatment of the skin in such cases, so as to favor as far as possible the excretion of sweat when the disease is presumably due to the presence and activity of the staphylococcus aureus.—*Brit. Med. Jour.*

PAINFUL SENSATIONS IN HEART-DISEASE.

While the subjective manifestations, dyspnœic troubles of all sorts, from which those afflicted with heart-disease suffer, have received full consideration by physicians at all times, the subjective sensations of pain which accompany valvular disease have received but slight notice.

Of 483 cases of heart-disease treated during the last seven years in Nothnagel's clinic, 127 (i. e., 26.2 per cent.) manifested painful sensations. Nothnagel excluded from this list all cases of paroxysmally recurring attacks of stenocardia; moreover, under painful sensations were included only those pricking, tearing, burning and boring pains in the cardiac region, which were more or less constant. At times the patients described a sensation as though the heart were being torn out; or there suddenly came on an excruciating pain, during the continuance of which the heart pulsated with great force. In either case, the pain was located in the left side or in the back. At times there occurred a feeling as if a foreign body lay in the left thoracic cavity, as if there were a sore in that region, or as if the heart trembled with pain. Nothnagel makes a further observation, however, which has not before been recorded, namely, that in these cases the objective sensibility is increased, and that not only in cases of paroxysmal stenocardia, but also in other painful conditions. Gently pinching a fold of the skin, lightly pricking with a pin, or pressure over an intercostal space in the line of an intercostal nerve, in the precordial region, elicits great tenderness, sometimes even severe pain.

In uncomplicated disease of the heart-muscle (myocarditis, fatty degeneration, arterio-sclerosis, and idiopathic hypertrophy), the subjective sensations are so pronounced sometimes as to almost establish the diagnosis. The clinical picture in these cases is similar to that of valvular disease.

The author does not give us a clear and uncontrovertible explanation of these painful phenomena, but leaves us to consider the algesia-cutaneous hyper and neuralgia eccentric irradiating manifestations.—*Zeitschrift für klinische Medizin*, Bd. 19, Heft 3.

SURGERY.

THE TREATMENT OF CHRONIC ULCERS BY MASSAGE.

Dr. A. Ernest Maylard, in the Glasgow *Med. Jour.*, publishes a short contribution to advocate a methed of treatment for a very common and always a very troublesome class of cases—that of chronic ulcers of the legs. The subject is based on a few cases which have been successfully treated in the wards of the Victoria Infirmary, the histories of which are related. The principles on which the treatment is founded, and its mode of application, are thus briefly described:

As a rule, these chronic ulcers arise from some slight accident to an area of the limb already in a condition to break down at the smallest incentive. The parts are in a condition of passive stagnation and engorgement, the result either, as most frequent, of varicose veins, or of some other obstructive influence. The result of this passive engorgement is a hyperplasia of the connective-tissue element, leading to much thickening of the parts around. This is shown by the denseness or hardness of the soft tissues, and not infrequently by some enlargement of the bone due to sub-periosteal deposits. Still further, the blood stagnation renders the new formed tissue, as also that of the old, of very low vital powers. An ulcer, then, once formed is only too likely to extend. Another important factor is the mechanical obstruction which this venous engorgement and tough new formed tissue causes in preventing the entrance of fresh arterial blood *to* the part, and the exit of used up material by the lymph channels *from* the part.

What, then, is needed in the treatment of these cases is 1. the relief of the engorged condition of the veins by the removal of the cause which engorges them; 2. the relief of the plugged condition of the lymph vessels; 3. the re-admission of arterial blood to the part; and 4. the removal of deleterious exciting influences from the surface of the ulcer itself.

The recumbent position, which is usually enforced on the patient, or, failing that, the application of an elastic bandage when the patient is erect, usually aids much in removing the cause of venous engorgement of the part. But helpful as are these passive measures they far from supply all the needs required. More active treatment is requisite to effect an entrance of arterial blood to the part, and an exit of effete material from it. This can only be done by "massaging" the

limb—to wit, by rubbing, pinching, and kneading the part. The forcibly stroking the limb in an upward direction tends to drive on the venous blood, and let in the arterial; to force out the contents of the lymphatics, and to allow the entrance of other effete products.

In order to massage the floor of the ulcer, he has adopted the following plan: A piece of jaconet, sufficient in size to be held tightly around the limb, is dipped in some 1 in 2,000 bichloride of mercury solution, and then placed with its non-glazed side over the ulcer and surrounding parts. The smooth surface is dried, and a small quantity of vaseline smeared upon it. The palmar surface of the hand is by this means permitted to pass easily over the ulcer, and thus admit of its being massaged like the surrounding parts.

While the immediate result of this treatment has in every way proved good, he believes its more remote effects will be found to be equally valuable, for the cicatrix of an ulcer that has been massaged is seen to be well vascularized, and therefore much less likely to break down than when the ulcer has sluggishly skinned over. Further, it is a treatment which can and should be continued by the patient, so as to maintain the parts in a healthy condition.

Where these ulcers are associated with varicose veins, such veins ought to be exercised; and thus a potent factor in the cause of the passive engorgement of the part removed.

The only other operative procedure (with the exception of skin grafting) which is sometimes of service is to dissect up a flap from the immediate neighborhood of the ulcer, twist it round over and on to the freshened surface and edges of the sore. As with skin grafting, this should be done when the ulcer is healing. For by this time the massaging of the part has revivified the floor of the ulcer, and rendered healthier and more active the skin around.

With regard to the fourth requirement, the removal of all deleterious exciting influences from the surface of the ulcer, this simply means the cleansing of the ulcer from all septic matter.

The following are his conclusions:

1. Improvement shows itself at once, and is most marked during the first week or two. The heaped up skin edges begin to disappear, and a sloping healing blue line is observed. The floor of the ulcer soon shows healthy granulations. The surrounding skin becomes early whitened or mottled, indicating the complete emptying of the congested venules.

2. Later, the skin around becomes more pliable, and can be pinched up and freely moved on the underlying tissues.

3. The cicatrix formed is well organized, and thus less liable to break down.

4. The treatment can be carried out by a nurse or by the patient's friends, and the massaging should be continued after healing has taken place, in order to maintain the skin and soft parts in a healthy condition.

OPERATIVE TREATMENT OF HYPERTROPHIED PROSTATE.

Bottini, of Pawia, related at the Berlin meeting of the International Medical Congress (*Wiener Medicinische Wochenschrift*, May 23rd, 1891) his methods and results in the treatment of 57 cases of hypertrophy of the prostate gland, by Galvano-cautery. His apparatus consists first, of a Galvano-cautery of about the calibre and curve of a Mercier's catheter, which contains four tubes; two for the transmission of electrical currents, and two for a stream of cold water with which to cool the apparatus, and; second, of a thermo-Galvanic knife for simply incising the gland. The first apparatus, which is for simple destruction of tissue, is suited for cases of partial or slight enlargement; the second for cases in which the hypertrophy is complete and uniform, or when, if partial, it is very great. The cautery knife resembles a Mercier's inciser with the difference that its edge is formed of a dull platinum rim, and also that it has two tubes for cold water.

There are three stages in the operation: 1st. Introduction, which is in accordance with rules for introduction of catheter: 2nd. Cutting or destruction of tissue, with heat *not greater than a red glow*, which is manifested by the hissing sound of burning tissue. 3rd. Removal of apparatus, also in accordance with rules for removal of catheter.

Of the 57 cases treated, 32 were completely cured, 11 improved, 13 without improvement, while 2 died. The fatal results were obtained with the old apparatus, before the introduction of the cold water tubes.—*Amer. Lancet.*

CEREBRAL SURGERY.

Dr. Frank P. Norbury, in the *Medical News*, in summing up what can be done in cerebral surgery quotes the conclusions of a report read before the International Medical Congress, 1890, by Victor Horsley, of Lon-

don, one of the foremost surgeons and experimenters in this line of work:

1. Operation should be done in every case of brain injury. It is the only means of restoring the patient to a normal condition and may prevent epilepsy and dementia.

2. In every case of intra-cerebral hæmorrhage, seen within four hours of the apoplectic attack, the common carotid artery should be tied.

3. Trephining should be done in cases of headache refractory to all other measures.

4. Cerebral gummata should be removed; iodide of potassium palliates but does not cure them.

5. Tubercles should be removed when practicable.

6. Operation should be performed when other tumors are present, even when multiple, if relief is not obtained from other measures in six weeks.

7. Operation should be performed for athetosis and other spasmodic affections.

8. Operation should be performed for Jacksonian epilepsy, after first testing the cortex with the faradic current to locate the point of origin of the convulsion.

9. Operation should be performed for fracture of the vertebral column when compression exists.

10. Operation should be done for paraplegia from spinal caries.

Horsley represents aggressive cerebral surgery. Perhaps he is an extremist, or possibly we have not yet awakened to the possibilities of operative surgery in diseases of the brain and spinal cord.

THE SURGERY OF THE CAUDA EQUINA.

Dr. Leopold Laquer, in the *Neurologisches Centralblatt*, describes a case of compression of the cauda equina that came under his notice in September, 1888. The patient at that time complained much of a pain in the sacrum, and was unable either to sit or to lie with any comfort. In December, 1889, there was an exaggeration of the previous symptoms, with marked alteration in motion and sensation, as well as some atrophy of the lower extremities. The electrical re-actions of both muscles and nerves were normal, and the reflexes were normal. Despite all treatment, the symptoms of pain and stiffness of the lower part of the back continued to increase in severity until September, 1890, when the patient was able to move only in the most careful way, and was obliged to hold his back in an attitude of extreme kyphosis. On the right side the patellar reflex was abolished, and on the left side it was very weak. Sensation was absent in the scrotum and perinæum, and also in the lower extremities. The sexual power was weak. There was some atrophy of the quadriceps of each side, but there were no trophic changes, and there was no ataxia. The patient's condition was one that obviously called for interference of some sort, as death from exhaustion was imminent. The symptoms, taken collectively, led the author to the diagnosis of compression of the cauda equina, from some unknown cause, followed by generative neuritis. Dr. Louis Rehen cut down upon the sacrum, and, laying open the entire canal, disclosed a small extradural tumor in the middle of its lumen. After its removal, further examination of the growth showed it to be a lymphangeioma cavernosum. Recovery was prompt. By the end of the second week after the operation the patient was free from pain, and sleep was natural. Four months later there was only a small opening left in the sacrum, the patient was able to go about holding the body in a normal attitude, the functions were nearly restored to the normal state, and the reflexes, though still diminished, were equal on both sides.—*N. Y. Med. Jour.*

STATISTICS OF STOMACH AND BOWEL RESECTIONS.

At the International Medical Congress last year at Berlin, Billroth reported the results of stomach and bowel resection. He gave the statistics of 124 resections which had been made in his clinic from 1880 to 1890; of which 83 were by himself, 3 by Wolfler, 8 by Hacker, and 15 by Saltzer and Eiselberg. The cases were all chronic processes with pyloric stenosis, malignant forms of swelling. There were 41 cases of pyloric resection (7 male and 34 females, with ages of from 26 to 58 years). The operations lasted from 1¼ to 3½ hours, with removal of 4 to 21 centimetres of the intestine. The cause of operation was: In 28 cases carcinoma; in one case sarcoma; in 12 cases callous cicatrices. Results; 19 cases recovered, 22 died. Of 27 typical pyloric resections, 12 were favorable and 15 fatal. Of the 13 cases of carcinoma that had endured the ordeal of the operation, 5 died after 10 months, and one after 5¼ years from recurrence. There were yet living three women of whom two had been operated upon 2½ and 4½ months.

There were six operations on account of scar stenosis, of whom three recovered. One patient died after three months from peritonitis, caused by an abscess in the cicatrix.

There were 28 gastro-enterostomies on account of carcioma with 14 recoveries. These all died in from one to eight months.

Of 11 resections of the small intestines (7 male and 4 females) all were favorable. (Eight times on account of preternatural anus, once traumatic opening of intestine, and once carcinoma).

Of 24 resections of the cœcum, there were eleven on account of carcinoma (with five recoveries); thirteen on account of fistula after perityphlitis (seven recoveries, five deaths, and one persistent fistula). Of total cases of cœcum resections, eleven deaths, thirteen recoveries.

Of 8 colon resections, four deaths and four recoveries.

Of 7 resections of rectum all recovered, five times with formation of fistula.—*Wiener Med. Wochenschrift.*

GYNÆCOLOGY.

THIOL IN DISEASES OF WOMEN.

Gottschalk (*Centralblatt f. Gynakologie*, March 21st, 1891) has used thiol in inflammations of the uterus and its appendages for nine months. He treats para and perimetric exudates with vaginal tampons impregnated with a ten or twenty per cent. glycerine solution of the drug. At the same time he has the abdomen rubbed once daily with a salve containing the same remedy. After the tampon has been placed, the patient, as a rule, feels a "drawing up" of the belly, and there is a free flow of vaginal secretion. The tampon is removed in twenty-four hours, and the flow ceases. The local effect of the drug on the skin of the abdominal wall is much the same as that of tincture of iodine. After six or eight days' application, it is well to intermit this part of the treatment until the skin has regained its normal condition. Under this treatment, which will eventually be supplemented by the internal use of the drug, large pelvic exudates have disappeared in a few weeks. Up to the present time, Gottschalk has not failed to cure any case of this kind by this treatment, which has passed through his hands. Baths and massage are very useful adjuncts to the treatment. Inflammatory erosions about the vagina are treated with equal success by dusting them with a dry thiol powder. Acute and chronic endometritis also yield readily to the remedy applied in solution on an applicator. The application is painless and without danger. The uterine colic which follows the use of iodine is not met with. No serious irritation has been observed to follow either the vaginal or intra-uterine applications. At times a slight blood discharge is seen to follow immediately after the treatment, due to the local irritating action of the drug upon the uterine mucous membrane. The mucous membrane is exfoliated after many applications.—*University Medical Magazine.*

MOLAR PREGNANCY AND ALBUMINURIA.

Dr. Schuhl (*Archiv. de Tocol. et de Gynéc.*, June 1891) discusses the question as to whether albuminuria in pregnancy is sometimes the cause of myxomatous degeneration of the chorionic villi. After a search through many statistical records, he believes that it may be laid down as a fact that albuminuria in molar pregnancy is usually precocious, as is very clearly indicated in 7 out of 132 cases of this form of abnormal gestation. In 1 of the 7 cases of albuminuria, the albumen appeared during the first month, in 1 during the third, in 3 during the fourth, in 1 during the fifth, and in 1 where the uterine fundus reached to about the level of the umbilicus. On the other hand, many authorities have shown that in otherwise normal gestation albuminuria most frequently occurs during the last three months; being very rare during the earlier periods. Dumas, Dr. Schuhl observes, quotes cases where albuminuria has appeared at the sixth week, and the third, fourth and fifth month, but maintains that these are quite exceptional. The rule, according to Dumas, is that in primiparæ albuminuria commences between the seventh and eighth months, whilst in multiparæ it does not begin until the ninth. From the above evidence, Dr. Schuhl concludes that there is some obscure relation of cause and effect between albuminuria and hydatid degeneration of the chorion.—*Brit. Med. Jour.*

HÆMATOSALPINX AND TUBAL GESTATION.

Dr. J. Veit (*Centralbl. f. Gynäk.*, May 30th, 1891) discusses the now very important question as to the distinction between ruptured early extra-uterine gestation and hæmatosalpinx from other causes. Under the latter category come cases of hæmorrhage into a tube already distended,

and cases where the distension follows the bleeding. Dr. Veit relates a case of hæmorrhage into a tube following torsion of a hydrosalpinx. New growths and even injuries may cause hæmorrhage into the tube, but such cases are very rare. The "tubal mole" is a difficult subject. The presence or absence of chorionic villi amongst the coagula in these cases is not the only distinction between ruptured tubal gestation and hæmatosalpinx. The abdominal end of the tube is always open in cases of early tubal pregnancy, excepting where migration of the ovum from the opposite ovary through the opposite tube and across the uterus has occurred. A distinctly closed ostium, sealed up by the usual inflammatory processes, in a tube full of blood or clot otherwise indicates hæmatosalpinx not due to abnormal pregnancy. This closure of the tube is also present in the hæmatosalpinx of atresia of the lower genital tract.—*Brit. Med. Jour.*

TORSION OF PEDICLE OF AN UNDIAGNOSED OVARIAN CYST IN THIRD MONTH OF PREGNANCY.

Dr. Baudron (*Bull. de la Soc. Anat. de Paris*, April-March, 1891, pt. 10) describes a case where a patient, aged 28, was seized with violent pains in the left iliac fossa in the third month of her third pregnancy. She had previously noted occasional pain in the same part. The whole abdomen was now swollen and tender. For a week the violent pains continued, becoming more severe at regular intervals, so that abortion was suspected. There was no rigors, no nausea, no vomiting. Diagnosis was very uncertain, parametritis, retro-uterine hæmatocele, and hydramnios being suggested by different observers. The uterus was of the size normally observed at the end of the seventh month, though the menstrual history indicated that pregnancy had not advanced beyond the third. On the tenth day the patient vomited, the abdomen felt very tender, and intermittent pains had been continuing for a week. M. Pozzi operated on the next day; digital exploration had proved that there was no evidence of threatened abortion. A dark liver-like body, fluctuating and adherent to the intestine, uterus, and and great omentum, lay above the uterus, which was, as expected, gravid, and at the third month of pregnancy. The body was punctured, and six quarts of dark fluid, fœtid blood escaped. The body was the left ovary, cystic, and with a large pedicle twisted three times from right to left This pedicle had been detected by palpation a few days previously, and taken for ectopic pregnancy in a rudimentary uterine cornu. The pedicle was ligatured and the tumor removed, the peritoneum flushed, and the wound closed, excepting at the inferior angle, where a strip of iodoform gauze was passed into Douglas's pouch. Abortion took place next day, and a dead macerated fœtus was expelled, without flooding. Three hours later, as the patient was asking for some drink, she was seized with a fatal attack of syncope.—*Brit. Med. Jour.*

OBSTETRICS.

THE CAUSES AND TREATMENT OF PUERPERAL OSTEOMALACIA.

Dr. H. Fehling, in the *Archiv. für Gynäkologie* says that the results in cases of puerperal osteomalacia have heretofore been exceedingly poor. According to Litzmann's and Hennig's statistics, eighty per cent. of the cases died. Cesarean section (Porro's method) gave better results than any other plan of treatment. According to Baumann, out of forty-four cases of osteomalacia who were delivered by this method, twenty-six recovered. Of these twenty-six, five died from other causes, such as heart disease, nephritis, and tuberculosis, leaving twenty-one cases who made excellent recoveries. These results led Fehling to believe that the removal of impregnation and nursing effected a cure, and, arguing from this, he decided to observe what effect would result in these cases by removing the ovaries. He operated upon fourteen cases in all, one of which died; the others made an excellent recovery. From the large number of cases occurring in this district we would consider the disease as epidemic in Basel. In examining the histories of those cases that were operated upon, we find that their ages varied between 28 and 51; that they had each borne from 4 to 10 children, the average being 5.4. The social condition does not seem to have any effect upon the acquiring of the disease, nor does long nursing.

According to these results, there can be no doubt that by performing oöphorectomy, and thus putting an end to ovulation and menstruation, a cure for osteomalacia can be accomplished. Other observers have obtained similar results, so that the total number of cases has now reached twenty.

As to the causation of the disease we are still very much in the dark. Some believed the disease to be due to a bacterium, and its epidemic character would make this seem plausible. But if such were the case, how could we explain the method of cure by means of removing the ovaries or by Porro's operation? Diminished alkalinity of the blood has also been given as a cause. Experiments were made upon the patients to test this. The results would not lead one to believe that this could be the cause. The diminished alkalinity merely shows the severity of the disease.

Certain positive factors in the disease are: First, that nearly all the cases were markedly worse when menstruating. This would lead us to suppose that the menstrual congestion stood in a certain relation to the disease. This is also confirmed by the fact that the disease occurs more frequently during pregnancy and in the puerperal state. Second, the marked diminution of the pains shortly after the operation. Two or three days after the operation the pains in the sternum and ribs cease, then later on those in the pelvis and lower limbs also disappear.

The result of these observations leads us to believe that the disease is due to a morbidly increased activity of the ovaries. The changes in the bones are to be looked upon as reflex. According to this, we must look upon osteomalacia as a trophoneurosis of the bones, especially of the pelvic bones, this trophoneurosis depending upon the generative process, especially in the ovaries.—*Amer. Jour. Obstet.*

THE DIAGNOSIS OF NON-PUERPERAL OVARIAN ABSCESSES.

Acute non-puerperal inflammations of the ovaries are extremely rare. Pathologico-anatomically considered, there are two forms of inflammation of the ovaries—the parenchymatous and the interstitial. The first form occurs in acute exanthemata, typhoid fever, recurrent fever, cholera, septic processes, phosphorous and arsenical poisoning, and has merely an anatomical interest; for, clinically it produces no characteristic symptoms, and is only discovered at the post-mortem table. The second form occurs very rarely; except after the puerperal state and in the beginning of the disease, the diagnosis is extremely difficult, for the symptoms could be considered as due to a perioöphoritis or a localized peritonitis. According to Olshausen, a positive diagnosis of acute oöphoritis can only be made when we can feel the enlarged ovary, and can be sure that the pain arises from it and that none of the surrounding organs are affected. Even then we cannot be sure, but, in order to be so, have to perform a laparotomy, or we make our diagnosis at the autopsy. The total number of cases that have been published being very few, the following case is cited in order to show the difficulties in making a diagnosis:

A woman, blonde, single, 23 years old, gave the following history: Menstruated regularly from her sixteenth year on. In June, 1888, had an abortion in the tenth week; does not know the cause. After that she had a discharge which lasted six weeks. Following this menstruation began again and continued to be regular. From September to November, 1889, she had a severe attack of acute articular rheumatism. Had a leucorrhœal discharge during this entire attack. In the beginning of February, 1890, she was suddenly taken with chills and fever; began to menstruate and had slight drawing pains in the left side of her abdomen. A physician who saw the patient diagnosed peritonitis. The pains became more severe and finally became cramp-like in character, extending from the left side toward the right and into the back. Complained of slight burning when urinating. Last menstruation March 22d, lasting four days. Six days later a severe hæmorrhage, lasting three days. Complains continually of pressure upon the bladder, and is compelled to urinate very frequently. Has very little appetite. Temperature below normal, rising in the evening to 38.7 C. Abdomen tense and retracted. Pressure upon the abdomen is not painful. By external palpation nothing can be made out. Uterus not enlarged; sharp anteflexion; freely movable. The right ovary, the size of an almond, can be easily felt. On the left side a tumor is felt, as large as an apple, and is attached to the fundus uteri, but can be separated from it. The consistence of the tumor is firm, but in several places soft spots can be felt. The tumor cannot be moved. The left ovary cannot be felt. A diagnosis of purulent tumor of the uterine adnexa was made. Whether it was of the tube or ovary remained a doubtful question. As the tumor had weakened the patient, and made her unfit for her work, and caused considerable pain, it was decided to perform laparotomy. This was done on April 14th. The abdominal incision began at the umbilicus and extended

to three centimetres above the symphysis. Intestines came into view and were pushed to one side. Then on the left side the tumor became visible. It was surrounded by the peritoneum, and was adherent to a loop of small intestine. It was loosened with considerable difficulty. In endeavoring to draw it out of the pelvis it burst, and the contents, which were greenish-white pus, about three tablespoonfuls in all, were evacuated into the abdominal cavity. It was carefully wiped away with sponges. That portion which was adherent to the intestine could not be separated without tearing the latter; it was therefore left behind and the rest removed. The tube was ligated at the uterine end, and was also removed. Abdomen was carefully cleansed and the wound closed. No reaction occurred until the tenth day, when a small superficial abscess of abdominal walls was developed. This lasted eight days. On the 10th of May the patient was discharged cured. Microscopically, portions of ovarian stroma were found in the abscess membrane. From the history the probability is that the abscess was due to a gonorrhœal infection. It would have been impossible in this case to tell whether it was a pyosalpinx or an ovarian abscess. It could also have been mistaken for a hydrosalpinx, hæmatosalpinx, tubo-ovarian cyst, and tuberculosis of the tubes. A hydrosalpinx has rather a characteristic form. Beginning at the uterine end, it swells as it goes out toward the side. The affection is usually bilateral. The amount of pain is very slight and there are very few symptoms. It is utterly impossible to diagnose a tubo-ovarian cyst if it undergoes suppuration from the disease in question. The same is true in cases of tuberculosis, when cheesy masses form. It may also be difficult to diagnose the disease from a parametritis or an intra-peritoneal pelvic exudation. The cause of the interstitial form of the disease is usually menstrual suppression or else gonorrhœal infection. The former cause is a rare one. The symptoms in the case just described pointed to gonorrhœa as the cause. The yellowish discharge, the burning and frequent desire to urinate, all point to this as the source.—Dr. Joseph Rheinstein, in *Archiv. für Gynäkologie.—Amer. Jour. Obstet.*

PÆDIATRICS.

LAPAROTOMY FOR THE TREATMENT OF TUBERCULAR PERITONITIS IN CHILDEN.

Surgical treatment of tubercular affections of the peritonæum presents, besides its practical importance, a great scientific interest on account of its mysterious and unaccountable action. There are three principal forms of tubercular peritonitis, classed as follows: 1. tubercular masses, without ascites, disseminated in the peritoneal cavity; 2. cystic effusion; 3. disseminated tubercles with general ascites. The course of the disease is acute, subacute or chronic. Excepting the form combined with ascites, which is often mistaken for a simple ascites, and which yields to tonic treatment and repeated punctures, the different forms of peritoneal tuberculosis present a grave prognosis, and Henoch even considers them incurable. The first cases of surgical treatment of the disease were due to errors of diagnosis. The results were so favorable that the cases have greatly multiplied. At the recent Congress at Berlin, König presented statistics of 131 cases of surgical intervention in tubercular peritonitis. The mortality was 3 per cent.; 84 cures, 23 improved. The operation consists in a large opening of the abdomen with evacuation of the liquid; the other procedures are accessory and only have a very little influence as to the result. The cure is not simply temporary; its continuation has been confirmed after 2, 12 and 25 years. In certain cases, the autopsy showed a complete disappearance of the tubercles, that is to say, *restitudio ad intergrum.* Before examining the results given by surgical intervention in tubercular pertonitis in children, the writer gives a case of his own, and a short résumé is here given. Anna K., aged 3 years and 9 months, entered the hospital Sept. 8, 1890; a brother died of tuberculosis. The patient had whooping-cough at 2 years, which lasted five months. Since July, 1890, diarrhœa, and abdomen swollen; dull; fluctuating. Temperature running from 38° to 39° C. Sept. 11, chloroform; an incision 5 centimetres long between the pubis and umbilicus; evacuation of the liquid; drainage; the wound closed by deep sutures; iodoform dressing; a piece of peritonæum examined by the microscope showed tubercles composed of giant cells, etc. Sept. 23, the sutures were removed, and the wound united by first intention; the temperature slightly lower. Sept. 27, icterus, fever, cough, œdema of the malleoli. Sept. 30, all the symptoms were better. Oct. 4, the fever persists, abdomen enlarged and dull in the lower region. Oct. 10, the abdomen was opened again on the line of cicatrization; both folds of the peritonæum were united by a gelatiniform substance covered with tubercles having a car-

tilaginous consistence. Abdomen was washed out with boracic acid solution; a thin layer of iodoform dressing; drainage. Oct. 22, the fever had fallen, abdomen diminished in size, patient gained weight, cure. The icterus noted in this case was only transient epidemic. Writers have wished to explain the action of laparotomy by the influence of light on the bacillus of Koch. But in cutaneous affections, this action of light, although much more prolonged, does little to prevent the evolution of the affection. König explains the action by suppression of the peritoneal cavity. The above case corroborates this hypothesis. In spite of the frequency of tubercular peritonitis in childhood, laparotomy has only been performed twenty times, including my case; twice in children, aged 3, once at 8 years, twice at 5 years, twice at 10 years, three times at 11 years, twice at 12, four times at 13 years, twice at 14 and once at 15; of these cases 6 were boys and 13 were girls. In every one of the twenty cases the result was favorable, and the patient was cured. In two cases there was a relapse; a second operation was performed at an interval of one month and was followed by success. Laparotomy is one of the best methods for the treatment of tubercular peritonitis in children.—*Alexandroff, in Wracht—Amn. Gyn. Pæd.*

HYGIENE.

PASSAGE OF THE BACILLUS OF TUBERCULOSIS FROM THE MOTHER TO THE FŒTUS.

Birch-Hirschfeld and Schmorl (*Beitrage zur Path. anat. und zur allg. Path.*, 1891, p. 429) have put on record a case which they claim is the first in which it has been definitively proved that in the human subject tubercle bacilli pass from the mother to the fœtus. The patient was a young woman who, shortly after the commencement of her first pregnancy, began to show signs of phthisis; these gradually became more marked, and she succumbed at the seventh month of her pregnancy. Immediately after the death of the mother the fœtus was removed by Cæsarean section. The necropsy on the mother showed abundant evidence of phthisis; not only in the lungs, but in other organs, tuberculosis was detected. Although the fœtus had been alive shortly before the death of the mother, it was dead when it was removed. The chest was at once opened, but there was nothing noteworthy about the lungs. The fœtus was then taken to the laboratory, the surface of the abdomen was washed with perchloride of mercury, and the cavity was opened with sterilized knives. No tubercles could be seen on any of the organs. Minute pieces of the liver, the spleen and the kidney were placed in the abdominal cavity of two guinea-pigs and a rabbit, with all antiseptic precautions. One of the guinea-pigs died in fourteen days, and tubercles were found in different parts of the abdominal cavity. The second one was killed about six weeks after inoculation, as it was clearly ill, and many tubercles were found in the peritoneal cavity. The rabbit lived three months; on its death many tubercles were found in the liver and the lung. Tubercle bacilli were found in the umbilical cord and the blood of the umbilical vein.—*Brit. Med. Jour.*

WARUM ICH NICHT MEHR VEGETARISCH LEBE.

Such is the title of an article containing the renunciation of Dr. Alanus, sent to the *Renish Courier*. He says:

"Having lived for a long time as a vegetarian without feeling any better or worse than formerly with mixed food, I made one day the disagreeable discovery that my arteries began to show signs of atheromatous degeneration. Particularly in the temporal and radial arteries this morbid process was unmistakable. Being still under forty, I could not interpret this symptom as a manifestation of old age, and being, furthermore, not addicted to drink, I was utterly unable to explain the matter. I turned it over and over in my mind without finding a solution of the enigma. I, however, found the explanation quite accidentally in a work of that excellent physician, Dr. E. Monin, of Paris. The following is the verbal translation of the passage in question: In order to continue the criticism of vegetarianism we must not ignore the work of the late lamented Gubler on the influence of a vegetable diet on the chalky degeneration of the arteries. Vegetable food, richer in mineral salts than that of animal origin, introduces more mineral salts into the blood. Raymond has observed numerous cases of atheroma in a monastery of vegetarian friars, amongst others that of the prior, a man scarcely thirty-two years old, whose arteries were already considerably indurated. The naval surgeon, Treille, has seen numerous cases of atheromatous degeneration in Bombay and Calcutta, where many people live exclusively on rice.

A vegetable diet, therefore, ruins the blood-vessels and makes permaturely old, if it is true that man is as old as his arteries. It must produce at the same time tartar, the senile arch of the cornea, and phosphaturia. Having unfortunately seen these newest results of medical investigation confirmed by my own case, I have, as a matter of course, returned to a mixed diet. I can no longer consider purely vegetable food as the normal diet of man, but only as a curative method, which is of the greatest service in various morbid states. Some patients may follow this diet for weeks and months, but it is not adapted for everybody's continued use. It is the same as with the starvation cure, which cures some patients, but is not fit to be used continually by the healthy. I have become richer by one experience, which has shown me that a single brutal fact can knock down the most beautiful theoretical structure."

MEDICAL CHEMISTRY.

A NEW ALKALOID FROM JAVA COCA-LEAVES.

Dr. F. Geisel communicates a note to the *Pharmaceutische Zeitung*, in which he mentions that the narrow-leaved Java coca contains up to 2 per cent. of alkaloids, but only very little cocaine. The principle alkaloids are cinnamyl compounds, besides crystallizable cinnamyl-cocaine, as well as truxilline. From 20 kilogrammes of the alkaloids he, by fractionation, obtained 1 kilogramme of cinnamyl-cocaine, and from the mother-liquor containing the amorphous cinnamyl compounds he has been able to isolate, as a hydrobromide, an alkaloid bearing a great resemblance to the dextro-cocaine which Einhorn prepared from dextro-ecgonine. Of this alkaloid Dr. Giesel has secured 80 grammes. It possesses the characteristics of cocaine and nearly-allied bodies, so far as physiological action on the tongue and behavior towards permanganate are concerned. The hydrobromide and nitrite of the alkaloid showed the same sparing solubility in water as dextro-cocaine does, and, like it, the free base separates as an oil, which, on dissolving in ether, can be obtained in crystals. The alkaloid so obtained melts at 49° C., as compared with 46–47° C., the figure for dextro-cocaine, and 97° C., that of cocaine. The hydrochloride of dextro-cocaine is fairly difficult to dissolve in water, but dissolves more easily in alcohol, and crystallizes from both solvents in needles. The hydrochloride of the new base dissolves easily in water, but with more difficulty in alcohol, and crystallizes from the solutions in small and pretty prisms. Salts of the new body, even in very dilute solution, give a crystalline precipitate with potassium bichromate, whereas similar solutions of cocaine and dextro-cocaine remain clear, or give an oily turbidity. The alkaloid does not affect polarized light. Concentrated hydrochloric acid splits it up into benzoic acid and ecgonine, in the calculated proportions for cocaine, without giving, as in the case of dextro-cocaine, a difficultly soluble intermediate product. In other respects the alkaloid shows differences from dextro-cocaine, and Dr. Geisel's conclusion is that it is an isomer or homologue of cocaine. The author adds some criticism of Hesse's recent work on hygiene, in which he maintains the natural existence of that body.—*Chemist and Druggist.*

PHOSPHORUS MADE BY ELECTRICITY.

The *Birmingham Post* has published an account of a new factory, lately established at Wednesfield by the "Electrical Construction Corporation," for the production of phosphorus by electricity. Patents for the extraction of phosphorus from the raw material had been taken out independently by Dr. Readman, of Edinburgh, and Mr. S. Parker, the managing director, and Mr. A. E. Robinson, F. C. S., the chemist of the Electrical Construction Corporation. These patentees, it appears, have amalgamated their interests, and it is said they have experimentally proved the success of their plans. They are commencing the manufacture on a limited scale, but they have taken land which gives them space to extend their operations largely. At present only a limited number of furnaces are set up, but the machinery provided will be powerful enough to produce an electrical current capable of heating other furnaces when the premises are extended. The engine is of 700-horse power, and attached to it is an alternating dynamo nearly eight feet in diameter. From the dynamo the current is conducted to the furnace, and generates intense heat, by means of powerful arc carbons. The furnace, which is the invention of Mr. Parker, occupies a comparatively small space, being only about eight feet square, and less in heighth. It is fitted with a hopper at the top, which is so constructed that the phosphates and coal can be poured in without any heat or vapor escaping. The furnace being "air-tight," no smoke is generated, and the whole of the ingredients placed

within, with the exception of a little slag, which is drawn occasionally by a process of tapping similar to that at ordinary blast-furnaces, pass away in a vaporous condition through pipes and condensers, where the phosphorus is deposited in such a pure condition that it requires but little refining, though, for marketable purposes, it is afterwards formed into circular cakes. The cost of production is said to be much less than by any other system. The *Post* states that the whole of the patents have been acquired by the Phosphorus Company (Limited), by whom the works will in future be carried on. It may be interesting to state that the estimated consumption of phosphorus throughout the world is about 2,000 tons per annum, and the Wednesfield works hope to place in the market at least half that quantity each year, at a price which may probably have a marked effect upon the price of matches, low as they are retailed at the present day.

NEWS AND MISCELLANY.

REDUCTION IN RAILROAD FARES.

The Trunk Lines, the New York and Boston lines, the Southern Passenger Association, and the Central Traffic Association will transport persons from points on their lines to Washington and return at the price of one and one-third the regular fare on the following conditions:

1. There must be an attendance at the meeting of not less than 100 persons holding special certificates.

2. The going ticket must be purchased within three days before the opening date of the meeting.

3. Each person availing himself of the concession must pay full first-class fare going to the meeting, and must obtain a certificate from the agent of whom the ticket is purchased.

4. Those holding such certificates, when countersigned by the proper officer at the Congress, can obtain return tickets at one-third the highest limited fare.

Certificates are not transferable, and the return tickets secured upon certificates are not transferable. If any of them are sold or transferred, they must be redeemed at the highest first-class rate by the person making such sale or transfer.

No refund of fare will be made on account of any person failing to obtain a certificate.

Those who wish to avail themselves of this method of obtaining reduction in fares, should present themselves at the office for certificates and tickets at least 30 minutes before departure of trains.

It is absolutely necessary for each passenger before starting to obtain a certificate from the ticket agent of whom the going ticket is purchased, otherwise he can obtain no reduction in the return fare.

There will be no stop-over privileges on the return tickets, which must always be by the same route as the going ticket.

Members may obtain tickets on these conditions for their wives and members of their families, as well as themselves.

THE LAY OF THE LYMPH.

The following appropriate lines have appeared in the *British Medical Journal:*

Who'll kill the bacillus?
"I," said Herr Koch,
"With my lymph and syringe,
I'll kill the bacillus."

Alas! Doctor Koch,
With false hopes you fill us;
For firm as a rock,
Holds the field—the bacillus.

And assembled bacilli
Through a cultur'd bacillus
Say, "We're not quite so silly
As to let Herr Koch kill us."

"Must admit," owns Herr Koch,
"I can't kill the bacillus,
Only cut off the stock
Of supplies from bacillus."

Replieth Herr Virchow,
"No lack of supply;
From one organ driven
To another he'll fly."

So some vow with a twinge,
"No more shall you drill us
With your lymph and syringe,
You can't starve the bacillus."

ILLINOIS ARMY AND NAVY MEDICAL ASSOCIATION.

"The Illinois Army and Navy Association" was organized at Springfield, Ill., June 26, 1890, with Dr. Hosmer A. Johnson, of Chicago, as President, and Dr. John H. Rauch, of Springfield, as Secretary. The objects of the society are the promotion of social, historical and medical subjects con-

nected with the late war. All reputable physicians now living in Illinois, whether in practice or not, who served in the army or navy, during the late war, and all who were surgeons or acting assistant surgeons, who were with Illinois troops, and are now non-residents of the State, are eligible to membership. At the second meeting of the association, held in Springfield, May 18th and 19th, 1891, Dr. John H. Rauch was elected president, vice Dr. Johnson, deceased, and Dr. Edward P. Bartlett, of Springfield, Ill., was elected secretary. The association adjourned to meet in Chicago, at the time of the unveiling of the Grant Monument. This adjourned meeting will take place at the Grand Pacific Hotel, Chicago, Oct. 7th and 8th, 1891. The unveiling of the monument will occur Oct. 7th, at 2 P. M. Half fare rates can be had to Chicago at that time, upon all railroads.

MODERN MEDICINE.

First they pumped him full of virus from some mediocre cow,
Lest the small-pox might assail him, and leave pit-marks on his brow;
Then one day a bull dog bit him—he was gunning down at Quogue—
And they filled his veins in Paris with an extract of mad dog;
Then he caught tuberculosis, so they took him to Berlin,
And injected half a gallon of baccilli into him;
Well his friends were all delighted at the quickness of the cure,
Till he caught the typhoid fever, and speedy death was sure;
Then the doctors with some sewage did inoculate a hen,
And injected half its gastric juice into his abdomen;
But as soon as he recovered, as of course he had to do,
There came along a rattlesnake and bit his thumb in two;
Once again his veins were opened to receive about a gill
Of some serpentine solution with a venom in it still;
To prepare him for a voyage in an Asiatic sea,
New blood was pumped into him from a lep'rous old Chinee;
Soon his appetite had vanished, and he could not eat at all;
So the virus of dyspepsia was injected in the fall;
But his blood was so diluted by the remedies he'd taken
That one day he laid down and died, and never did awaken;
With the Brown-Sequard elixir they tried resuscitation,
He never showed a symptom of reviving animation;
Yet his doctor still could save him (he persistently maintains,)
If he only could inject a little life into his veins.—*Puck.*

PURIFICATION OF CHLOROFORM.

According to a telegram in the *Times* of June 24th, which has a somewhat commercial smack, M. Raoul Retet is arranging with manufacturers of chloroform in Berlin for the purpose of purifying this anæsthetic by means of intense cold—freezing it, in fact. He produces it absolutely pure, it is said. By his process he is able to reduce its temperature to—130° C. The impurities can, it is stated, be separated at—23° C. (the melting point of chloroform is—70° C.) We doubt whether this purification will rid it of its inherent dangers as an anæsthetic. Good chloroform as now manufactured from pure acetone is probably as chemically pure as commerce can supply it. Absolute chloroform has hitherto proved very unstable.

DEATH AFTER A DOSE OF SALOL.

Salol is usually considered a tolerably innocuous drug, but there are not wanting clinical observations which tend to show that, under certain circumstances at least, its use may be followed by dire results. Thus a case was some time ago reported by Aufrecht and Behm in which death followed its use in acute endocarditis, and more recently Dr. Chlapowski has published in a Bohemian medical journal an account of a case in which a similar fatal result followed a fifteen-grain dose ordered to a patient who was suffering from severe gastric symptoms, and who was being examined by Ewald's method. After taking the salol the patient became restless and unconscious, the pupils dilated, the pulse became irregular, there was constant vomiting, and the urine became dark, and contained salicylic acid. Death occurred twelve days later. At the necropsy there were found gastritis and hæmorrhagic enteritis, a gastric ulcer cicatrized at the cardiac end, chronic endometritis, and a cyst of the ovary. No doubt was entertained that the salol had caused the symptoms of poisoning.—*Lancet.*

THE RESIGNATION OF PROF. KOCH.

Dr. Robert Koch, though he has resigned his Professorship of Hygiene on his appointment as Director of the newly-founded Institute for Infectious Diseases at Berlin, still retains the title of Honorary Professor Ordinarius, which gives him the power of lecturing in the University if he sees fit.

FRACTURED RIBS IN THE INSANE.

The words heading this paragraph are the title of a highly instructive memoir by Dr. Claye Shaw in the new volume of the *St. Bartholomew's Hospital Reports.* He observes that nothing gives so bad an impression of the management of an asylum as the occurrence of fractured ribs amongst its inmates. Hence he endeavors to throw some light on the pathology of broken ribs in the insane. He has made experiments, and tabulates the weight required to cause fracture of the rib, and the seat of the fracture. He concludes that a considerable difference is found to exist not only in the weight of the ribs on the two sides of the body, but also in the average breaking weight. The lighter rib is often found to bear the heavier weight, and there appears to be no proportion between the weight of the rib and the number of pounds that it is capable of sustaining, whence it would appear that physical conditions of structure have no more to do with the strain-resisting power than chemical change. Persons suffering from disease of the heart or blood vessels bear less strain than others. Persons suffering from advanced constitutional disease, such as phthisis, may have ribs that support a strain much above the average, and hence there is no direct relation between constitutional strength and that of the ribs. When a blow causes fracture, this is dependent not so much on the weight of the rib and its power of bearing strain as on other conditions. Altogether the idea that the ribs of the insane are more brittle than those of the same is true only to a very limited extent, and is almost confined to those affected with degeneration of the circulatory system. Dr. Shaw rightly notes that he has not had the opportunity of testing the breaking weight of the ribs of general hospital patients. Attendants at asylums, he observes, knowing the penalties, are very careful not to give violent blows when patients are in such a position that the natural elasticity of the ribs can act, and that, even if they did, such blows would not cause fracture. Whether the person be sane or insane, a slight blow given when the body is in a certain position will cause fracture, and when that does occur, it is more often than not done accidentally—*Brit. Med. Jour.*

THE COMPOSITION OF THE LONDON FOG.

An important paper on London fog was read at the Hygienic Congress by Dr. Russell, who has made it the subject of special study. He says, first of all, that the number of fogs is constantly increasing in the metropolis. From 1870 to 1875 there were 93 of them; from 1875 to 1880, 119; from 1880 to 1885, 131; and from 1885 to 1890, 156. This is the direct result of the increased consumption of coal, which amounted to 6,400,000 tons in 1890 as against 4,400,000 in 1885. Dr. Russell claims to have proved that increased smoke makes fogs more frequent, as well as thicker, by adding to impurities in the air. Fogs, he adds, are especially likely to occur in still, cold weather. The composition of London fog is as follows:

Carbon,	39.0
Hydro-carbons,	12.3
Organic traces,	2.0
Sulphuric acid,	4.3
Hydrochloric acid,	1.4
Metallic iron and magnetic oxide,	2.6
Ammonia,	1.4
Mineral matter, chiefly silica and ferric oxide,	31.2
Water,	5.8
	100.0

The actual effect of fog upon human life is uncertain. It has been noticed, however, that fogs in cold weather are accompanied by a rise in the death rate. This may be due chiefly to the cold, but it must be remembered that cold is intensified by fog, which obstructs the rays of the sun. There is no doubt of the injurious effect of fog upon vegetation, which is affected, even at a distance of thirty or forty miles from London. It is the sulphur, probably, that does the mischief. There seems to be no room for doubt that the number of fogs will increase in London in exact proportion to the growth of the city, unless some means are discovered of getting rid of the smoke, which comes, it must be added, from the domestic hearths, not from factories. How this problem will be solved, if ever, no one can now tell. Two plans are suggested, one, the use of improved grates, the other, the substitution of gas for coal fires.

Clinical Lectures.

AMPUTATION OF THE FORE-ARM—SEBACEOUS CYST—RACHITIS—CANCER OF THE BREAST.

BY PROFESSOR ROSWELL PARK,

BUFFALO, N. Y.

AMPUTATION OF FORE-ARM.

Gentlemen:—The first case was a patient whose fore-arm had been amputated ten days before. The operation had been done with every antiseptic precaution and there had been no pain nor fever nor other symptoms calling for a removing of the dressing. The deeper dressings were somewhat moist from perspiration or some discharge, but there was no evidence of suppuration. With the exception of a few points at which the skin had not quite healed, union by first intention had occurred in ten days under the primary dressing.

SEBACEOUS CYST.

The next patient was a young man who exhibited a swelling just in front of the hyoid bone, of about the size of a horse chestnut, dark in color and fluctuating on pressure. The patient complained of tenderness and much discomfort on account of the growth, and stated that a similar one had been removed from the same place two years ago. Pressure on the tumor caused its contents to exude, much resembling a Pharaoh's serpent as it burns. This phenomenon showed the tumor to be a sebaceous cyst and its discoloration, the pain and local heat and the appearance of the contents showed that it was inflamed and suppurating. Dr. Park remarked that such cysts might occur almost anywhere about the body though they were most common about the head and neck. He had once removed one from the toughest part of the heel. He called attention to the fact that the opening through which the matter was pressed was the natural opening of the sebaceous duct in which the contents had accumulated so as to form a cyst. From the irritation of clothing, etc., inflammation in such cysts was a common occurrence and there was nothing to prevent the entrance through the duct of micro-organisms which would cause the breaking down of the sebaceous matter into pus. Such tumors had a tendency to recur and, therefore, the proper method of treatment consisted in a removal of the sac whenever possible. Whether this had been done at the former operation could not be learned from the patient. The blackness of the skin overlying the tumor indicated that it would soon slough away if nothing were done and thus a spontaneous evacuation of the cyst would take place. After injecting a cocaine solution, an incision was made, opening the tumor and allowing the semi-purulent sebaceous matter to escape. Contrary to the usual state of affairs, the cyst wall was so adherent to the surrounding tissues that it could not be removed readily. The pyophylactic membrane (a term which Dr. Park prefers to the misleading one of pyogenic membrane) was, therefore, cut away in pieces, and to make sure of its extirpation, the cavity was swabbed out with a caustic; carbolic acid being used on account of its combining the properties of a caustic, an antiseptic and an anæsthetic. The cavity was then packed with antiseptic gauze so as to ensure its healing by granulations from the bottom, and a dressing applied.

RACHITIS.

The next patient was a child eight years old with marked evidences of rachitis. There was a very exaggerated anterior curvature of the right femur and much lateral curvature of the left femur and of both tibiæ. The deformity of the bones caused knock-knee, uncertainty of gait and a peculiar carriage of the body. The thighs had been previously cleansed and protected with antiseptic band-

ages in anticipation of the operation. A small incision was made just above the inner condyle of the femur, the chisel inserted and osteotomy performed. Dr. Park referred to this operation as a purposely inflicted compound fracture, all the circumstances being favorable and particular pains being taken to preserve asepsis. An antiseptic dressing was bound over each wound and after a little delay the deformity was corrected and a plaster of Paris bandage applied to each limb.

A woman of fifty presented herself with a tumor pouching into the cheek from the jaw. There was no history of tumor in the family. The patient had known of the existence of the growth for nineteen years. The growth was painless although annoying on account of the mechanical interference with talking and eating. It had grown very slowly till four years ago when the patient conceived the idea that if she had her teeth pulled, the growth would be checked. The removal of the teeth, however had rather the opposite effect though the increase in size had not been rapid.

By the history of its long duration and the absence of adhesions, ulceration and pain, malignant tumor was excluded. The most common non-malignant growths from the jaw, Dr. Park said, were fibrous or cystic or both combined. Fibrous tumors sprang very frequently from the periosteum. Any kind of tumor springing from the jaw was called epulis by a certain class of writers but he objected to this general use of the term epulis which he thought should be restricted in its application to a fibro-sarcoma very slightly malignant in the beginning but which may develop increased malignancy. The present tumor was moveable and extended back no further than the end of the alreolar process and did not reach as high as the orbital plate. There was no fluctuation and the diagnosis was made of a fibroma which might possibly contain a small cyst in its interior. Although the growth could have been removed much more easily by an external incision for the cosmetic effect the opening was made from within the cavity of the mouth. Only the fingers and a pair of scissors were used in dissecting the tumor out of the cheek. It was a hard, somewhat modulated mass, the size of a hen's egg and entirely fibrous in its nature.

CANCER OF THE BREAST.

The next patient was a woman 45 years of age, who had had eight children. Although there was no history of cancer in the family and no history of any lesion of the breast—not even a fissure of the nipple—yet a year ago a lump had appeared in the breast and had increased in size and now presented unmistakable evidences of malignancy. Of late the patient had suffered much from pain, referred as is often the case, to the arm. This was due to interference with the intercosto-humeral nerve.

Dr. Park said, "A tumor of any considerable size occurring in the breast of a woman at about the menopause when there is the history of even the slightest increase in size, accompanied by a certain fixation of the growth in the surrounding tissues, is almost always of cancerous nature." If with this condition there is some retraction of the nipple and an enlargement of the glands in the axilla, or along the border of the pecteralis major leading to the axilla, the diagnosis becomes still more certain, and but one advice can be given to the patient as to treatment if the case is seen early enough—immediate removal. In removing the mammary gland alone for cancer, we afford only half the benefit which the surgeon can give. We should remove in addition the cellular tissue and lymphatic glands of the axilla. It is the general opinion of the best surgeons the world over, that the axilla should be "cleaned out" in all cases of cancer of the breast when a radical cure is possible. Even if all the cancerous tissue is not removed by the operation, death is usually delayed. I might enumerate five purposes which we may have in view in operating on cancers. First of all, the radical removal of the growth which we often achieve if the case is seen early enough. Secondly, we operate later for temporary relief and to prolong life, such operations are frequently repeated. Thirdly, we operate sometimes purely for relief of pain, removing structures that are highly sensitive on account of the disease. A fourth indication for operation is excessive sloughing. The growth may be scraped repeatedly if necessary. A fifth indication is hæmorrhage as in a fungous cancer. The operation for the removal of the breast is simple but sanguinary. It is not dangerous. An elliptical incision is made, the nipple being removed, leaving enough skin, if possible, to close the wound after the removal of the gland.

In preparing for the operation the razor was used, not because of an excessive amount of hair, but because the razor is regarded by Dr. Park as an efficient dermal curette, and because he considers that the fine down is as

capable of lodging bacteria as true hair. The cancerous mass had grown outward and was just on the point of ulcerating. It was removed according to the method indicated as thoroughly as possible, but it had extended so far that Dr. Park expressed his doubts as to the ultimate cure of the case. The tumor was found to be, as had been predicted, a scirrhous cancer, the only form of carcinoma which is at all common in the breast.

COMMUNICATIONS.

RIGHT OCCIPITO-POSTERIOR DELIVERY.

A. L. BENEDICT, M. D.,
BUFFALO, N. Y.

On Thursday, June 18, I was called to see Olive S., aged 19, in labor with her first child. Two months prior I had prescribed for her on account of gonorrhœa, but the treatment had not been persisted in and there still remained suppuration in one of the vulvo-vaginal glands. There was no very definite history of symptoms that could be construed as indicating gonorrhœal involvement of the uterus, tubes, or peritoneum.

The patient stated that she had had what she took for labor pains on Sunday, and that since Tuesday night the pains had been more acute and quite frequent. Two physicians had seen the case in turn before I was summoned. At 12 o'clock Thursday noon, I made my first examination. The child occupied the normal axis of the uterus, the head was down, the fœtal heart-beat could be heard indistinctly and momentarily at different points below the umbilicus and the fœtal movements were quite active. The cervix was thick and tough. The os was about the size of a quarter, distended by the unruptured bag of waters. The head had apparently not yet engaged. A bichloride douche was given and an enema ordered.

At 10.30 P. M. the os was a little larger, the fœtal head was lower but had not yet engaged. It seemed to distend the cervix anteriorly but behind, the finger met with no obstruction through the amniotic sac except that something soft, apparently an arm or leg or the cord, could just be touched. The heart beat could be heard distintly below the umbilicus, first on the left side, then on the right of the mother's abdomen. It could not be heard in the same place long enough to be counted. The patient had suffered considerable pain since noon.

At 6 A. M., June 19, the waters broke, about a vesselful being discharged. At 7.15 I found the os the size of a half dollar, with the head engaged. The heart-beat could now be distinctly heard in its usual location obliquely downward and to the left from the umbilicus. It was 156 to the minute. The patient slept most of the time from the breaking of the waters until 9 o'clock when the pains began again. At 10.15 another examination was made showing that some progress in labor had occurred. At 2 P. M. the cervix was dilated nearly to its full extent but it still retained the thickness and inelasticity already referred to. Other examinations were made at 5 and at 10 P. M., slow progress being noted at each examination. Full dilatation of the cervix was not quite accomplished at 10 o'clock. The labor, although delayed considerably after the rupture of the amniotic sac was not dry, in fact there had apparently been a condition of moderate hydramnion.

At 1.30 A. M., June 20, the head was on the perineum and the pains were frequent and severe. At 2.10 the head was born, the occiput pointing posteriorily and to the right. The mechanism of final expulsion, as aided by the hand, being first flexion till the occiput emerged posteriorly and then extension followed by spontaneous external rotation. The cord was found to be hooked over the right shoulder. It was slipped off and the body of the child extracted. The child made only one or two feeble attempts at respiration. The throat was clear but plugs of tenacious mucus hung from the nostrils, having evidently been inspired from the vagina. These were removed, the cord tied and cut and artificial respiration tried for some minutes. As this was not successful, the child was immersed in hot water but no reflex effort at breathing could be evoked. Repeated brief auscultations of the chest showed that both the heart and the lungs were quiet. After about twenty minutes, artificial respiration was abandoned and attention turned to the placenta. Meanwhile the mother had been resting without pains. After a little manipulation by Crédé's method and two pains, the placenta was expelled, accompanied by a double handful of clots. I would like to protest, in passing, against the forcible expulsion of the placenta by the external hand. It is cruel, unnecessary and unsafe to exert all one's strength in pushing the uterus against the spinal column as some men do.

The proper idea, it seems to me, is first to stimulate a uterine contraction and then to brace the hand against the uterus so as to give it the same degree of support which the abdominal muscles do in the second stage but which they can no longer render on account of the diminished size of the uterus. If moderate pressure from without is ineffectual after a reasonable time, it is better to remove the placenta by the hand in the uterus using proper antiseptic precautions than to exert violent pressure.

The placenta in this instance was pale, somewhat friable on the uterine surface and the decidua was thickened. The secundines had rather a bad odor. Fluid extract of ergot, 2 c. c. was administered by the mouth and a 1–5000 warm bichloride injection was given. After some further delay, the patient was cleansed, an occlusion bandage applied and direction given to let the breasts—which were unusually large—entirely alone.

At ten o'clock the patient was doing well, having flowed very little. An autopsy on the child's body was made at which the following notes were taken: Female child (confer rapidity of heart-beat), length 17 inches, circumference of head 12 inches, length of cord 18 inches. Head molded so that the occiput is flattened, the anterior portion of the skull projecting upward. Large caput succedaneum over left fronto-parietal region. Very little vernix caseosa. Reddish patches under axillæ and over arms. Petechiæ over dorsa of fore-arms and hands and over abdomen. Peritoneum distended with reddish-yellow fluid, almost entire atelectasis of lungs. The liver weighed 5¾ ounces, the spleen one ounce, the estimated weight of the body being seven or eight pounds. According to Prof. Hirst of the University of Pennsylvania, the normal ratio of the weight of the spleen to that of the body is 1–300 and for the liver the ratio is 1–30. In this case the ratios were approximately 1–120 and 1–122. Although the suspicion of syphilis existed, no positive evidence of it could be found. An examination for fatty metamorphosis at the lower epiphyseal line of the femur could not be made on account of the objection of friends.

On the afternoon of June 21, the day following the completion of labor, I was called in haste to see the patient. She had been somewhat irrational and about five o'clock she had jumped from bed and crossed the room when she almost fainted. The pulse was found to be weak and rapid, the temperature was slightly over 100°, and the lochia were fœtid. Whisky was given to relieve the faintness and directions were sent to an assistant to give an intra-uterine douche, but, on account of a misunderstanding, only a vaginal douche was given. A prescription was left for quinine capsules, containing fifteen centigrammes each, with directions to take two that night and afterward three daily.

The next morning a vaginal followed by an intra-uterine douche (1 : 4000) was given and in the afternoon, a vaginal douche alone of the same strength was given. This treatment was repeated Tuesday and Wednesday, the fœtor of the lochia being diminished, but not removed, and the temperature ranging from 100° in the morning to not quite 103° in the afternoon. Thursday and Friday only vaginal injections were thought necessary, as the temperature fell nearly to normal, and a good recovery has since been made. There was slight caking of the breasts, which disappeared under the "let-alone" treatment. They were, however, supported by a bandage.

As I began my attendance on the case with a bichloride douche and followed the completion of the third stage of labor with another, used a bichloride solution for the hands before all manipulations and applied an antiseptic occlusion bandage after labor, I do not feel responsible for the septic element which entered into the case. The tedious labor predisposed to it and the gonorrhœal discharge and possibly earlier digital examinations would fully explain it. Forceps were not used, as at each examination some progress was noted. Rest was secured once by the use of morphine, later by bromide of potassium, one gramme and acetanilid, twenty-five centigrammes.

I will frankly admit an error in diagnosing the position. The child was plainly in the normal axis of the uterus and pelvis, the skull was presenting. Owing to the resistance of the perinæum and to the density of the cervix, the vaginal examination was not very satisfactory. Early in labor only a small circle of the fœtal skull could be felt, later the land marks were obscured by the caput succedaneum. On account of the thickness of the abdominal walls and the excess of liquor amnei the limbs of the fœtus could not be felt anteriorly and the distinctness with which the heart sounds were heard after the head had engaged, led me to believe that the child's back was turned anteriorly. It was not until late in labor, therefore that the true condition was appreciated. I am inclined to think that the moveable body which I felt behind the

head early in labor was the cord which had prolapsed far enough to catch over the right shoulder. It does not seem, however, as if it could have been shortened sufficiently to have delayed labor.

APPENDICITIS.

BY WM. L. CONKLIN, M. D.,

ROCHESTER, N. Y.

(*Read before the Monroe County Medical Society, May, 1891.*)

REPORT OF CASE.

Wednesday, December 3rd, 1890, I was called to see Chas. B.; 19 years of age; a shoemaker by trade. He gave a history of uniform good health up to that time.

For the relief of constipation, which had been troublesome for a few days, he took a cathartic Monday evening, which resulted in a free movement Tuesday morning. That afternoon some tenderness of the bowels was complained of, and the following night he was awakened by severe pain in the abdomen. When seen Wednesday morning the pain had diminished, and was confined to the right iliac region. There was slight tenderness on firm pressure over the vermiform appendix. During the afternoon the pain gradually increased, and opiates were given for its relief. Several hours of sleep and partial relief of pain were secured by a moderate use of morphine that night.

2nd day. Pain was not severe in the morning, but tenderness had increased and was most marked near the McBurney point. During the forenoon pain was complained of again. I made a diagnosis of appendicitis and asked that counsel be called. Dr. Zimmer saw the patient that afternoon, and after a thorough examination, confirmed the diagnosis of trouble in the region of the appendix.

He thought the time for operation had not come and advised a continuation of the morphine in sufficient quantities to control pain. Poultices were applied but could not be borne. An enæma of soap and water brought away a small quantity of fœcal matter.

3rd day. Though a thorough examination was made, under chloroform, no tumor could be detected, either by abdominal palpation or through the rectum. There was great rigidity of the abdominal muscles even after a free use of the anæsthetic. In the afternoon the patient was seen by Drs. Whitbeck and Zimmer. It was not thought that pus had formed at that time and further delay in operating was deemed advisable. Troublesome nausea appeared for the first time. An ounce of castor oil was given followed by ½ oz. epsom salts. No effect.

4th day. Gave grs. x calomel, followed by 2 ozs. solution citrate magnesia every hour for four hours. No effect.

5th day. Nausea had disappeared. A rubber tube was carried about 12 inches into the bowel and water and glycerine injected. This resulted in two or three evacuations containing some solid fæces.

6th day. Still complained of pain. Gave 12 oz. solution citrate magnesia in two doses. This was followed by two liquid stools.

7th day. I was able to detect a small swelling, an inch to the inner side of the anterior superior spinous process on a line drawn from that process to the umbilicus.

8th day. Severe pain complained of at one time during the night. The presence of fœtid pus was demonstrated by introducing a hypodermic needle at the point of greatest tenderness. That afternoon an operation was performed by Dr. Zimmer, assisted by Drs. Wilson, Dow and Combs. A four-inch incision was made parallel with the crest of the ilium and Poupart's ligament, with its center one inch from the anterior superior spinous process. After careful dissection through skin, superficial fascia, aponeurosis of external oblique internal oblique, transversalis and transversalis fascia, the abscess was found and evacuated. The pus cavity extended upwards parallel with the crest of the ilium and contained an ounce or more of fœtid pus. The appendix could not be found. It was thought that it had either ulcerated off or become embedded in new tissue. The cavity was washed out with boiled water and a rubber drainage tube passed through the incision and a counter opening above. The incision was closed with catgut sutures passing through the skin and superficial fascia and an antiseptic dressing applied. A fœtid discharge continued for two weeks, the odor then disappeared and the wound healed rapidly and completely.

Remarks.—I wish to refer briefly to a few points suggested by the study of this case, which seem to me of special interest, and upon which I should be glad to hear an expression of opinion.

First, as to diagnosis. In a paper on "Appendicitis," by Prof. Lewis A. Stimson,

read before the New York Surgical Society, Oct. 8th, 1890, (*N. Y. Medical Journal*, Oct. 25th, 1890) I find the following:

"The localization of the maximum pain, or of the only pain, on pressure at or very near the point indicated by Dr. McBurney, two inches from the anterior superior spine of the ilium, on a line drawn from it to the umbilicus, has been constant, and, in pointing out this symptom, Dr. McBurney has rendered us a service which it is difficult to estimate too highly. It has made the recognition of appendicitis, in its early stages, at least, easy for everyone."

It is doubtful whether all would place as high a value upon the McBurney point as does Prof. Stimson, but I am told that in the discussion of the subject at Albany last winter its importance as a means of diagnosis was fully recognized. In the case just reported the point of greatest tenderness was a little to the outer side of the McBurney point. But though it may be a comparatively easy matter to diagnose appendicitis in its early stages, it is by no means easy to say what its course will be—whether it is to end quickly in resolution; result in the formation of an abscess which will seriously menace the life of the patient, or by an unprotected perforation light up an almost surely fatal peritonitis. These are hard problems to solve, and, unfortunately the aids to their solution are not numerous or altogether trustworthy.

The temperature does not seem to be a reliable guide. In the case reported it was 98° the morning of the first day; 101° and 102° the second and third days; subnormal the 4th; normal the 5th and 6th, and slightly elevated the 7th and 8th. On the 4th day, when the mouth and axillary temperature were sub-normal (97 1-5) the rectal temperature 100 2-5, a difference of 3 1-5°. In another case (Stimson's)there was a difference of 6¼° between the temperature of the mouth and that of the rectum on the 6th day. Whether this unusual difference is of any diagnostic value I am unable to say. Dr. Chas. K. Briddon thinks that when the pus forms in the pelvic cavity, to a limited extent, and becomes encysted, the temperature falls. Prof. Stimson says: "If the temperature is above 102° two days after the beginning of the attack, suppuration is imminent or already present."

The pulse is thought to be of more value than the temperature as an aid to diagnosis; but it may be found to furnish very unsatisfactory information, if any, especially if the abscess is small. In the case of Chas B. it did not exceed 84 and was 78 just before the operation.

Great pain may be followed by resolution, and slight pain by fatal perforation; severe pain appearing suddenly during the course of an attack would certainly be looked upon with suspicion. It may be impossible to detect a tumor, or a dull percussion note for several days after the first symptoms appear. I was unable to do so until the 7th day. It is certainly not by attention to any one symptom, taken in connection with the time which has elapsed since the attack began, that we may hope to obtain a true idea of each individual case.

The difficulty of determining the pathological condition present after a diagnosis of appendicitis has been made, taken in connection with the dangers of delay, furnishes a strong argument in favor of early operative interference. In a series of 11 cases, with 10 recovered, recently reported by Dr. McBurney, (*N. Y. Med. Jour.*, Dec. 21, 1889) an operation was performed in from 40 hours to 7 days. In 9 of the 11 cases the appendix was removed. Pus was found in 7 or more. In one case operated in 49 hours after pain was first noticed the appendix consisted of a thin-walled sac, shut off from the cæcum by stricture, and containing at least half an ounce of fœtid pus. That a rupture of this sac, producing a fatal peritonitis, would have resulted from a delay in operating of a few days, or even hours, is at least probable. In another case, reported by Dr. Lange, "Not only perforation but extensive destruction of the appendix and far gone infection of the peritoneum had been found by the middle of the second day." Out of a series of 21 operations reported by Dr. Stimson, 5 were performed in the early or doubtful stage without a death, and, as he says, without a moment's anxiety beyond that which belonged to the taking of the step. Dr. McBurney says, "If it can be shown by future experience that the exploratory incision for inspection of the diseased appendix is much more free from danger than the expectant treatment, then there could be but one answer to the question—what is the best treatment?"

The use of certain terms in articles on this subject may fairly be criticised, because they do not accurately describe the true pathological condition.

We read of *extra*-peritoneal abscess resulting from appendicitis. If an abscess results from inflammation of the appendix it must certainly be of *intra*-peritoneal origin, and should be called an intra-peritoneal abscess,

unless the pus has forced its way through the peritoneum, and there is abundant proof that this latter condition is a very rare one indeed. McBurney says further that in not a single one of the early operations for appendicitis which he has done or seen done has there been the slightest doubt as to the fact that the incipient abscess was entirely within the peritoneal cavity. Stimson says, in speaking of a series of 21 cases already referred to: "The pus in all the cases, with possibly one exception, was *intra*-peritoneal." This is an important point in the pathology of appendicitis, because of its bearing on the questions of operation. In the evacuation of an abscess the peritoneum must be cut to a greater or less extent, whether the oblique incision is made, or the one along the outer border of the rectus. This being the case it would seem that, as a rule, the latter is to be preferred, because of the better opportunity it gives for the removal of the appendix, if that should be deemed advisable.

A CASE OF FRACTURE AND DISLOCATION OF THE SPINE WITH OPERATION.*

*Read before the Ohio State Medical Society, June 18, 1891.

BY A. W. RIDENOUR, M. D.,

MASSILLON, OHIO.

In view of the rarity of these cases with the almost invariable result, I have thought proper to report a case that marks a new era—at least in my practice.

Dec. 11th, 1890, Martin Nye, aged 28, laborer, while driving through a shed on a load of lumber was caught between an overhead beam in such a manner as to crush the center of his back forwards at an acute angle, frightfully lacerating and crushing both hard and soft parts in that region.

Within half an hour after the accident I found the patient pulseless, the skin cold and clammy, the respiration sighing; very restless; jactitation, suffering frightful pain in back; sensation and motion absent from injury down; knee-jerk absent; reflex in legs absent.

On inspection at seat of injury I found a depression of fully one inch corresponding to seventh dorsal vertebræ, with absence of spinous process of eighth dorsal. This at once led me to inform the patient and friends of the exceeding gravity of the case, and that the only hope of life lay in a speedy operation. Consent was readily given and at once carried out.

With the usual and necessary antiseptic preliminaries an incision about twelve inches long was made, commencing at the third and terminating at the ninth dorsal, separating muscles from either side and exposing the bony roof of the cord from the sixth to the ninth dorsal, inclusive. The muscles were crushed, soft, pulpy and mangled beyond recognition in the region of injury. The lamina of seventh dorsal was broken and separated from the body; the transverse process on either side of seventh was fractured, and the articulation for the ribs torn completely off; the ends of the ribs stuck up in the wound like two fists; the *body* of seventh vertebræ was dislocated forwards fully one inch, nearly slipping out anteriorly. The spinous process of seventh vertebræ was split and crushed. The spinous process of the eighth dorsal was not only split but actually inverted penetrating the cord and crushing it. The lamina of eighth was fractured, and the body fractured, but not dislocated. The membranes were punctured and badly lacerated at different points with full hæmorrhage in the aracnoid space. The cord was crushed at the juncture of the seventh vertebræ by the inverted spinous process of eighth; the cord was carried forward with the dislocated seventh vertebræ; and there was compression at the juncture with the sixth and eighth. Altogether I can not conceive of a more frightful injury unless we might include cutting off the cord and the immediate death of patient. The trephine was not resorted to because it did not seem necessary or safe, as the bones being soft can be separated readily with safer bone instruments.

All of the bony roof, from middle of ninth dorsal to and including middle of eighth dorsal vertebræ was removed. Passing my finger between the body of seventh dorsal I elevated it into position, smoothed all rough or sharp bony prominences; removed all clots; stopped all hæmorrhage; replaced the dislocated ribs as well as I could without any articular facets, and placed strands of catgut along the bottom of the wound in such a manner that the cord would not come in contact with them, or in fact with anything, (requiring some care here in the disposal of remaining bones and overlying muscles). The muscles were sutured carefully on either side; then sutured the skin; and finally applied a dry dressing.

The after treatment of this case was un-

eventful. Sensation returned at once in both lower extremities, motion was perceptible in the recti muscles at end of the 4th day. A catheter was used to pass urine until the 7th day when normal micturition returned. There was no control over the spinchter anii until the end of the 1st week. The knee-jerk was restored at end of 2d week. He could raise his limbs from bed at the end of the 5th week. He could walk with crutches at the end of three months. I applied plaster-of-paris jacket for support at end of 2d week.

The wound healed primarily in one week, without any pus and with three dressings. No fever at any time. Urine did not present any albumin or sugar, no casts or abnormal deposits, sp.-gr. 1.020.

The patient suffered no pain after the operation ; no atrophy of muscles of the lower limbs since the operation ; the joints were not thickened. The patient walks about with the aid of a cane, June 5th, 1891.

The patient is under the care of Dr. Marchand, of Canton, and is at the Stark county Infirmary. The Doctor reports the patient rapidly recovering his bodily vigor ; can get around rapidly ; and that the plaster was removed during April. *There is no deformity.* I would have wished the plaster bandage had remained on longer, but it seems that no ill effects followed its removal. I was kindly assisted in the operation by Drs. Miller and Reed, of Massillon.

The only plea I have to make in these cases where the diagnosis is made, is for an immediate, thorough and careful operation. A few hours delay, in my opinion, is sufficient to render the operation futile, and I have no hesitation in placing the cause of failure in so many of these operations to this cause. About eight years ago I reported a case to this society where I had made the operation three years after injury with the result of complete failure, the patient dying two weeks after of acute albuminuria.

But in doing this work the utmost care is required not only in removing all bony or other foreign material from the vicinity of the cord, but that no possible chance for subsequent hæmorrhage or pressure can occur, as even the pressure of a super-imposed muscle will be sufficient to deprive the cord of functional activity, or a small shaving of bone will cause inflammatory softening and death. Slight hæmorrhage will cause a clot that will act more rapidly than in the brain in causing death ; but the operation can be done and should be made safe by care and without hurry, and I will repeat, no patient should be allowed to die without an attempt to save him.

TRAUMATIC PARALYSIS.[1]

BY F. J. GRONER, M. D.,
GRAND RAPIDS, MICH.

I introduced this topic before the Section of Surgery with the desire that some knowledge may be added to such an important subject, slighted as it is in our text books on surgery. The persistence of the present generation in bringing suits for damage against the attending physician makes it very important that the literature in this special field be advanced. Paralysis from injury is not uncommon, and it may as likely occur in your first case as in your second hundred.

I will illustrate my subject by giving you the history of several cases.

Case I. A young man in good health, aged 17 years, was struck by a falling tree. The patient was brought six miles on a logging car, and I saw him three hours after the accident. He was then in a state of profound collapse, almost pulseless, showing the effect of severe injury. I gave ¼ grain morphia and 1–150 grain of atropine hypodermically and ordered external heat and brandy administered freely. I saw the patient several hours later. Condition slightly improved. I found fracture of right thigh, which I reduced, and severe injury of right shoulder and arm. As there was a relaxed condition of muscles and ligaments about shoulder joint, I applied a well padded shoulder cap and through splint to back of arm and forearm for support, as I intended to have patient moved to the Hospital the next day. The patient had not completely rallied from the shock the next morning. This showed the severity of the injury. At the Hospital I applied Buck's extension, for fractured thigh, removed the support from the arm and applied an evaporating lotion. The entire arm, forearm and hand became very much swollen, so much so that the entire arm was covered with blisters from the passive hyperæmia, and in many places there was necrosis of superficial tissues ; the scars still remain. I at one time feared gangrenous sloughing of the entire tissue of the arm. The swelling gradually subsided and at the end of the fourth week, there was such

[1] Read before the Surgical Section of the Michigan State Medical Society, June, 1891.

marked anæsthesia of the limb that we suspicioned paralysis, and so informed the patient and relatives.

In spite of friction, electricity, iodide of potassium, strychnia, etc., there is complete paralysis of all of the muscles of the shoulder, arm and forearm. The skin took on a glossy appearance; disorders of secretion, eczematous eruptions; there is practically complete atrophy of the muscles. The fingers are in a state of flexion so patient can lift and carry a pail of water. This is the only use that can be made of the arm. Electrical contractility is almost entirely lost.

One interesting feature in this case is, I have been charged with causing the paralysis. My reply is, "I was not the falling tree." Some physician suggested to the patient that I bandaged the arm too tightly and this caused the paralysis. This I deny in toto as the felt splints were heavily padded and secured by a many tailed bandage very loosely applied, and as I removed the dressing myself the next day, I found no constriction or evidence of pressure. You may ask why I applied support if there was no fracture or dislocation? I did it to keep the parts at rest while the patient was being moved to the Hospital, and to satisfy friends and relatives who were looking on. In private practice should you find a severely bruised member and do nothing for it you would be accused of neglect, especially if dealing with an ignorant class as in this instance.

To disprove the accusation that the dressing had anything to do with the paralysis, I will give you the history of a similar case with like result where no dressings whatever were applied.

Case II. Janury 21st, 1890, I was called to see a patient who was struck by a falling tree. He was brought ten miles from the woods to his home in Big Rapids. I saw the patient four hours after the accident. He was about twenty-five years of age, and had every appearance of previous perfect health. He was suffering from shock, but not quite so severely as case 1. He was struck on left shoulder and back. I found evidence of fracture of 6th and 7th ribs. The skin was not broken but evidence of severe bruising could be seen. Patient expectorated blood and a slight traumatic pneumonia followed. The fractured ribs were strapped, a wide bandage applied around the body and the elbow and forearm supported by a sling. There was some degree of swelling but not so extensive as in case 1. The patient had no control of deltoid or muscles of arm or forearm, and as there was partial anæsthesia and limited electrical contractility my prognosis was atrophy and permanent paralysis. Feb. 11th, I called in two physicians to examine the case. (This is a very important matter for self-protection.) They thought improvement would follow the use of the faradic current, but it did not. The atrophy and paralysis are as complete as in the first case reported. And this was not the result of tight dressings as no dressings were applied.

There is a case in Big Rapids, in which a man aged 50 years, received a supra-condyloid fracture of the humerus and there followed complete paralysis of forearm and hand. There is no evidence whatever that the treatment was not perfectly proper; there is no displacement of fragments or callus pressing on nerve. I have exhibited these three cases to the members of the Union Medical Society of Northern Michigan.

It has occurred in my experience repeatedly to pass my opinion as an expert on patients with similar conditions. So the cases I have reported are not rare ones. I have always been asked if the doctor who managed the case was not liable for damages. In fact the lawyers informed my first case that if he could get the doctors to swear that I was to blame for the result, it was advisable to bring suit against me. I have seen many cases of traumatic paralysis of the deltoid, and apparent luxation from loss of support. This muscle usually recovers its functions on the application of proper treatment.

Those of you who have had extensive experience with fractured legs have observed many cases of crutch paralysis. Sensation and motion are rapidly restored on dispensing with the crutches and applying a battery.

In 1883, I assisted in cutting down on the musculo-spiral nerve. It was almost covered in a bed of callus after a supra-condyloid fracture. All the parts supplied by this nerve were paralyzed. Sensation and motion were completely restored by chiseling away the callus.

There have been repeated reports of paralysis following the injection of ether; the ether having been injected in the neighborhood of the nerve paralyzed. Alcohol produces the same effect and experimental study shows that the portion of the nerve with which the alcohol comes in contact undergoes necrosis.

Alamertine reports a case of paralysis and atrophy of the muscles of the arm from wound of the hand by a fragment of hot

iron. He considers it a case of reflex muscular atrophy. It is necessary to be very guarded in prognosis, for if the result is not as good as you promise, others will say the bad result is due to lack of skill or carelessness. You will meet with fracture of the humerus far down where the musculo-spiral nerve is so damaged that the extensors and supinators become powerless, and this condition remains permanent.

Cases come under the care of the surgeon often following what at the time appeared to be a trivial injury, such as a prick of a needle or splinter stuck in the finger. The whole arm finally becomes very much wasted from the neuritis.

I could continue with a list of cases embracing other parts of the body, especially the lower extremities. My illustrations are sufficient for thought on traumatic paralysis without extending them.

The particular question I raise is, why should a severe blow upon the shoulder be followed by complete paralysis of the entire limb? It is an injury of the cord, the brachial plexus or is it a simple neuritis?

We have every form of traumatic lesion of nerves with compression, hæmorrhage into, or even rupture, and this may extend to the cord or cerebral centers. From hæmorrhage into the nerve we can get fatty degeneration or degenerative atrophy, or a chronic parenchymatous neuritis.

There is some difficulty in studying the pathological condition in these lesions. Post mortems are rare, and, if made, would seldom be by those competent to make a proper microscopical investigation of the nerves and cord.

I am inclined to consider my two cases a neuritis of the brachial flexus, and the consequent dengenerative atrophy.

The prognosis in traumatic paralysis varies according to the intensity of the nerve lesions. If the nerve is completely divided and nutrition markedly affected, the chronicity of the affection will only increase the dangers. The less the electro-muscular contractility and sensibility have been affected, the sooner will electricity produce good results. The prognosis is favorable if contractility is diminished, but sensation has suffered little or not at all. When all phenonena of contraction and sensation are abolished, the paralyzed muscles will be atrophy, even though they respond to the faradic current. Duchenne says, the return of sensibility and the transformation of anæsthesia into hyperæsthesia constitute favorable signs which are indicative of beginning recovery; the temperature muscular tonicity, and power of voluntary motion will then gradually return to the normal.

With regard to treatment, if the nerves are ruptured they should be sutured. If there is pressure from dislocation, callus or inflammatory thickening, it should be removed. Friction and massage to stimulate circulation. Electrical treatment plays the most important role. The constant current at first, then the induced current. The effect on the peripheral nerves must depend mainly upon its catalytic action, upon its effects on circulation and nutrition, upon inflammation, and its consequences, upon cicatrical tissue, upon cirrhosis and degeneration, the absorption of extravasations and exudations into nerves and nerve sheaths. The faradic treatment is more serviceable and more indicated in old than recent cases. Daily sittings of ten to fifteen minutes. The strength of the current may be gauged approximately by the sensation. The treatment should not be too much prolonged.

The indication for medical treatment will depend on each individual case.

SOME RECENT ADVANCES IN THE TREATMENT OF DISEASES OF THE SKIN. [1]

BY A. W. FINCH NOYES, JUN., F. R. C. S. (EDIN.)
MELBOURNE.

The object of this paper is to give a short *resumé* of some recent and important advances that have of late years been made in the treatment of affections of the skin by Dr. Unna, of Hamburg, whose system is fast becoming famous throughout the world. Most of the facts are taken from my own private notes, collected at Dr. Unna's clinic, or from abstracts or translations of articles that have appeared from time to time in the *Monatshefte für Praktische Dermatologie*, or other journals, the reference to which will be given in each instance.

Rather than enter into any abstract questions regarding the actions of topical applications on the cutaneous surface, rather than attempt to explain on theoretical grounds the "keratolytic" or "keratoplastic" reactions that are set up under certain conditions, I would proceed at once to the practical discussions of the various new methods of applying drugs in affections of the skin; and

[1] From the *New Zealand Med. Jour.*

I would discuss the subject under two headings:—

I.—New forms of application in skin diseases.

II.—Those diseases to which these applications are adapted.

I.—New Forms of Application in Skin Diseases.

Since the time of Ferdinand Hebra, no single individual has introduced such extensive reform into the domain of Dermatology as Dr. Unna, of Hamburg. To him we are indebted for much that is new in the histology and in the bacteriology of the skin, and for almost all that is new in the therapeutics of the most extensive sense organ of the body. The improvements that have been made are almost wholly in the direction of topical applications, the chief of which are—(1*a*) Plaster, (*b*) Salve Mulls, (2) Glycogelatines, (3) Pastes, (4) Soaps (over fatty, etc.,) (5) Salve and Paste Pencils.

(1*a*) *Plaster Mulls.*

These elegant topical applications are composed of oleate of alum and gutta-percha, with which drugs in varying strengths are incorporated. The oleate of alum constitutes their adhesive element, and possesses the marked advantage over other such applications in that it is absolutely unirritating. The gutta-percha forms an impermeable basis for the drug incorporation, the whole being spread in a thin layer on fine mull or muslin. Almost any drug may be incorporated with the plaster mass, though varying expedients have to be resorted to in order to ensure satisfactory results. No less than eighty varieties are at present prepared by Beiersdorf, of Hamburg. Those chiefly in use are —Mercury, mercury and carbolic acid, mercury and salicylic acid, mercury and zinc oxide, salicylic acid, salicylic acid and cannabis indica, zinc oxide, lead, boracic acid, chrysarobin, and resorcin.

They are applicable in nearly all localized affections—patchy eczemas, psoriasis, lupus, acne rosacea, and acne vulgaris, etc. Their method of application consists in cutting the plaster to the size of the lesion to be treated, and applying it forthwith. Further details as to their use will be discussed under the individual diseases in the next section.

They possess the following advantages over other methods of local application—they are cleanly, readily applied, are in constant contact with the diseased part; they protect from external irritants, and are comfortable to the patient. They have, therefore, justly come into very general use in the treatment of a large variety of skin diseases.

(*b*) *Salve Mulls.*

These preparations differ from the plaster mulls in that they contain neither gutta-percha nor oleate of alum, but consist simply of an ointment mass, spread very accurately and evenly by machinery on mull, or undressed muslin. Those chiefly in use are—Zinc oxide salve mull, zinc oxide ichthyol salve mull, and lead and carbolic acid salve mull.

There is nothing especially new in this form of application, and Unna[1] only claims for it that it is "a neat, convenient, more adaptable, and therefore more efficacious, form of the strips of cloth coated with ointment, which are used by the school of Hebra." It is not claimed for them that they are to replace ointments altogether, but simply that they are elegant, cleanly, and comfortable applications; especially useful in localized eczemas of hands, feet, face, nostrils, external auditory meatus, &c. The mercurial salve mull is especially recommended in cases of hereditary syphilis—it is cleaner and more easily managed than inunction.

(2) *Glyco-gelatine.*

In recent years, no more useful advance has been made in the treatment of skin diseases than the adoption by Unna of a compound of glycerine and gelatine (glyco-gelatine). Professor Pick, of Prague, was the first who foresaw the utility of these two substances, but he used to apply them separately —a far less convenient method than when in combination. The best basis for the incorporation of all other drugs appears to be the zinc oxide glyco-gelatine,[2] of which there are two forms (A soft, B hard), composed as follows:

A (Soft).

Zinc oxide, ...	15 parts
Gelatine, ...	15 "
Glycerine, ...	25 "
Water, ...	45 "
	100 "

[1] *British Medical Journal*, August 27, 1887.

[2] *Monatshefte fur Prakt. Dermatologie*, 1887, p. 317. Abstract from *Artzler Vereinsblat*, 1886, No. 176.

B (Hard).

Zinc oxide,	10	parts
Gelatine,	30	"
Glycerine,	30	"
Water,	30	"
	—	"
	100	"

Iodide of lead, precipitate, chrysarobin, sulphur, and iodoform, are all miscible in any proportion—5 to 10 per cent. is a suitable proportion for the first three mentioned, 20 to 30 per cent. for the last two. Carbolic acid, salicylic acid, resorcin, naphthol, creosote, and sulphide of potash exercise an inhibitory action on the setting of the gelatine, and should only be incorporated with the Hard variety up to 10 per cent. Fats, balsams, tars, and ichthyol have a diluting and loosening effect, and should be prescribed with the Hard variety, and not in larger proportion than 33 per cent. Substances in powder form may be used, but never in greater quantity than the proportion of gelatine. Camphor and chloral may be incorporated up to 2 per cent., ext. cannabis indica to 5 per cent., hydrarg. perchlor. up to 3 per cent.

The method of application to diseased parts is excessively simple. The solid glycogelatine is melted in a hot water bath. It is then applied with a paint brush to the affected region, and dabbed over immediately afterwards with a roll of absorbent cotton wool; thus a sort of skin is formed, which acts as a protector, and as a medium by which the medicaments may be kept in constant contact with the skin. Besides this, it acts beneficially by its slight compressing effects, producing a localized anæmia, also favoring the absorption of inflammatory products.

Indications for application—

(*a*) Pruritis, both simple and senile, if uncomplicated.

(*b*) Artificial dermatitis, produced by free use of mercurial ointments, alcoholic inunctions, irritation from chrysarobin, salicylic acid, resorcin, &c.

(*c*) Erythema and rhagades, which disappear very quickly.

(*d*) Acute and localized eczema, when not weeping.

(*e*) Pruritic eczemas (the ichthyol 2 per cent., or cannabis indica 5 per cent., zinc glyco-gelatine.)

(*f*) Inflammatory acne. (In some cases a 20 per cent. sulphur, or 5 to 10 per cent. resorcin, zinc gelatine acts admirably.)

Besides the above indications, zinc glycogelatine is very useful as an adjuvant in the treatment of lupus, tinea tonsurans, &c. It is also an excellent fixing agent in the use of the plaster and salve mulls. For efficacy, cleanliness, and comfort, glycogelatines cannot in selected cases be equalled by any other method of topical application.

(3) *Pastes.*[1]

These preparations, though not introduced by Unna, have been largely augmented and elaborated by him.

The conditions which a well-made paste should fulfil are—that it can be easily and rapidly spread over the surface in a thin layer, it must dry rapidly, and leave behind a closely adherent coating.

Bolus alb. (kaolin), starch, dextrin, and gum, each have their advocates as bases in the preparation of the pastes—

Bolus Paste.—R. Boli alb. 2, ol. lini. 1 Misce. Ft. pasta. An excellent foundation. If more ol. lini. be added, a liniment is formed, which leaves a coating on the skin after drying. A good eczema paste is made by adding oxide of zinc and liq. plumbi, thus—R. Boli alb. 3, zinci oxidi 2, ol. lini. 3, liq. plumbi 2. In making the foregoing, the bolus and oil must be mixed before adding the other medicaments, else decomposition will result.

Starch Paste.—R. Amyli 3, glycerini 2, aquæ 15. To be boiled down to 15 parts. To this foundation half or more of their volume of powdered medicament may be added. If, however, more than half the bulk is to be added, then the quantity of glycerine is to be increased in proportion—R. Zinci oxidi 50, acidi salicyl. 2, amyli 15, glycerini 15, aquæ 75. Mix, and boil down to 140 parts; an excellent starch paste in the treatment of eczema.

Dextrin Paste.—The foundation consists of dextrin, glycerine and water in equal proportions. To the foregoing oxide of zinc, &c., may be added as necessary.

Gum Pastes.—The basis consists of one part of mucilage of gum arabic and one part of glycerine, to which two parts of a powder, as oxide of zinc, are added. Carbolic acid, salicylic acid, &c., may be incorporated thus—R. Zinci oxidi 50, acidi carbolici *a* 2 muc. gummi arabici, glycerini *a* 25. Ft. pasta.

Sulphur may be mixed with the starch, dextrin, and gum pastes. Results are not so satisfactory when mixed with bolus paste.

Ichthyol salts are miscible with all the pastes except gum.

[1] *Monatshefte fur Prakt. Dermatologie*, 1884, p. 38.

Tar best in starch, dextrin or gum pastes.

Naphthol, carbolic acid, chloral hydrate, camphor, salicylic acid, sublimate, calomel, red and white precipitate may be mixed with all the varieties.

Iodine, iodoform, chrysarobin, pyragallol, are best suited to the bolus and gum pastes. Fats and soaps may be added to any variety, but only in small quantities.

(4) *Soaps.*[1]

Over-Fatty Soap.—This soap is used as a basis (Grundseife) for the incorporation of all drugs which enter into the formation of the medicated soaps. In its simple non-medicated form, it is an excellent preparation for ordinary toilet purposes, especially adapted for patients whose skins are irritable, or have a tendency to become dry and chapped. It is produced by the addition of two parts of soda and one of potash lye to ordinary beef suet. To this mixture olive oil, about 4 per cent. in excess of that required for saponification, is added, and thus the super-fatty condition is determined.

Over-Fatty Marble Soap.—Consists of super-fatty basis soap, to which 20 per cent. of marble dust is added. Its action on parakeratoses and acne is not medicinal, but simply mechanical.

Ichthyol Soap.—Indicated in rosacea and dry eczemas, is produced by adding 10 per cent. of ichthyol to the over-fatty basis soap.

Salicylate Soap.—Prepared like ichthyol soap, and indicated in subacute and chronic eczemas, in acne vulgaris, and in mycotic affections, tinea tonsurans, &c.

Zinc Soap has a drying action on the skin, and is useful in seborrhœa oleosa, hyberidrosis, and bromidrosis.

Perchloride of mercury, tannate of soda, tar, sulphur, camphor, iodide of potash, and naphthol may all be incorporated with the over-fatty basis soap, and form useful adjuncts to treatment.

(5) *Salve and Paste Sticks.*[2]

These preparations, as their names imply, are composed of two essentially different bases—(*a*) The salve sticks, or pencils, contain fatty elements as the bulk of their ingredients, which are insoluble in water; (*b*) the paste sticks, or pencils, contain non-fatty elements, which are easily dissolved by the aid of moisture.

The first variety (salve sticks) is useful when it is desirable to leave a thin layer of some drug on the fat-covered epidermis of the skin, as in dry eczemas, psoriasis, &c., for ordinary non-fatty solutions would not mix with the oleaginous excretions lying on the surface of the epidermis, hence the medicament could not come into intimate contact with the diseased surface. These pencils are prepared about the thickness of the little finger, and about the consistency of an ordinary cosmetic stick. The latter property is obtained by a judicious combination of olive oil and wax, to which the requisite drug may be added in varying quantities.

If very heavy drugs, as mercury, are to be incorporated, then some suspensory element, such as oil soap, must be added, thus—

Sublimate Salve Pencil (10 per cent.)—Sublimate 10 parts, oil soap 20, pine resin, 5, wax 35, olive oil 30.

The coherence of the mass is materially increased by the addition of ordinary resin, or, if creasote is used, then olibanum resin is best, thus—

Creasote Salve Pencil (10 per cent.)—Creasote 10 parts, olibanum resin 20, olive oil 30, wax 40.

The second variety (paste pencil) is indicated when the epidermis is absent, and there is moisture present to dissolve the elements of the pencil, and no fatty excretion to prevent intimate contact of the medicament with the diseased surface. Thus, these pencils are especially useful in the application of topical remedies to such conditions as chancres (hard or soft), condylomata, ulcers of the mucous membrane of the mouth, nose, conjunctiva, &c.; also in ulcerating or non-ulcerating lupus. In the latter, the sharpened point of the pencil is to be bored into the soft lupus nodule, thus destroying the affected tissue by both mechanical and therapeutic measures, since a coating of the distinctive drug is left in close contact with any diseased tissue that may remain round the walls of the cavity produced by mechanical means.

These pencils consist of short sticks, very brittle, and about the thickness of a slate pencil. They may be sharpened at the point, or not, as necessary. Their basis consists of starch, sugar, dextrin, or gum arabic, and tragacanth, thus—

Iodoform Paste Pencil (40 per cent.)—Iodoform 40 parts, tragacanth 5, starch 10, dextrin 30, white sugar 15.

Cocaine Paste Pencil (5 per cent.)—Cocaine 5 parts, tragacanth 5, starch 35, dextrin 35, white sugar 20.

---

[1] *Monatshefte fur Prakt. Dermatologie* (Digest), and Volkmann's "Sammlung Klinischer Vorträge," No. 252.

[2] *Monatshefte fur Prakt. Dermatologie* '86, p. 157.

These preparations, besides being cleanly and convenient when applied by a medical man, are especially adapted for application by patients themselves, who may without inconvenience carry them in their pockets, and apply them at intervals during the day.

II.—The Diseases to which these Applications are Adapted.[1]

Before proceeding to discuss the second part of this subject, *i. e.*, those diseases to which the methods of application described in Part I. are adapted, it will be necessary to briefly explain a term—eczema seborrhoicum—which is now in frequent use in dermatological phraseology, and which originated with Dr. Unna.

Clinically, the condition which, according to Unna,[2] arises from a perverted condition of the sweat glands, which secrete fatty as well as watery products, presents the following characteristics—

(1) "Eczema seborrhoicum almost invariably starts upon the hairy scalp as a latent catarrh, the first traces being the sticking together of the horny layers, sensible exfoliation of scales, abnormal distribution of oily matter, and drying of the hair, through blocking of the mouths of the follicles.

(2) "It has a remarkable predilection for certain positions, which are—Scalp, forehead at junction with hairy scalp, temples, ears, nose, corona around mouth, sternum, axillæ, arms (flexor surfaces), abdomen, chest, back, legs, hands and feet, intertrigo positions, and buttocks.

(3) "It usually spreads from the scalp downwards, over the temples and ears to neck, sternum, axillæ, &c., and assumes one of three forms—(*a*) As a progressive slight scaliness of scalp (pityriasis capitis), with progressive alopecia (alopecia pityroids) scaly form. (*b*) As a progressive baldness, with heaping-up of scales on the scalp, and of a corona seborrhoicum at the junction of the forehead with the hairy scalp, spreading to the temples and ears, or skipping over to regions of the nose and cheeks, particularly apt to occur on the sternum—the crusty form. (*c*) The moist form, in which weeping occurs, is especially apt to attack the temporal regions and ears, the fatty scales are lost, and the part looks red, moist and shining. The lesions most typical of eczema seborrhoicum are—circular or oval red patches of the size of a finger-nail, fading in the centre, the red color of which is masked by a covering of the yellowish crumbling scales. The margin consists of prominent red papules. Groups of such patches or rings form and coalesce with one another, till a festooned figure is formed. It is characteristic of eczema seborrhoicum that it tends to assume certain forms in certain parts of the body, *e. g.*, the scaly form on the scalp and face, the moist in the axillæ, temples, ears, back of hands and fingers, and in intertrigo positions; the crusty form on the trunk. On the palms and soles it resembles psoriasis guttatta, and passes into a peeling condition, but does not weep. The scaly and crusty forms which occur in the beard or moustache are not accompanied by falling out of the hair. On the nose, forehead, and cheeks red papulus, with congestion, may prevail, with pityriasis capitis, and unless cured, passes into acne rosacea. The nails are seldom attacked."

It will thus be seen that many conditions are included under the above name, which were formerly described as varieties of ordinary eczema and psoriasis. With the following exceptions, all cases once so described are now placed by Unna in his class, seborrhoric eczema:—

(1) Eczema papulosum, *i. e.* those cases of eczema in which papules constitute the morbid change in the skin, which with great rarity go on to vesiculation.

(2) Eczema nervosum, which is produced by nervous tension of any sort in neurotic individuals.

(3) Eczema pruriginosum.

(4) Eczema tuberculosum, or scrofulous eczema, which occurs in scrofulous children, is very obstinate, is often accompanied by conjunctivitis, otitis, etc., and generally begins on the face, and extends from above downwards to other parts.

(5) Eczema folliculorum, that form of eczema which appears as grouped papules, affecting the hair follicles.

(6) Psoriasis.—No case is regarded as one of *true* psoriasis, unless the patches appear in typical positions (elbows and knees,) and unless the scales are typically silvery in appearance, without admixture of greasy elements. Many cases which are now recognized as generalized psoriasis, especially of the guttata variety, would thus be excluded, and would be classed as an eczema seborrhoicum.

Treatment.

There is a large class of remedies which

[1] Only the more common diseases have been selected, and it is impossible in a short paper to give more than the bare indications in each case.

[2] "Year Book of Treatment," 1889.

act almost like specifics—resorcin, ichthyol, chrysarobin, pyrogallyl, and sulphur, especially the latter. They be applied as ointments, paste mulls, or sprays.

Unna insists on the condition known as dry seborrhœa of the scalp, or pityriasis capitis, being really an eczema seborrhoicum, having its origin in derangement of the sweat apparatus. He traces the origin of eczema seborrhoicum of the face and body to past or present seborrhœa of the scalp, and thus whenever it exists he treats it very vigorously.

Eczema Seborrhoicum of Scalp (Pityriasis Capitis, Dry Seborrhœa.)

(1) Wash the head every morning with spiritus kalinus of Hebra.

(2) After drying, take an ointment containing sulphur 2 to 3 per cent., resorcin 2 per cent., and apply it very thoroughly to all parts of the head. Apply again at night, and wash it off with spiritus kalinus in the morning. This treatment should be kept up, but with diminishing vigor, for four weeks or more.

If the hair is dark in color, the following is a very excellent application :—R. resorcini 5, ichthyolis 5, acidi salicylici 1, vaselini 88. Ft. unguentum. If the condition is very slight, then a resorcin spray (resorcin 5, spirit 100,) is quite sufficient.

Ears, Neck, and Face.

If non-weeping.—Zinc glyco-gelatine, to which ichthyol 2 per cent. has been added. The gelatine exerts a slight pressure on any œdema present; the ichthyol controls the hyperæmic and inflammatory condition, and relieves itching.

If weeping.—use pasta zinci (Unna's paste) —R. zinci oxidi 10; terra silicæ 10, vaselini 75. Ft. paste, et adde sulphur, 5 per cent.

If crusted.—Having got rid of crusts, apply zinc sulphur salve mull. When the process is very acute, with much itching and burning, watery solutions of resorcin act well— R. resorcini 10, glycerini 10, spiritus 10, aquæ 70. Ft. lotion. To be mixed with water in proportions of five, four, three, two, or one, to one of lotion, according to the acuteness of the condition.

Anterior Nares and External Auditory Meatus.

A very excellent application consists of the yellow or red oxide of mercury salve mull, which is easily applied to the affected surface by making a roll of it, with about an inch projecting from the nares and meatus. The projecting portion is slit into small flaps, which are turned back and held in position by adhesive plaster.

Chronic Eczema Seborrhoicum about the face or extremities is often very satisfactorily treated with resorcin wet dressing,[1] which is applied thus:—A piece of lint is well moistened with a solution of resorcin of the necessary strength, and applied to the affected region; it is covered with an impermeable sheet of gutta-percha and fastened in its place by a bandage. The contained moisture produces swelling of the horny layer, and prevents penetration of the normal fats of the skin, thus rendering it more permeable to the drug. The impermeable covering acts also as a soothing and slight anæmic-producing agent. If this method is unsuccessful, then try resorcin or pyrogallol as an ointment—R. resorcini 5, ichthyolis 5, acidi salicylici 2, vaselini 88. Ft. unguentum—on the scalp and face, and uncovered parts; however, it is advisable to use resorcin without ichthyol, as the latter discolors the hair and the skin. R. Pyrogallolis 5, ichthyolis 5, acidi salicylici 2, vaselini 88. Ft, unguentum.

Chrysarobin is very efficacious, but must never be used on the face, on account of its tendency to produce severe conjunctivitis. Plaster mulls of pyrogallol or resorcin, 1 to 10 per cent., may be used with advantage on small, inveterate spots.

Eczema Seborrhoicum of Scrotum and Anus.

In this position the affection is often excessively rebellious to treatment. Ichthyol asphalt, however, has a very excellent effect on many cases, causing marked subsidence of the inflammatory condition, and a very decided diminution of the accompanying pruritus. If all other remedies fail—resorcin, pyrogallol, tar, ichthyol, etc.,—then resort may be had to Paquelin's cautery. The whole infiltrated surface of skin is seared with a flat blade, especially made for the purpose. The wound may be dressed with iodoform, and when it has healed, may be treated with ordinary remedies, which will probably effect a complete cure. If much intertrigo of scrotum and anus present, the resorcin wet dressing should be used first. If this produces no beneficial effect, paint on a 30 or 40 per cent. solution of ichthyol, and cover it with glyco-gelatine. If there is much moisture about the parts, the gelatine must be dispensed with, as it would undergo solution.

---

[1] *Montsehefte fur Prak. Dermotologie*, 1889, p. 44.

Psoriasis.

A very large majority of the cases now designated psoriasis, are called by Unna, eczema seborrhoicum. These cases must be treated according to the directions given when discussing the treatment of that affection. The treatment of true psoriasis differs very little from that at present followed by the majority of dermatologists. The scales are to be got rid of by the use of soft soap and a hot bath; or if there is much infiltration on the patches, the plaques may be removed surgically. Afterwards chrysarobin, pyrogallon, resorcin, or sulphur, must be used freely. Arsenic may be given internally.

Acne Vulgaris.[1]

The pathological process, which culminates in the formation of acne papules, is divided by Unna into two stages—

(1) The blocking of the mouth of the follicle, and comedone formation.

(2) Inoculation with pus cocci, and consequent inflammation and suppuration.

The first part of the process is brought about by an abnormally firm cohesion of the layers of the horny stratum of the skin; this, accompanied by absence of the desquamation, naturally blocks the mouth of the follicle. The duct also becomes blocked by a continuation of the "parakeratosis," thus producing a comedone. The second part of process, *i.e.*, inflammation, occurs only in those ducts that have been inoculated by pus cocci previous to the blocking of the follicle.

The indications for treatment are, therefore, as pointed out by Unna—

(1) To loosen the horny layer of the epidermis.

(2) To kill the pus cocci.

The first indication is fulfilled by the use of strong "keratolytic" remedies—poultices, salves, or pastes, containing green soap—brushing with 5 per cent. liq. potassæ, or acetic acid, or salicylic acid plaster mulls. Sulphur, resorcin, and perchloride of mercury, however, fulfil both indications, as they are keratolytic, as well as antiseptic.

To commence with, patient must wash his face at night with hot water and soap (Hebra's soap spirit, marble or sublimate soap.) He must then apply a paste of sulphur, or resorcin, allowing it to remain on all night, and washing it off in the morning. During the day, a resorcin or sublimate spirit is more conveniently applied—

Resorcin Paste (for nocturnal use)—R. resorcini 10, terræ silicæ 10, ung. zinci benzoate 80.

Sublimate spirit (for daily application)—R. hydrarg. perchloridi 1, glycerini 1.0 aq. aurantii floris 20.0, spiritus 80.0

To prevent relapses, a weak resorcin paste or spirit must be applied for a lengthy period. During the above medicinal treatment, it is important to carry out mechanical treatment, by frequently evacuating the follicles of contents by compression, and by giving exit to pent-up inflammatory products.

Rosacea (Acne Rosacea).[2]

There is no necessary connection between acne and rosacea, though it is true acne is often a complication of rosacea, but the reverse does not hold good. From an extended experience, Unna has come to the conclusion that about 80 per cent. of rosacea cases are associated with eczema seborrhoicum. He therefore separates rosacea into two classes—the one associated eczema seborrhoicum, the other idiopatic, or unassociated with a seborrhoic condition.

The cure of the first variety depends on the successful treatment of the eczema seborrhoicum and pityriasis capitis; whilst that exists, there is always a tendency to return of the disease.

The second variety is best treated by ichthyol, both internally and externally. Internally, in the form of pill, one to two grammes per diem; externally, to be applied as an aqueous solution at night, or better perhaps, the following paste:—R. ung. zinci 20, pulv. oryzæ 4, sulph. 2. Ft. pasta.

In a later stage of the disease, when the vessels become permanently dilated, the parts must be treated with a very marked preparation of resorcin (50 per cent.), which sets up a very strong keratolytic process. After this, the individual vessels must be slit up with a Hebra's lancet, or be cauterized with Unna's modification of Paquelin. If there is much irritation of the face, it must be covered with a glyco-gelatine mask, which also helps to detach the horny layer.

The early and mild form of the third stage, *i.e.*, the stage of connective tissue development, may be treated like the second stage; but if the rhinopymatous development becomes very marked, then there is nothing left in the way of treatment but deep scarification, or ablation. To remove the yellowish stain which is frequently left on the face

[1] *Monatshefte fur Prakt, Dermatologie*, 1888, p. 54.

[2] *Monatshefte fur Prakt. Dermatologie*, 1888, p. 112.

after the disappearance of rosacea, use the following once a day:—R. bismuthi oxychlor. 20, hydrarg. perchlor. 0.1, vaselini 20.

Sycosis.

Two varieties of sycosis are usually recognized—the parasitic and non-parasitic forms—the former being due to inoculation of the hair and hair follicles with trycophyton fungus; the latter, to inoculation with one of the pus-producing cocci; hence the latter is no less parasitic than the former. Unna would therefore substitute the terms hyphogenic (parasitic) and coccogenic (non-parasitic), sycosis.

The diagnosis between these two forms is clearly set forth in all text-books on diseases of the skin. It is not, therefore, necessary to discuss the subject here. Having recognized the variety, it will be necessary to treat it accordingly.

Hyphogenic Sycosis.[1]

(*a*) In the superficial variety, if the beard is not shaved, use an ointment consisting of resorcin 10 per cent., and hydrarg. perchlor. ¼ per cent., to be rubbed in night and morning. If hair is shaved use the following:—R. resorcini 2, hydrarg. perchloridi .05, terræ silicæ 10, ung. zinci 90. Ft. pasta.

In these cases the salve sticks are very useful. Sublimate salve stick, or resorcin salve stick, to be used twice daily. As an adjunct, the resorcin spirit spray is to be recommended—R. resorcini 5 parts, hydrarg. perchloridi .01 to .05, ol. ricini 1.0, aq. cologniensis, spiritus *a* 50. Misce.

(*b*) The deeper nodular variety is best treated with plastêr mulls. The beard must be shaved, then a mull of mercury and carbolic acid is to be applied, and fastened on with zinc glyco-gelatine. Under this treatment, some nodules undergo rapid resolution, others suppurate painlessly, and with but little loss of tissue. Warm fomentations and epilations are valuable adjuncts to the treatment.

Coccogenic Sycosis.[2]

Having shaved the beard, patient must wear a plaster mull of mercury and carbolic acid, or of resorcin, during the day. The suppurating follicles are to be epilated, and touched with a 5 per cent. resorcin spirit. The following drugs may be applied as salves or 2 to 5 per cent. wet dressing at night time—Resorcin pyrogallol, chrysarobin, sulphur, or ichthyol; the latter is especially useful as a 10 per cent. wet dressing.

If patient objects to shaving, the superficial follicles must be regularly epilated, and then smeared with a salve of oxide of zinc and sulphur, or resorcin and sublimate. Scarification is not to be recommended, as it leads to fresh inoculation of cocci. Epilation is to be practiced on the follicles which are affected superficially, in order to allow of their more easy disinfection with antiseptics. When the affection is cured, fresh outbreaks must be guarded against by the destruction of newly arising postules by epilation, and cauterization with a pointed sublimate paste pencil, and by subsequent use of weak resorcin or sublimate applications.

Lichen Planus.

The remedy which exercises the most beneficial effects on this troublesome form of skin disease, is the perchloride of mercury. It may be applied in various ways. The following ointment, with which carbolic acid is incorporated, acts very effectively, dispersing the papules, and controlling the pruritus, which occasionally is almost intolerable:—R. hydrarg. perchloridi 1, acidi carbolici 20, vaselini 80. Ft. unguentum.

A good method is to apply the perchloride in collodion and spirit, which is to be brushed over each individual papule at first daily, and then three timez a week—R. collodion 20, spiritus 20, hydrarg. perchloridi 2.

The administration of arsenic forms also an important part of the treatment of lichen planus.

Lupus Vulgaris.[3]

The treatment of this aection has for itsff object the total destruction of the tubercular lesions which are situated in the cutis vera. With this object the curette or Paquelin's cautery must be freely used. The latter is preferred by Unna, since the micro-organism of the disease is less likely to develop afresh in the tissue that is wholly destroyed by the cautery, than it is in the raw surfaces left by the sharp curette. Also, a firmer cicatrix is produced by the cautery.

Having then, whilst the patient is under chloroform, thoroughly destroyed all the nodules of lupus tissue, the raw surface must be rendered quite aseptic by application of the following:—R. spiritus ætheris 80, acidi carbolici 16, hydrarg. perchloridi 4. The next step is the application of salicylic, creasote, or salicylic quaiacol plaster mull, whilst the patient is still under chloroform. The plaster

[1] *Monatshefte fur Prakt. Dermatologie*, 1888, p. 345.

[2] *Monatshefte fur Prakt. Dermatologie* 1888, p. 555.

[3] *Monatshefte fur Prak. Dermatologie*, 1889, p. 337

is to be cut a shade larger than the affected surface, and to be fixed in its place by zinc glyco-gelatine.

The plaster mull must be renewed every day; but before replacing the new one, the raw surface must be cocainized, and any nodules of lupus tissue that can be found undestroyed by the cautery, must be bored out with a sharp-pointed sublimate paste pencil (10 per cent.) The sublimate pencil is then smeared freely over the whole surface, and the new plaster mull is adapted as at the first dressing. If the salicylic plaster mull is not obtainable, the following, spread on a double layer of gauze, may be substituted—R. acidi salicylici 20, creasote 40, cerati 40. Ft. pasta.—*Australian Medical Journal.*

Selected Formulæ.

PISTOIA POWDER.

There is a powder made in a convent near Pistoia, Italy, and it is used very extensively as a protective against gout. The following is said by Mr. Chastaing to be its composition:

℞ Bryonia root,
Gentian,
Chamomile, aa.....grammes x.
Colchicum root..... " xx.
Betony..... " l.

This is made into 365 powders, one of which is taken each day of the year in a full glass of cold or hot water.—*Medical Record.*

SANTAL OIL FOR COUGH.

Curtin (*Philada. Hosp. Rep.*) finds that sandal wood oil often gives relief to the cough in phthisis, catarrhal pneumonia, chronic bronchitis, with asthma and influenza. It is given on sugar or floated on water.

TREATMENT OF CONDYLOMATA.

Dr. G. Finco (*Gazetta Medica Lombarda*) recommends the following in the treatment of condylomata:

℞ Collodion.....grammes 2.00.
Mercur corrosiv..... " 0.02.

The collodion should be poured into a small cup, the corrosive sublimate added, and the whole well shaken, as the sublimate does not dissolve in collodion.

The largest condylomata may be touched with a small brush dipped into the mixture following this with the local application of cold water. On the following days the others may be treated until all are removed.

THE CLINICAL VALUE OF THE DIAZO-REACTION.

The following solutions are necessary to make the diazoreaction:

A.

℞ Sulphanile acid.....gtt. lxxv.
Muriatic acid.....f℥ss.
Distilled water.....f℥xxx.

B.

℞ Nitrite of sodium.....gr. viij.
Water.....f℥iij.

When ready for use 75 drops of solution *B* are to be added to 8 ounces of solution *A*, and this reagent should be prepared fresh for every test. Then to equal parts of the reagent and urine, ⅓ volume of ammonia is added, and shaken up. In certain febrile diseases the fluid turns red, which is especially noticeable in the foam. This reaction is observed in typhoid fever, as well as in severe cases of phthisis, pneumonia and measles. Dr. Victor Grosstern (*Gazeta tekarskb*) formulates the following conclusions derived from this reaction in pulmonary tuberculosis and typhoid fever: 1. In pulmonary tuberculosis the intensity of the reaction is an index to the severity of the affection, and always means an unfavorable prognosis. 2. The reaction is always present in miliary tuberculosis. 3. The diazoreaction taken in connection with splenic enlargement and the roseolar eruption is one of the earliest symptoms of typhoid fever. 4. The diazoreaction is never present in febrile intestinal catarrh. 5. The course of the fever and the various methods of treatment have no influence on the reaction in typhoid fever. 6. The disappearance of the reaction in the second and third week of the disease indicates an early crisis; whereas, if the reaction persists, the typhoid fever will be long continued and severe. 7. Relapses are attended with a recurrence of the reaction.—*Wiener med. Presse,* April 19, 1891.

OPIUM SMOKING IN PHTHISIS.

Dill (*Lancet*) has obtained great improvement in several cases of phthisis by giving the patient tobacco to smoke which has been steeped in a solution of opium. In no case were any bad effects from the opium noticed.

FORMULÆ FOR GOUT.

The following (*Hygiea,* No. 3, 1891) is recommended as a local application in gout:

℞ Collodii.....grammes 5.
Æther sulphur..... " 5.
Acid salicyl..... " 4.
Morph. sulph.....gramme 1.

M. S. Apply locally with a camel's-hair brush every hour.

THE

MEDICAL AND SURGICAL

REPORTER.

ISSUED EVERY SATURDAY.

EDWARD T. REICHERT, M. D.,

PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF PENNA.,

EDITOR AND MANAGER.

Nos. 518-520 MINOR STREET,

P. O. Box 843. Philadelphia, Pa.

THE MEDICAL AND SURGICAL REPORTER.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

At the termination of the period of subscription, we will promptly discontinue sending THE REPORTER unless directed to the contrary by the subscriber.

Remittances should be made by draft, check, postal note, or money order payable to Edward T. Reichert.

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy." Unless this is done, newspapers are not looked at.

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

MASSAGE IN SURGERY.

Massage has undergone serious and conscientious trials and has apparently been equal to the test in the various domains of the healing art. Unlike hypnotism, the elixir of Brown-Sequard, the ill-fated treatment of Koch, etc., massage has not revolutionized the ideas of that profession which is ever eager to grasp whatever serves to cure or even alleviate human suffering, although probably more real benefit has been derived from this simple manual procedure than from the more pretentious remedies mentioned.

While massage should not be looked upon as the great panacea of the modern practice of physic, nor does it pretend to be, there is sufficient clinical evidence to show that it has produced gratifying results in the treatment of medical, surgical and gynæcological cases. Of late, it has been largely used in surgery, and many are the reported instances in which even permanent good has been obtained.

In reviewing this subject, Gilles asserts that massage has effected cures in cases of articular disease, in lumbago, in luxations, syphilitic and blenorrhagic arthritis, in acute and chronic epididymitis, in acute and chronic myositis, torticolis, muscular contractions, muscular atrophy, and muscular paralysis. We can easily understand how in many of these cases massage was effective. For instance, the active and passive movements of muscular massage act favorably on arthritis, and the continuous treatment of this affection, would undoubtedly tend to arrest the invading progress of atrophy. The same may be said of muscular contractions and paralysis. In other instances of a similar nature, suspension, which may be looked upon as an indirect massage, was applied. It seemed to give the best results. Be this as it may, this procedure is a violent one and should be modified. But we cannot yet understand, much less explain, how massage can act favorably, as reported, in cases of infectious diseases of the joints, such, for example, as syphilitic and blenorrhagic arthritis.

In this connection we may refer to a research of J. R. Kappeler, (*Fort. der Med.* Apr. 1, 1890.) This investigator has endeavored to determine whether through massage, pathogenic micro-organisms can be removed by means of the lymphatic glands from the seat of infection, and whether such removal could be effected before any specific action of the bacteria became manifested at the seat of inoculation. It was likewise the object of the experimenter to determine whether the organisms thus treated perished or still retained their specific properties. The experiments were made with the *staphylococcus aureus*,of which an artificial pure culture was employed. The seat of inoculation was the knee-joints of rabbits. After the injection the joint was rubbed for seven minutes, the operation being repeated after half an hour. It was afterwards continued for several days, twice daily, and for fully ten minutes during each operation. After many careful experiments the observer found that both joints in which were and in those which were not rubbed, an effusion of pus occurred,by the fourth day, and continued to increase slightly for a day or two and then stopped. The pus was yellow and creamy and contained the *staphylococcus* which retained its vitality and specific power even when left in the joint for a period of a hundred and twenty days. Severe diarrhœa in all cases, and pneumonia in a few instances, occurred. No disease was found in the long bones or other joints in any of the animals experimented upon. In many of them, however, secondary abscesses of the kidney and liver were observed conjointly, and the *staphylococcus* could be cultivated from the pus of the joint subjected to massage as well as from that which had been left at rest.

These and other results, all of which were of a negative character, simply appear to show that massage alone is incapable of removing a specific pyogenic germ (staphylococcus pyogenes paureus) from the knee-joint by means of the lymphatic vessels.

It is true that in such cases as these massage appears to exercise no serious deleterious influence; but it cannot be inferred from this that the process would be harmless if applied to more vascular seats of inoculation. It is, however, probable that the removal of bacteria might be hastened by massage in places where the effusion of leucocytes might not be sufficient to block the lymphatic vessels.

Notwithstanding the above facts, massage has produced gratifying results in the treatment of a variety of surgical cases, and we cannot but admit its undoubted usefulness in many instances especially where other measures have entirely failed. Thus Douglas Graham (*St. Louis Medical and Surgical Journal*, July, 1890) who has made a critical study of massage in surgery, and who has published some interesting statistics, asserts that cases of sprains got well in one-third the time under massage than without it, and with less tendency to subsequent pain, weakness and stiffness. Many French surgeons, notably Championierre and Rafin, have treated fractures by means of massage, and usually with the best results. In such cases the movements promoted the absorption of effused products, prevented the stiffness of joints, and the atrophy of muscles, and generally hastened the repair of tissues. Rafin has seen recovery take place in 13, 22 and 12 days respectively, in three cases of fracture of the fibula; in two of fracture of the radius in 19 and 20 days; in a double fracture of the ulna in 27; in a fracture of the external condyle of the humerus of a child, in 9 days; in a fracture of both malleoli in a child, in 15 days; in another fracture of both malleoli, with subluxation of foot outwards and backwards, in an adult, in 40 days. Recoveries from transverse fractures of the patella have been observed by Tilanus of Amsterdam, under massage and early movements of the joints. Six patients treated by this author, could walk very well in the course of fourteen days. The same results were obtained in five cases of the same nature, according to Wagner of the Austrian Army, and in which even the application of bandages was dispensed with. In all these latter cases, the effusion being quickly dispelled, both atrophy and stiffness

were prevented. Three cases of relaxation of ligaments in which the most excellent effects were produced by massage are reported by Graham himself. In all of them the paralyzed muscles, from want of use, and which were unable to extend the affected leg at all, could, in a few weeks, hold it fully and voluntarily for seven, nine and ten minutes respectively. The first case was one of a lady who had the remains of an old synovitis. The second was that of a man, 63 years of age, with a rheumatismal arthritis of the left knee which had developed as a result of an injury. The third case was that of a woman suffering from relaxation of the quadriceps extensor, which allowed the patella to slip externally without power, voluntary or involuntary, of replacement.

If all these results be correct as reported, certainly massage is a remedial measure of no inferior value in surgical practice; but here, more so than in the treatment of medical cases, extreme care should be exercised in its application, lest the doors of a sacred sanctuary be opened to a reckless and evil-producing charlatanism.

PERISCOPE.

THERAPEUTICS.

ON RESCUING DROWNING PERSONS.

The following directions to swimmers for rescuing drowning persons are given by Herr Tetens, President of the Seaman's Society in Hamburg:

1. When you approach a drowning person, call to him in a loud voice that he shall be saved.

2. Before springing into the water, undress as completely and as rapidly as possible. Tear the clothes off if necessary; at any rate, loosen the drawers below if they are bound about the ankles, else they fill with water and hold back the swimmer.

3. Do not touch the drowning person so long as he still struggles strongly in the water; wait a few seconds until he becomes quiet. It is foolhardiness to touch any one while he struggles with the waves, and he who does this subjects himself to much danger.

4. When the unfortunate is still, seize him by the hair of the head; throw him as quickly as possible upon his back, and give him a push to hold him up. Then throw yourself upon your own back and swim thus for land, meanwhile holding with both hands the drowning person by the hair—of course with face upward and his head resting upon your own body. In this way one reaches land more quickly and surely, and a skilful swimmer may even keep two or three persons above water. A great advantage of this expedient is that the rescuer is in the most favorable position for keeping his own head as well as that of the unfortunate above water. One can also remain in this position a long while, which is of importance when obliged to wait for a boat.

5. The "death-grip," practically, is a thing of rare occurrence. As soon as a person becomes weak and begins to lose his senses, his grip becomes weaker, and his hand at last completely loses its hold. He, therefore, who has an idea of saving a person by swimming, need have no fear of the "death-grip."

6. If the person has sunk before he could be reached, the location of the body will be very accurately indicated by the bubbles which rise to the surface now and then. In flowing water which prevents the perpendicular rising of bubbles, allowance must of course be made for the direction and the rapidity of the current.

7. In diving after a body, it should be seized by the hair with only one hand, while the other hand and the feet are used in regaining the surface.

8. In salt water when the current sets from the land, as when the tide is going out, it is a mistake to struggle to reach land. One should rather throw himself upon his back, whether alone or encumbered, and await help from the shore. Many persons perish by exhausting themselves in vain attempts at swimming against the current, when they might have thrown themselves upon their back and awaited help from shore.

9. These rules are applicable in all cases, whether in still water or in the roughest sea.—*Schweiz. Blatter f. Gesundh.*

VACCINATION IN WHOOPING-COUGH.

Dr. Cachoza (*Norsk Magazin for Lægevidenskab*, No. 5, 1891), after an accidental observation of improvement in a child with whooping-cough after vaccination, vaccinated five children, of which four were very severely attacked, having spasms, vomiting

and hæmorrhages from the nose and mouth. After vaccination and the consequent fever the scene was entirely altered; the cough ceased to be spasmodic and entirely disappeared after eight or ten days. Inhalations of a 1 per cent. carbolic acid solution completed the treatment necessary.

AVOIDANCE OF STIMULANTS DURING HÆMORRHAGE.

It is customary, when the accident of hæmorrhage occurs, for the operator, or some by-stander, to administer wine, brandy, or some other alcoholic stimulant to the patient, under the false idea of sustaining the vital power. It is my solemn duty to protest against this practice on the strictest and purest scientific grounds. The action of alcohol, under such circumstances, is injurious all around. It excites the patient, and renders him or her nervous and restless. It relaxes the arteries, and favors the escape of blood through the divided structures. Entering the circulation in a diluted state, it acts after the manner of a salt in destroying the coagulating quality of the blood; and, above all other mischiefs, it increases the action of the heart, stimulating it to throw out more blood through the divided vessels. These are all serious mischiefs, but the last named is the worst. In hæmorrhage the very key-stone of success lies so much in quietness of the circulation that actual failure of the heart, up to faintness, is an advantage, for it brings the blood at the bleeding-point to a standstill, enables it to clot firmly, when it has that tendency, and forms the most effective possible check upon the flow from the vessels. Dr. Richardson (*Asclepiad*, No. 29, 1891), refers to a case in which three pounds of blood was lost and the patient was unconscious, but which recovered. He refers to this as typical, because, if a stimulant were not wanted in it, a stimulant cannot be called for in examples less severe. The course followed was simply to lay the patient quite recumbent when signs of faintness supervened, and, so long as he could swallow, to feed him with warm milk and water freely. Such, in my opinion, is the proper treatment to be employed in every instance of syncope from loss of blood.—*Dietetic Gazette*, June, 1891.

BROMOFORM AS A TOPICAL APPLICATION.

Dr. Solomon Solis-Cohen, writes in the *News*: I have recently employed bromoform in a severe case of ozœna as a topical application to the nasal mucous membrane after thorough cleansing with hydrogen dioxide. The absence of the severe local reaction anticipated, together with the extraordinary success of the measure, not only in destroying the odor but in controlling the morbid secretion, encourged me, after preliminary trial upon my tongue and pharynx, to use the same agent as a topical application to tuberculous and other ulcers of the larynx, after cleansing with hydrogen dioxide. Here the agent seemed to exert analgesic as well as disinfectant properties, as pain was relieved and healing apparently promoted. The agent being extremely volatile, the immediate effect is transient, and I have, therefore, followed the application of bromoform with insufflation of iodoform in powder. While this somewhat obscures the therapy, yet the effect was better than when iodoform had been used without bromoform in the same cases. This preliminary note is published at this time to induce further trial and report by others.

THE GOOD RESULTS OF MASSAGE.

Dr. Agostini (*Archivio di Orlopedio*) presents the statistics of 417 cases observed during the last six years, both in private and hospital practice. He thinks that massage should only be employed by the physician, and cites a case where the brutal manipulation of an inexperienced masseur produced serious disorders. His material consisted of the following traumatic lesions: 41 cases of dislocations of the tibio-tarsal joint, 12 of the radio-carpal, 6 of the elbow, 3 of the knee, 15 cases of contusions, 12 cases of rupture and laceration of muscles, 9 of fractures and 5 of luxations. He has also treated 74 cases of severe inflammation of the joints and the resulting articular degenerations, with rapid and complete recovery. Articular and muscular rheumatism were also relieved. —*Revue d' Hygiéne Thérapeutique*, January, 1891.

PHYSIOLOGICAL EFFECT OF BATHS IN TYPHOID FEVER.

"Dr. Kurkutoff, who has examined the physiological effects of the baths administered to typhoid fever patients in Professor Manassein's clinic in St. Petersburg, finds that such baths exert only a slight effect on the assimilation of the fatty constituents of foods, which, as in other fevers, is notably less than in healthy persons, and indeed varies directly with the gravity of the case; but there seems to be a good deal of differ-

ence as to the power of assimilation of fatty matter in different cases, probably depending on the functional disturbance in the bowel and on the amount of the individual peculiarities of the patient. In the graver cases the effect of the baths was to improve somewhat the assimilation of fat to the average extent of nearly four per cent. In slight cases, however, the effect was, apparently at least, to diminish the assimilation to the average extent of rather more than six per cent."—*Lancet.*

A PRACTICABLE AND PAINLESS METHOD OF USING IODINE HYPODERMICALLY.

In the *Medical News* of April 14, 1891, Dr. E. Fletcher Ingals, discussing the Shurly-Gibbes treatment of pulmonary tuberculosis, says: "It is usually best, excepting in advanced cases, to begin with iodine, though it is apt to cause considerable smarting," etc. In the *Therapeutic Gazette* for April, 1891, Drs. Shurly and Gibbes say: "The iodine solution gives considerable pain to some people, to others very little; but the gold solution gives little or none. We hope that a solution can be made with lanolin, or something of that sort, which will obviate this objection in the case of iodine."

Having found the use of the iodine solution exceedingly painful, in one case so severe as to lead to the conclusion that if its use was persisted in, local anæsthesia, by means of spray or other more or less inconvenient method, must be resorted to, I found that the injection could be rendered absolutely painless by incorporating with the mixture as used by Drs. Shurly and Gibbes, a small quantity of creasote, or better, guaiacol. Another objection to the solution as prepared by Drs. Shurly and Gibbes is the large *quantity* necessary to be injected when it is desired to administer the full dose of one-half grain of iodine. This requires that sixty minims be introduced beneath the skin, and since the hypodermatic syringe, as usually made, has a capacity of but thirty minims, either the barrel must be unscrewed and refilled, the needle meanwhile being left sticking in the skin, or if the needle is withdrawn a second puncture must be made, all requiring time and causing additional pain. This might be avoided by increasing the strength of the solution, which, I infer, has been found impracticable, because of increased pain or other reasons. The object can be attained by incorporating iodoform in the solution to be used, and thus combined, the anæsthetic effect of the guaiacol is increased and prolonged. The formula that I have adopted after a number of trials as most eligible is as follows:

℞ Eucalyptol, pure.....ℳ xxxij.
Guaiacol, pure.....ℳ xvj.
Iodoform.....gr. viij.
Iodine.....gr. jv.
Ol. amygdal. dulc. (sterilized) q.s. ad. f℥j.
Sig. For hypodermatic use · 10 to 30 minims daily or alternating with gold and sodium solution, as desired.

The anæsthetic properties of this solution are such that patients prefer its use to that of the gold solution, although the latter is nearly painless. Larger doses of the guaiacol and eucalyptol than are contained in the thirty minims of the above solution have, in my hands, caused excessive and exhausting sweating, with no proportionate benefit. The amount of iodine in this formula is the same as that contained in the Shurly-Gibbes solution, with, as will be seen, double that quantity of iodoform. Therefore the dose may be but one-third to one-half of that of the Shurly-Gibbes solution.—Dr. A. O. Squier, in *Med. News.*

THE TREATMENT OF VARIOUS TOXIC AMBLYOPIÆ.

1. *Alcoholic Amblyopia:*—Complete abstinence from alcoholic drinks. Aid nutrition by administration of tonics and healthy foods; calm cerebral excitement by a course of bromides. Locally, by instillation of eserine or of pilocarpine the existing mydriasis can be overcome. Recourse should be had to hypodermatic injections of strychnia, the galvanic battery, hydrotherapy and to ocular douches.

2. *Tobacco Amblyopia:*—Moderate use of tobacco. According to Sichel and Mackensie, the smoking of fifteen to twenty grammes (about half an ounce) of tobacco per day is a toxic dose; never smoke but two-thirds of a cigar, as the last third is a reservoir for nicotine. The preceding is prophylaxis. If amblyopia exists, use of tobacco must be prohibited. Stimulate nutrition, give inhalations of nitrite of amyl, injections of strychnia, constant current of electricity and ocular douches.

3. *Saturnine Amblyopia:*—The treatment is that for saturnism: purgatives, sulphur baths, iodide of potassium in large doses, and tonic regime.

4. *Quinine Amblyopia:*—The elimination of the drug is facilitated by giving purgatives and diuretics; use also inhalations of nitrate of amyl, injections of strychnia and electricity.

5. *Amblyopia from Antipyrine:*—The author cites numerous cases of amblyopia

associated with ischæmia of the retina following the use of large doses (four to seven grammes) of antipyrine taken through a period of several weeks. Discontinuance of the use of the drug restored vision at the end of about ten days.

6. *Amblyopia from the Fumes of Carbon Disulphide:*—The patient will have to abandon his occupation as one of the first requisites to recovery. The use of tonics, iron and quinine, a substantial diet, subcutaneous injections of strychnia, inhalations of nitrate of amyl, and galvanic electricity will all aid toward effecting a cure. As a means of prevention, prohibit the manufacture in rooms; ventilate perfectly; hermetically seal containers; observe great cleanliness on the part of workmen; they should change their clothes on leaving the factory. —*L'Union Médicale du Canada.*

BORAX IN EPILEPSY.

Dr. Dijoud has tried this remedy in twenty-five cases, and he claims to have entirely cured one, and to have relieved all except six. The duration of the treatment varied from one to seven months, and he was able without inconvenience to carry the dose up to ninety grains a day. This was only possible if a beginning were made with small doses, which were gradually increased; and when the dose exceeded sixty grains daily he found it advisable to add some glycerine to the water and syrup in which the drug was usually administered. It should also be mentioned that the patients to whom Dr. Dijoud administered borax had been treated unsuccessfully with the bromides, and there seems now to be little doubt that in certain cases of epilepsy, borax is of very considerable use. It is desirable that particulars should be furnished of the time that elapsed between the cessation of the treatment by bromides and the inauguration of that by borax, as it is well known that epileptics who have been treated with bromides often improve much in their condition after the drug has been left off; and it is necessary to distinguish this improvement, which at least occasionally occurs, from that which may be due to the administration of a fresh remedy. —*Lancet.*

ANTIPYRIN AND ANTIFEBRIN IN POLYURIA.

In the *Meditzinskoïe Obozrenië*, No. 5, 1890, p. 487, Dr. I. I. Maslovsky, of Bürnak, draws attention to antipyrin and antifebrin as remedies for diabetes insipidus, and adduces an interesting illustrative case referring to a sickly and highly nervous peasant-lad, sixteen years old, with polyuria of a nervous origin and of six years' standing, in which the use of these drugs was followed by a striking and apparently permanent decrease of both thirst and amount of urine. Antipyrin was administered at first in eight-grain doses four times daily; later twelve grains five times a day; then finally twenty-four and twenty-six grains four times daily, the whole course lasting thirteen days. The daily quantity of urine fell from 11.700 cubic centimeters to 6.100; that of water ingested from 10.600 to c. c. to 6.200. After an interval of three days, antifebrin was resorted to in from six to eight-grain doses four times daily, for eight days. The daily quantity of urine decreased from 6.300 c. c. to 4.100; that of water ingested from 7.450 to 4.590. No unpleasant effects were ever noticed from either of the remedies.

MEDICINE.

ELIMINATION AND ITS USES IN PREVENTING AND CURING DISEASE.

The above was the title of the Cavendish Lecture, delivered June 12th, by Dr. T. Lauder Brunton. Particular emphasis was placed on the importance of free elimination by the bowels. Not only the brain, but the heart, lungs, liver, stomach and kidneys have their functions impaired when the bowels cease to do their duty. Napoleon's disaster at the battle of Leipzig is popularly set down to his having eaten a bun in a hurry, and so brought on dyspepsia; but it would be a very curious page of history if we could learn how many wars, how much bloodshed, and how much cruelty have had their origin in imperfect action of the bowels. Washington Irving, in his "Lives of the Caliphs," tells of a certain emir named Al Hejagi, who suffered for many years from dyspepsia and abdominal pains, and this wretched man distinguished himself, perhaps above all other rulers who ever lived, in the enormous number of people whom he sentenced to imprisonment and death. He is said to have caused the death of no less than 120,000 persons, besides those who fell in battle, and to have left 50,000 in prison when he died himself. How much of all this misery might have been averted by the judicious use of mild aperients, it is as impossible for any one now

to tell, as it is to estimate the debt of gratitude which Europe owes to the physician of Louis XIV for the care he took of the bowels of that august monarch.

In mitral disease and in dropsy, either cardiac or renal, the benefit derived from the free use of the compound jalap powder is very great; and in his work on "Purgative Medicines," Dr. Hamilton describes most forcibly the advantages he obtained from purgatives employed in such a way as merely to clear the bowels, not to produce violent purging, in typhus fever, malaria, scarlet fever, hysteria, chorea and tetanus.

Most persons can regulate their bowels by exercise and diet, but these sometimes fail, and we must have recourse to so-called aperients. The dinner-pill supplies a very useful stimulus, and Dr. Brunton knows a man who has taken one every day of his life for forty years, apparently with great benefit to himself. But there are some people who do not seem to thrive on dinner-pills, and they either do not get any action at all, or they get too much. In such cases, instead of giving the intestines one great push once a day by the dinner-pill, one may give them a series of gentle jogs by adding to each meal a minute quantity of a purgative; and Dr. Brunton has found that one-tenth of a grain of aloin given with each meal sometimes succeeds when other means fail, and even these minute doses sometimes seem to be too much.

But many persons, besides the dinner-pill, require a weekly clear-out; and if this be not given to them by means of a cholagogue purgative, they have a regular sweep-out once a month by getting a violent migrane with bilious vomiting; and generally they are obliged to fast for at least one day during the continuance of the headache. The effect of a cholagogue purgative such as a mild mercurial, followed by some saline, is sometimes very remarkable. Dr. Brunton has seen a quarter of a grain of calomel, with a Seidlitz powder next morning, surprisingly change the temper of a sulky boy or girl; and he has more than once taken the "naughtiness" out of a peevish child by a dose of Gregory powder, which, being nasty to the taste, has both a moral effect and a physical action.

Not infrequently adults suffer from nervous irritability, depression, weakness, and inability to do anything; and this is often put down to neurasthenia and hypochondriasis. They are treated with nervine tonics and sedatives, change of scene, baths, etc., to little purpose; nervous and depressed they still remain. In some of these cases, we may notice a large amount of mucus in the motions, and sometimes there appear to be actual casts of the intestines, long, membraneous-looking shreds, apparently tubular in their character. This condition has been described by Dr. James Simpson, under the name of "membranous enceritis"; and it is not usually said to be associated with hypochondriasis, but often it is looked upon as a consequence rather than the cause of the nervous condition which is its usual concomitant. But it is no use here to treat the nerves. If you wish for any good result, you must treat the bowels. In some, probably many cases, conditions depend upon partial constriction of the intestine near the junction of the sigmoid flexure with the rectum. The motions, lodging here, cause an inflammatory condition of the mucous membrane and profuse secretion of mucus, which either simply coats the fæcal matter, or forms a kind of false membrane. In adults, prolapse of the sigmoid flexure into the rectum may give rise to great nervous disturbance lasting for years, unless its existence be suspected and the proper treatment adopted. One useful remedy is the injection of two to four ounces of cold water immediately after a motion. This is to be retained, and has the tonic effect of a cold bath on the intestine, increasing the contractile power and lessening the tendency to prolapse. In all cases of this kind the regular use of suitable laxatives should be enjoined.

Dr. Brunton, in the same lecture, urges the importance of maintaining a healthy state of the renal function, and speaks of the benefit in gouty and rheumatic cases, and in bilious colic, of making patients drink a big tumber of water, and especially hot water, every morning, with or without some Carlsbad salts added to it, and, if necessary, repeating the hot water once or twice in the day.—*Boston Med. Surg. Jour.*

THE NERVES OF THE CORNEA.

Dr. A. C. Dogel, has examined eyes which had been taken from the body from five to seventeen hours after death. The result of these examinations, as published in a Russian opthalmic review, was that he found the cornea provided with from sixty to eighty small nerve branches, some with and some without medulla, of which from twenty to thirty go to the posterior corneal surface, and from forty to fifty to the anterior. In these nerves a central filament and a peripheral axis cylinder substance may be distinguished.

The central filament resolves itself into single nerve fibrillæ. Within the corneal parenchyma the nerves and their branches form a primary plexus. This primary plexus gives out secondary branches, called "rami perforantes," which form the sub-epithelial plexus, and this again gives rise to still finer ramifications forming an intra-epithelial plexus. The same nerve branch generally shares with its branches of the second order in the formation of all these plexuses. The nerve terminations in the epithelium are bulb-shaped, and form ganglions. An especial thickness and zigzag course distinguish those filament which go to the stroma of the cornea. These also form a plexus. Each layer of the cornea has a separate plexus except the membrane of Descemet and the next layer, which have no nerve plexus. The author believes, in opposition to Kuehne and Waldeyer, that the nerves of the cornea have no sort of connection with its cells and corpuscles, but are merely situated between them.—*Lancet.*

A NEW POINT—NOTE ON THE VIRILE REFLEX.

Dr. C. H. Hughes says in the *Alienist and Neurologist*: If you take a perfectly healthy individual, whose spinal cord is entirely normal, especially in its genito-spinal center, and place him on a couch without head-rest, supine and nude about the loins, and make the sheath of the penis tense by clasping the foreskin with the left index finger and thumb at about the place of the frænum, and pulling it firmly towards the umbilicus, placing the middle, ring and little finger low down upon the dorsum of the virile organ, for perceptive purposes, and then sharply percuss the dorsum or sides of the penis, near the perineal extremity, a quick and very sensible reflex motor response or retraction of the bulbocavernous portion will be felt to result from this sudden percussional impression, like that which follows, though less pronounced, in the testicles, after sensory irritation of the inner aspect of the thighs, and known as the cremasteric reflex. The reflex jerk is away from the irritating impulse, though it is down towards the perinæum in the penis reflex, while it is upwards in both the cremasteric and patellar tendon phenomena. I have not seen this phenomenon described before.

This reflex symptom is of important clinical and physiological significance. Its full value for diagnostic and prognostic purposes has yet to be determined by further investigation than I have given it. But I have learned enough to confidently commend it to neurological clinicians.

I have called it the virile reflex, because it seems to be actively present in all healthy adult males with normal spinal cords, whom I have examined, and absent in infants, and feeble or absent in male children who have not attained the age of puberty. A number of years ago I ventured the assertion that the absence of the cremasterick reflex would be found of significance in the determination of impaired virility from sexual excess and masturbation. This subsequent experience has only been confirmed. Now this new sign—the penis percussion reflex—present, impaired or absent, gives us another valuable evidence of the vigor, impairment, loss or abeyance of the sexual powers in man.

After prolonged excessive venery it becomes impaired or disappears,to return again with sexual recuperation.

After excessive masturbation, long continued, with accompanying neurasthenia, I have found it impaired, but seldom entirely absent in young subjects. It is not impaired in masturbation when the habit has not destroyed the sexual power. It disappears in some cases of chronic meconism, and becomes abeyant in long and beastly intoxication, though often excitable in acute alcoholism. This subject needs further investigation.

It is lowered and abeyant in the later stages of typhoid fever, and I have found it also in the moribund state. I have found it absent in old men who have acknowledged and sought treatment for entire virile incapacity.

It is often, but by no means uniformly, found in sympathy with the other reflexes in spinal cord disease of the lumbo-dorsal spine as the quadriceps extensor femoris tendon reflex, the anal, vesical and cremasteric reflex, the Achilles reflex and ankle clonus.

A kind of erector penis clonus, characterized by a succession of jerks, continuing after the percussion or while the foreskin is kept stretched, much like the characteristic ankle clonus, having been elicited in one case of transverse dorsal spinal myelitis with double ankle clonus only to fade away as the ankle clonus disappeared. I found it absent in another case.

This phenomenon may also be elicited by suddenly jerking the foreskin after it has been made tense, or by pinching the theca of the penis when it is in this stretched condition. This reflex may be reinforced like the knee phenomenon. Electrical excitation will also

evoke it. A clonus may sometimes be elicited in this way.

Some skill in palpation—a sort of *tactus eruditus* is necessary in examining for this sign, the characteristic jerking back of the bulbous urethra within the sheath of the penis being felt only when carefully sought for. It is not ordinarily to be seen.

This sign does not always sympathize with the other reflexes in spinal column or cord disease. I have lately found the sign absent in the case of a married man, aged 45, sent me by Dr. Charles Barck, the accomplished opthalmologist of the Marion-Sims Medical College, who diagnosed white atrophy of the retina. This man has also unequal pupils, exaggerated patellar reflexes, and other evidences of *scleros in plaques*. He gave a history of syphilis, and confessed to feeble virile powers. In him the virile reflex was scarcely perceptible. I found it absent on the same day in another, but older patient, with optic atrophy, unequal pupils and cerebral sclerosis, which I regard as one of multiple cerebro-spinal disease. The optic atrophy was diagnosed by Dr. Post and Dr. Wolfner. This man's age, however, is fifty-six, but the sign is not normally absent at that age in healthy men. I have found this sign absent in the status epilepticus, but not necessarily modified in hemiplegia. It was exaggerated in a case of paraplegia of cerebral origin.

It should receive further consideration at the hands of neurological clinicians, for it appears worthy a place in clinical neurology with Westphal's papadoxical contraction, Erb's reaction of degeneration, or any of the hitherto recognized diagnostic reflexes.

SOME PRACTICAL POINTS IN THE DIFFERENTIAL DIAGNOSIS OF IRITIS AND CONJUNCTIVITIS.

Dr. Frederick E. Cheney, writes in the *Boston Med. Surg. Jour.* that the importance of making a correct and early diagnosis, in cases of iritis, and of using atropine, or some other mydriatic, until the inflammation has subsided, is evident, when it is considered that many patients are afflicted with permanent poor vision and not a few with blindness, as a result of improper treatment in this disease. In most of these cases the trouble has probably been mistaken for conjunctivitis, the eye has been treated with "borax and camphor," or some other mild astringent collyrium, and a disease which usually terminates favorably when treated from the beginning with atropine terminates most unfavorably.

The presence or absence of pain, and its character and situation, if present, is a symptom of great value, and cannot be too carefully investigated. In conjunctivitis, there is often no pain, other than a feeling of "sticks and sand" in the eyes, while at other times pain of moderate severity is complained of and is referred by the patient to the eyeball. In iritis, on the other hand, pain is usually a prominent symptom, it is paroxysmal in character, coming on most frequently in the early hours of the morning, and is not situated to any degree in the eyeball itself, but in the brow and temple, sometimes extending over the entire side of the head. If this neuralgic pain is of great severity, especially if accompanied by a marked rise of temperature and a loss of appetite and flesh, the redness of the eye may be overlooked both by the patient and physician, or regarded simply as a congestion secondary to the neuralgia. Neuralgia of the temple and brow, in connection with redness of the eye, should always make one suspect iritis as the cause, and should lead to a careful examination of the pupil, as to its size and reaction to light. Having placed the patient facing a bright light, the well eye is to be covered, while the inflamed eye is to be shaded from the light with the examiner's hand. If the case is one of conjunctivitis, the pupil will quickly dilate when the eye is shaded and again contract when exposed to light. If iritis, however, it will be noticed that the pupil is smaller than normal, and that it reacts little or not at all when the eye is alternately shaded and exposed. These three symptoms, redness of the eye, neuralgic pains in the temple and brow, and a pupil which reacts sluggishly or not at all to light, are most valuable diagnostic symptoms in iritis, and when present, should leave doubt as to the nature of the disease. Intolerance of light is usually present in iritis, but may also be present in conjunctivitis. The iritis tissue is usually discolored in iritis, the change at times being very noticeable, while at other times it is slight and can be easily overlooked. The character of the vascular injection should of course be noticed, the circumcorneal vessels being injected in iritis, and the conjunctival vessels in conjunctivitis. It is not uncommon, however, to see a moderate injection of the circumcorneal vessels in conjunctivitis, or to see a considerable injection of the conjunctival vessel, and even œdema of the tissue, in iritis.

To emphasize what has already been said, the symptoms most to be depended upon in making a diagnosis of iritis, are, redness of the eye in connection with neuralgic pains of the temple and brow, and a contracted pupil that reacts sluggishly or not at all to light. Sub-acute and chronic cases are at times met with in which the pain is slight or absent, and the circumcorneal injection but poorly marked. The pupil will, however, be contracted and sluggish, and as the trouble often exists for some time before medical advice is sought, firm adhesions between the pupillary border and lens will probably be found after atropine has been used. Also, in acute iritis, pain may not be complained of the first few days, and in exceptional cases may be absent during the entire course of the disease. The absence of supra-orbital and temporal pain, therefore, although a most frequent and valuable diagnostic symptom, does not exclude iritis, and the presence of other symptoms must always be looked for. If, after careful examination, a doubt as to the nature of the disease still exists, a safe rule to follow is; when in doubt, use atropine. If the disease proves to be conjunctivitis, the use of atropine for the first day or two will have caused no permanent harm, the mydryasis and paralysis of accommodation passing off within ten days or a fortnight. If, on the other hand, it is iritis, we shall have the pupil well dilated, and if kept so by the use of atropine until the inflammation has subsided, it will be almost impossible for adhesions to form between the iris and the lens.

The value of the early and constant use of atropine in iritis cannot be too strongly insisted upon. A wide dilation of the pupil is of course the end in view; and while, as a rule, a one-per-cent. solution of atropine sulphate used three or four times a day will accomplish this, a more frequent instillation or stronger solution is sometimes required.

SURGERY.

METASTATIC CARCINOMA OF THE FOREARM.

The law, that while sarcomata often spread by the blood, carcinomata follow the lymph-channels, has its exceptions. Helferich (Abst. in *Centralblatt f. Chirurgie*, 1891, 14,) gives a unique case of a man 78 years old, with a large spindle-shaped growth which had developed, entirely independently of the skin, deep in the muscles of the forearm. The diagnosis wavered between enchondroma and myositis ossificans. The microscopical examination, however, showed it to be a carcinoma. A second, more careful, examination of the patient then revealed a small tumor the size of a pea, covered with a crust, in the lower lip. This was extirpated and proved to have the same microscopical structure as the tumor in the arm. Inasmuch as this lip-growth had existed for four years, while that in the arm had developed within a year, it seems reasonable to suppose that the latter was a metastasis from the former. The patient made a good recovery after an exarticulation at the shoulder. —*Exchange.*

THE CLOSING OF TREPHINE OPENINGS BY CELLULOID PLATES.

A case was presented to the Vienna Medical Society by Hinterstoisser (*Wiener Med. Presse*, No. 42, Bd. xxxi) showing the successful result of an effort to close a trephine opening by a celluloid plate. The patient, some months after recovering from a comminuted fracture of the left parietal bone, suffered from giddiness, weakness, loss of power in the right side, and chronic twitchings of the right facial region and the corresponding upper extremity. Three years later epilepsy developed. Examination showed a hyperæsthetic depressed cicatrix corresponding to the position of the upper portion of the ascending parietal convolution. There was also bilateral concentric narrowing of the field of vision, diplopia on looking to the left, and sensory and motor paresis of the left side. The cicatrix was excised, a periosteal flap raised, the depressed bone removed, and the healthy non-adherent dura incised, showing normal brain cortex. The dura was sutured; on the fourth day it was found united. A polished celluloid plate was now fitted over the trephine opening, the periosteum was stitched over this, and finally the skin wound was sutured. Healing was prompt and all brain symptoms ceased. Two other successful cases were also reported where celluloid plates were used in a similar manner.—Quoted in *Amer. Jour. Med Sc.*, June, 1891.

THE EXTRACTION OF BROKEN NEEDLES.

Dr. Charles Steele, thus writes in the *Lancet*: All who have had much to do with this minor operation know how frequently a satisfactory result fails to be obtained unless the indications for a safe operative procedure

are strictly observed. It is most unpleasant, after cutting and probing with the finger and forceps, to be obliged to tell a patient who has endured some pain and much discomfort that further attempts are useless, and that the fragment is still there; and perhaps suggest as the best consolation that the needle has a more free opening by which to work its way out. I have for many years declined to cut unless I could make out the situation of a point, and that the other end had a firm bearing to rest upon; giving the assurance that patience and watching are the proper treatment for the time being.

Lately I have adopted a very simple, painless, and reliable plan, and have regretted that I had not thought of it in many previous instances. Last autumn, when I was visiting a child, a young lady, his sister, came into the room using her right foot naturally, but resting only on the toes of her left foot, and explained that she had gone about in this way for fully three weeks, as she had broken a needle into her left heel, and the slightest touch gave her great pain. The point of entrance was visible in the middle line in front of the tuberosities of the os calcis; the end of the fragment could be recognized through the skin, but the slightest pressure made it recede. I declined to operate, but directed that two thick felt corn plasters, one on the other, should be applied, with the puncture occupying the central hole, and that she should walk freely and bear well upon the heel. This she did with perfect ease, and after ten days the needle presented, and was withdrawn readily. It was the eyed end, and almost an inch long. Soon after I saw a little girl, aged three years, who when away from home in the summer had also trodden upon a needle, which broke and entered between the ends of the metatarsal and tarsal bones. A surgeon saw her promptly, cut down, and tried for some time to extract, but failed. She often felt no inconvenience, but at intervals limped suddenly, and complained of pain. She was persuaded to wear a corn plaster, and after three weeks the portion of needle, which had been in more than three months after producing a little superficial irritation, showed itself, and her nurse drew it out. The wrist and the ball of the thumb are not unfrequently punctured, and if the fragment enters obliquely, or lies close to arteries or nerves, and cannot be forced into prominence, attempts at extraction are, to say the least, undesirable; whereas, by adopting this simple method, after the manner of removing a thorn with the pipe of a key, and producing pressure with an elastic wristlet or slight steel spring like a small truss, the fragment will work out, and not give pain from knocks while under the skin. In that awkward position, the soft parts by the sides of the ligamentum patellæ, this plan can be used. It recommends itself to everyone's common sense, and has the great advantage of not leaving any cicatrix.

A FEW SURGICAL EXPERIENCES AND WARNINGS.

Mr. W. F. Favell read a paper before the Sheffield Medico-Chirurgical Society in which he said that while freely acknowledging the great results which had followed upon the improved surgical procedure of the last 20 or 30 years, he defended the principle of conservation in surgery, and laid down as a general proposition that in the case of malignant growths, for example, unless they could be removed wholly, they were better left alone altogether. He instanced some cases in point from his own experience. He had a great dislike to incompetent operations. He deprecated exploratory incisions in the case of tumors, unless the surgeon was prepared at the time to remove the tumor bodily, if necessary, all such measures tending to stimulate the growth into increased activity. Mr. Favell then referred to the danger in certain cases of going to the other extreme, and of the severity and magnitude of the operation, risking life without the fair prospect of good ultimate results in so-called "successful" cases. He instanced the recommendation of Mr. Mitchell Banks, that in all cases of removal of malignant tumor from the breast, all the auxilliary glands should be extirpated at the time, whether diseased or not. This, which was a large operation, was not without immediate danger to the life of the patient, and Mr. Favell doubted the alleged greatly diminished probability of return after its performance. He had grave doubts as to the wisdom of meddling with an axilla in which there was no evidence of cancerous implication. Axillary glands were very difficult to clear away from their deep situation and attachments, and he believed the tearing of the cellular tissue, where the use of the knife was contra-indicated, might be productive of irritation calculated to increase the liability to a return of malignant growth. Thus he instanced a very striking case bearing on his remarks, which had occurred in his own practice. Mr. Favell then proceeded to speak of the danger of catheterization in certain cases of retention from chronic

prostatic enlargement, when the bladder contained a considerable amount of residual urine and the kidneys were diseased; quoting from Sir Benjamin Brodie, who suggested the advisability of only at first partially emptying the bladder from time to time, Mr. Favell mentioned a case in which he had seen adynamic symptoms, followed by a fatal result in three or four weeks, after the first introduction of the catheter, and on the other hand he had known other people live with a condition of incontinence from overflow, in comparative comfort for months and years, where catheterization had not been resorted to.

TRANSPLANTATION OF TEETH.

In a monograph on this subject, Dr. Julius Scheff details a large number of experiments made on animals, together with histological examinations, which tend to show that, in the majority of instances, the union is periosteal. It may take place by first intention, the alveolar periosteum uniting directly with the cement of the tooth without absorption of the latter; or the periosteal proliferation may produce a more or less extensive absorption of the cement, which if carried too far, may result in extrusion of the tooth. The experiments also demonstrated that the pulp of every implanted tooth becomes necrotic, and this condition may exist, notwithstanding the occurrence of firm periosteal adhesions; or a new tissue may take the place of the necrotic structures. In the dog, this new tissue originates in the pulp canals, and consists of a delicate vascular connective tissue, which differs from the normal pulp by the absence of odontoblasts, or it may result from a proliferation of the periosteum into the pulp canals through openings caused by absorption of their walls. If the latter occurs, the periosteum may undergo osseous transformation, after absorption has ceased.

Of great interest in this connection are the investigations recently made by a Russian physician, Dr. Znamensky regarding the implantation of artificial teeth both in animals and human beings. He experimented with teeth constructed of porcelain, hard rubber, and metal, at the roots of which he made a large number of fine incisions. The process consisted in a proliferation of granulation tissue from the alveolar walls into the fine openings at the root of the tooth, thus holding it firmly in position. It is questionable whether artificial teeth can be embedded with sufficient firmness to withstand, for any length of time, the violence to which they are subjected during mastication.—*International Journal of Surgery.*

THE QUESTION OF SURGICAL INTERFERENCE IN PERFORATING WOUNDS OF THE STOMACH AND INTESTINES.

Reclus (*Cblt. of Chirurg.*) gives three new cases, from the French literature, where the opium treatment without laparotomy gave favorable results. Altogether Reclus has gathered ninety-one cases in which systematic expectant treatment was carried out with 75 per cent. of recoveries. On this basis he believes that laparotomy should be employed only for one or more of the following indications: (1) Cases where the intestines protrude through the external wound; (2) where signs of internal or external hæmorrhage are present; (3) where percussion in the region of the liver, or the introduction of a catheter through the external wound shows the escape of gas or intestinal contents into the peritoneal cavity; (4) when the nature of the trauma (e. g. the full force of a horse-kick) renders probable an extensive laceration of some viscus; (5) when in spite of energetic internal medication the signs of a peritonitis occur. The last indication Reclus admits to be very questionable.—*Ex.*

GYNÆCOLOGY.

SALPINGITIS AND CASTRATION; ARTIFICIAL EVACUATION OF COLLECTIONS OF FLUID IN THE TUBES THROUGH DILATATION AND DRAINAGE OF THE UTERUS.

Doléris (*Nouv. Arch. d' Obstet. et de Gyn.*) speaks against the abuse of castration in salpingitis, which can be found even to-day. Very often the operation is performed without the presence of sufficient indication; frequently in cases which are still amenable to conservative treatment. After a description of the different kinds of collections of fluid, he emphasizes once more in the conclusions that every salpingitis should be watched for months, and castration should be regarded as a *derniere ressort.* A large number of cases could be cured by artificial evacuation through the uterus.

His procedure consists in:

1. Dilatation of the uterus. First, laminaria tents are used, then sponge, which is rendered aseptic and pushed up to the fun-

dus uteri. Through the swelling of the sponge the uterine openings of the tubes are dilated.

2. Careful curetting of the uterine recesses, in order to remove hindrances which might interfere with the discharge, and which are often caused through a proliferation of the mucous membrane near the orifices of the tubes.

3. Drainage of the uterine cavity by packing it with iodoform gauze soaked in glycerine. The gauze must be changed every day; at most, every second day. According to the diminution of the tumor, the amount of gauze is gradually diminished.

After the operation the patient receives daily antiseptic irrigations of the vagina; afterward, an iodoform-glycerin tampon is introduced.

Doléris emphasizes especially the fact that the patient should rest for a long time after treatment, and especially should remain in bed at the time of the first menstruation.

Not in all cases has Doléris had the desired result.—*Ann. Gyn. Pœd.*

THE TREATMENT OF UTERINE FIBROIDS WITH APOSTOLI'S METHOD.

N. Kjaerguard, Copenhagen (*ibid.*), has treated twenty cases and gives the history and results of treatment in detail. Two deaths occurred—one in a very weak patient, with a cardiac lesion and with a growth in the uterus the size of a child's head. There were very severe hæmorrhages which resisted all forms of treatment. She had had eight applications of positive intra-uterine galvanism, ranging in intensity from 40 to 140 milliampères, and had borne them well; she was then given negative intra-uterine applications, and after the third séance (185 milliampères) fever set in and on the eighth day she died from heart weakness (?). No autopsy.

In the second fatal case the patient suffered with chronic bronchitis, with dilated bronchi, and had a growth of about the size of a child's head. In this case the hæmorrhage was only temporarily arrested by positive intra-uterine applications. In the last séance the hæmorrhage following was so great as to necessitate an intra-uterine tampon. A hysterectomy was then done, but the patient died within twenty-four hours. In the uterine cavity was found a large venous opening of about the size of the radial artery. Presumably the copious hæmorrhage occurred from this opening.

In the remaining cases the results obtained were very good; the hæmorrhages were arrested or, at least, much diminished; the pains vanished, and the symptoms due to pressure decreased in a marked degree.

TORSION OF THE PEDICLE IN OVARIAN CYSTS.

Küstner (*Centralblatt für Gynäkologie*, 1891) has made a number of observations bearing on this interesting subject, and differs from other authors in his explanation of the etiology. In his last thirty-six ovariotomies he found in fourteen cases (38.8 per cent.) torsion of the pedicle up to at least 180°. Rokitansky records 13 per cent., Thornton 9.5 per cent., Olshausen 6.3 per cent., and Horwitz 23.2 per cent. He explains the greater frequency of this complication in the Dorpat clinic by the fact that in most of the cases inflammatory adhesions existed. In the majority of the cysts of the right ovary the torsion was toward the *left*, in those of the left ovary toward the *right*. His explanation is as follows: As soon as the tumor rises out of the pelvis and comes in contact with the abdominal wall it tends to fall forward, displacing the uterus backward. The ovarian ligament is now put on the stretch and crosses the tube, so that when the tumor lies in contact with the abdominal wall there is really a torsion of its pedicle to the extent of 90°, which is usually overlooked at the time of operation. If the pedicle is small, and the abdominal wall relaxed, changes in the centre of gravity of the tumor are readily produced by changes in the position of the patient; when she lies upon her left side it tends to rotate from right to left, since the infundibulo-pelvic ligament (which is its principal attachment) extends from the posterior wall of the pelvis anteriorly from right to left. The reverse is the case when she lies on her right side. This torsion is probably only temporary. After the neoplasm occupies the abdominal cavity the pressure of the intestines upon its posterior surface during peristalsis tends to increase the existing torsion; this pressure on the right side is exerted most upon the left side of the tumor and *vice versa*. This theory was supported by a case of double ovariotomy of the writer's, in which the pedicle of the left tumor was twisted 180° to the right, and that of the right to the left.—*Amer. Jour. Med. Sci.*

OBSTETRICS.

FIVE HUNDRED LABORS WITHOUT INTERNAL DISINFECTION.

Mermann completes his account of a series of 500 labors without an internal disinfection, in the *Centralblatt für Gynakologie*, No. 20, 1891. In the 500 cases there occurred no death from sepsis or its complications. In the last 200 cases a vaginal douche was given once, in a case of placenta prævia which had been tamponed before admission to the hospital. The complications of pregnancy and labor are all fairly represented in the series, and with surprisingly good results. The only precaution taken against ophthalmia was irrigating the eyes with distilled water; but one case, and that a mild one, occurred.

Mermann employs scrupulous cleanliness and antisepsis externally but none internally, and limits vaginal examinations to the least possible number.—*Amer. Jour. Med. Sc.*

AN EPIDEMIC OF PUERPERAL FEVER.

This unusual occurrence in a well-conducted clinic forms the subject of an interesting narration by Döderlein, of Leipzig (*Archiv. für Gynäkologie*, Band xl. Heft 1), whose contributions on the bacteriology of sepsis are familar. Three cases of lymphatic infection by the staphylococcus pyogenes aureus and streptococcus pyogenes occurred, the focus of infection being suppuration beneath an ill-fitting glass eye in a patient's orbit. In some manner the midwife who examined her infected her genital tract and that of two others, one of whom died. By control experiments upon animals it was observed that the union of the two microorganisms produced an especially virulent infection. From the standpoint of treatment the intra-uterine douche is of value as soon as high fever announces the infection; if delayed, the micro-organisms are beyond the reach of the antiseptic and the douche is harmful. It is given by Döderlein by inserting a Cusco's speculum, washing out the vagina with sterile water and inserting a glass douche-tube into the uterus through which sterile water is allowed to run until it is seen that the flow is uninterrupted. A 2 per cent. creolin solution is then used to thoroughly douche the uterus. For the treatment of puerperal peritonitis, he advises absolute rest, ice to the abdomen, antipyretics, and opium. He believes that internal examination for diagnosis should be as infrequent as possible.

EXAMINATIONS IN REFERENCE TO THE CONSISTENCE OF THE BLOOD DURING PREGNANCY AND IN THE PUERPERIUM, AND THE COMPOSITION OF THE AMNIOTIC FLUID.

Nasse, in 1836 made examination of the blood of twenty-seven pregnancy cases, and at the end of twenty years had examined thirty-seven more. His results showed that the specific gravity is diminished, especially up to the eighth month, the fibrin is increase, there is a diminution of hemoglobin and a diminished number of red blood corpuscles, so that the condition during pregnancy is really one of chlorosis, and that this condition will explain many of the symptoms. Spiegelberg and Gscheidlein, on the other hand, found (experimenting on pregnant dogs) that the amount of blood was increased during the last half of pregnancy; that the amount of hemoglobin is rather increased than diminished, and that the amount of water contained is only slightly increased, if at all. Cohnstein observed that the amount of hemoglobin is increased, but that there is a diminution in the number of red blood corpuscles (experimenting upon pregnant sheep.) Fehling experimented upon pregnant women, and found that the hemoglobin was increased, as were the number of red blood corpuscles. He also examined the blood post partum, and found that in the majority of the cases (forty-seven out of eighty-three) the amount of hemoglobin was diminished, in ten it remained unchanged, and in twenty-six there was slight increase. The greatest diminution (forty-one per cent) occurred in cases of placenta previa, due, of course, to the great loss of blood. Counting the red blood corpuscles showed three to four million to one cubic millimetre (minimum 2,330,000, maximum 4,750,000.) After delivery a diminution of their number occurred. This would go to prove that a chloro-anemic condition is not a normal condition in pregnant women. For these experiments Fleischl's apparatus was employed.

Meyer made experiments in Berne, and they gave entirely different results from Fehling's. He showed, first, that in pregnant women during the latter months the number of red blood corpuscles and the hemoglobin are diminished; second, a short time after delivery the number of red blood corpuscles and the amount of hemoglobin are markedly

diminished—this must be atributed to the loss of blood during labor; third, in the puerperal state an increase of red blood corpuscles and hemoglobin occurs, and this is sometimes greater at the end of the second week than it was during pregnancy.

Reinl, seeing that the two previous experimenters differed so materially, took up the subject, and his results corresponded quite closely with those of Fehling, namely, that there is no chloro-anemic condition normally existing during pregnancy.

In making his experiments, Shrœder (*Archiv. f. Gynœkologie*) employed two instruments—Fleischl's hemometer and Gowers' hemoglobinometer. The blood was obtained by pricking the finger of the patient with a needle and mixing it with distilled water. To count the number of red blood corpuscles, the melangeur of Thoma-Zeiss was employed. The blood was mixed with ordinary salt solution. Two drops were always counted. Experiments were made upon forty-two cases, eight of these living in the hospital during pregnancy; the remainder did not enter until just before their delivery. Of these eight, three showed a small amount of increase of the hemoglobin, three a marked diminution in the same, and two were chlorotic patients. In all but one case a diminution in the number of red blood corpuscles was observed. Of the thirty-four who lived out of the hospital, twenty-five showed an increase in the amount of hemoglobin, and only nine showed a diminution. From these results we must acknowledge that an increase in the amount of hemoglobin occurs three times as often as does a diminution, as shown by my experiments as well as those of Fehling and Reinl. As to the number of red blood corpuscles in these cases, in the nine there was diminution corresponding to the diminution in the amount of hemoglobin. Of the twenty-five cases, in all but four there was an increase in the number of red blood corpuscles. These experiments were all made before delivery.

The blood was next examined two days after delivery, and in nearly all of the cases there was a dimunition both in the amount of hemoglobin and the number of red blood corpuscles. This fact can probably be attributed to the blood loss during labor.

The third series of experiments were made upon the women from ten to twelve days after delivery. In twenty-five of the cases the amount of hemoglobin was increased, in eight it was diminished, and in four it remained unchanged. In twenty-two cases the number of red blood corpuscles was increased; in fifteen cases it was diminished.

Experiments were also made with reference to the relationship between the conditions of the amniotic fluid and the hemoglobin, with the following results: We must consider the amniotic fluid as a serous transudation from the maternal vessels, and this undergoes the same changes as does the blood during pregnancy. If the amount of hemoglobin is increased, then the amount of albumen in the amniotic fluid is also increased.

PÆDIATRICS.

THE ETIOLOGY OF CROUPOUS PNEUMONIA.

Modern medical research has devoted considerable attention to the study of the etiology of disease. In the department of bacteriology discovery upon discovery, indicative of the causal relation between microörganisms and disease, has been made and verified. In the enthusiasm and excessive zeal which attended the promulgation of a new and promising doctrine, the indifferent student is apt to ignore important accessory conditions in a desire to reach a preconceived ideal.

At this day no unprejudiced mind will attempt to controvert the validity of the germ-theory of disease; but we have not done in accepting the principle which the theory implies. Something more than a germ is requisite for the production of disease—not that the germ is a mere concomitant, but that, while perhaps the most important, it is but one of a number of elements, the association of which is the essential factor in the determination of a definite result; the soil must be fertile and the conditions propitious for growth and development. How else explain the immunity of some and the infection of others exposed to like influences under conditions apparently similar? Though we may never be able to explain the mode of action, it is well to recognize this association of etiological elements; while not detracting from the importance of the part played by microörganisms in the production of disease, we must not ignore or underrate the significance of other factors.

In a study of one hundred cases of uncomplicated croupous pneumonia, Brunner (*Deutsch. Archiv für klin Medicin*, Hefte 1 and 2, 1891) was able to determine that the

disease is more common in males than in females; that most cases occur in the third and fourth decades of life; that those who lead active lives in the open air are predisposed; that the right lung is more commonly involved than the left; that the onset usually takes place in the morning with a chill; and that the disease is most pervalent in winter and in spring. Careful comparative observations upon the mean temperature, the mean humidity of the atmosphere, relative and absolute, the mean barometric pressure, as well as upon other meteorological conditions, in conjunction with the number of cases of pneumonia observed at different periods, revealed the fact that most cases occurred when the temperature was low, the absolute humidity slight, the relative humidity great, and the barometric pressure very high or very low. It appeared that those meteorological conditions that increased the physiological activity of the lungs favored the development of pneumonia.

The brief period of incubation which characterizes pneumonia may be explained by the almost constant presence of pneumonia-cocci in the air-passages, suitable extrinsic and intrinsic conditions conferring virulent properties upon a hitherto innocuous agent.

From many considerations it therefore appears that merely waging warfare against bacteria will not eradicate disease. The physical difficulties to be overcome alone render such a mode of treatment impracticable. A rational prophylaxis will have for its object the avoidance, as far as possible, of exposure to infection to deleterious influences of all kinds.—*Med. News.*

EUCALYPTUS OIL IN THE TREATMENT OF SCARLET FEVER.

As being the first person to bring before the notice of the profession the method of treatment of scarlet fever by inunction of eucalyptus oil in combination with other essential oils and camphors, allow me to point out to Dr. Knox Bond that his treatment of scarlet fever by eucalyptus oil was not after the method recommended by me in a paper to be found in the Transactions of the Epidemiological Society, and which has been republished by Lewis in a separate form. I am not astonished that his trial failed, and could have told him that it would if he had communicated with me. I and my son and many medical men have during the last two years treated all scarlet fever cases by inunction of Tucker's Eucalyptus Disinfectant with uniform success, shortening the duration of the fever, enabling the patients to mix with the rest of the family after ten days, requiring no isolation, and preventing all serious sequelæ. He will see in my paper that I condemn all greasy preparations for inunction, but the essential oils and camphors composing the disinfectant are all highly volatile, and are in no way greasy. I should like also to inform him that most of the eucalyptus oil of commerce does not possess the antiseptic qualities that are absolutely necessary for its successful use in infectious diseases. I have for some years tested experimentally the different eucalyptus oils, as well as other essential oils, and hope one day to make known the results of my inquiries, for there are some of these oils that are more powerful antiseptics and germicides than the oil of eucalyptus globulus.—Dr. J. Brendon Curgenven in the *Lancet.*

HYGIENE.

SULPHURING OR BLEACHING DRIED FRUIT A MISTAKE, IF NOT A CRIME.

Dr. Joel W. Smith, in a paper before the American Public Health Association, calls attention to a subject which should command the careful attention of consumers of dried fruit, of conscientious fruit dealers, and of all health authorities.

As fresh fruit is not always obtainable, various methods for preserving it are in use, drying being one of the oldest and best for many fruits. Middle-aged people recollect when sun or air drying was the only method for market. Then some good housewife discovered that more rapid drying by artificial heat, with or without the addition of sugar, was a cleaner method, safer against fermentation and decay, retained the flavor better, and the fruit was also lighter colored, than when sun or air dried. The present evaporators are only an enlargement of the idea of such more rapid drying, while canning consists in the exclusion of the microörganic germs of fermentation.

This is an age of progress, yet experience often shows that not all changes are improvements. It is about fifteen years since the sulphuring or bleaching of dried fruit began. At first only the uniform light color was sought, as in apples, pears, etc., but for some years past nearly all the large evaporating establishments have "sulphured" all kinds of fruits and some vegetables, and now

much of the California sun-dried fruit for market is also treated in the same manner. The light color, especially of apples. early attracted unthinking consumers and commercial men, thus materially increasing the price of such fruit. That caused the practice to spread even to those who disapproved of it. The expense and trouble were very slight. Fruit so treated is said to dry more readily, consequently all now prefer to do it.

While the apparent change is only in color, there is a loss of the natural fruit flavor, even by the most careful sulphuring. Unfortunately, some people do not notice the difference, but careful comparison shows it, as is admitted by the manufacturers of such fruit.

The practice began in California with apricots, as early as 1879. At the Twelfth State Fruit Growers' Convention, held in Fresno during four days in November, 1889, a paper on "Fruit Drying" was read by J. L. Mosher, of San José, and in his paper he remarked,—"If fruit be picked before ripe and over-sulphured to produce whiteness, it is devoid of its true rich taste and flavor, and *only requires polishing to make buttons.*" (The italics are his.) In discussing the paper, one gentleman said,—"I believe sulphuring the fruit is the greatest mistake in the world. I do it, but I believe it is wrong: the flavor of the fruit is gone after it is sulphured."

This change in quality was the first thing that called the attention of the writer's family to what was lacking in the "nice, uniformly colored" bleached fruits.

Later investigations have proved the presence of sulphate of zinc, "white vitrol," in all samples of fruit where zinc-surfaced trays were used to hold the sulphured fruit while drying. Interested parties have charged the German prohibition of American evaporated apples to rival trade opposition, but there is no German fruit to compete with them. The real cause was the finding of zinc poison in considerable quantity. A good paternal government aims to protect its people.

WHY SULPHUR FRUIT AT ALL?

The advocates of sulphuring fruit say,—(1) It dries quicker, (2) looks better, (3) keeps better, and (4) sells better. Besides, it makes ripe, unripe, and poor fruit all look alike; and if not so good for it, but few know it.

Sulphurous acid is formed by burning sulphur, and is readily absorbed by water. It abstracts oxygen from many vegetable substances, and thereby bleaches them. It also tends to prevent microscopic organizations that cause fermentation. The acid in liquid form is colorless, very cheap, and smells like burning sulphur; is antiseptic, a preservative fluid for some substances,—sample fruits, etc. Sulphur is often burned to disinfect sick-rooms of disease germs, and to kill rats, mice, and vermin, but its use with food is objectionable. Ants and other insects, it is said, will not touch sulphured fruit, while they readily attack well ripened fruit that is not sulphured. The instinct of insects and animals is sometimes better than the practice of human beings. In general, substances that repel such creatures are hardly safe for human food.

THE EFFECT ON CONSUMPTION

has seemed to be a decided falling off in demand among the more intelligent class of people. Retail grocers know that many who once used dried fruit extensively say, "Somehow we have lost our relish for it," and have almost ceased to use it since the craze for sulphuring fruits began. Fruit men say, "The public demands sulphured fruit, will pay more for it, and we will supply it." The public will yet show them that it can get its eyes open. As the green and canned fruit interests are the only permanent gainers by the sulphuring process, they are interested to have it continued.

DIFFICULT TO OBTAIN.

It is not easy to obtain a superior quality of unbleached fruit. In 1889 several retail grocers who understood the question corresponded with parties evaporating apples. The reply was, that "if an order for not less than twenty barrels was received at one time, apples would be furnished unbleached, otherwise not."

SULPHURING NOT DESIRABLE.

The slightly yellowish-brown color of unbleached dried fruit is an evidence of ripeness, good quality, and proper drying. The more rapid the lighter will be the color, and the fruit will keep well if at once properly excluded from the air. When sulphured, the good, the poor, and the unripe all look alike. Not so with the unbleached. No poor nor unripe fruit can make good dried fruit. The gain of sulphuring is always with the dealer, and not with the consumer.

HEALTH AGAINST LOOKS.

In preferring looks to quality, the people are often at fault. Public enlightenment

will correct most dietetic errors. Good health is now sought by many, and will be by more in the near future, through correct living, rather than by the swallowing of drugs. And in that more excellent way, "in the good time coming," there will be no demand for sulphured and other drugged fruit among intelligent people.

DANGERS.

There is danger from fruit in metal cans, as is well known, and fresh fruit is frequently unobtainable, while both are often more expensive than dried fruits. Good unsophisticated dried fruits are always harmless. If green fruits are at times unobtainable, canned fruits dangerous, and a popular craze has rendered dried fruits also dangerous, what can the suffering public do? It is between the alternatives of using no fruit, or that which is injured or poisonous. Is the sulphuring of fruit a mistake, or a crime?

TO CORRECT THE ERROR,

enlighten the people, and prohibit injurious practices. Legal suasion only will stop it at present. The common schools in many states are required to teach the effects of alcohol and narcotics. Why not also include the effects of different foods?

MEDICAL CHEMISTRY.

APYONIN.

Apyonin is the name of a substance of the methyl violet class which has been introduced as an antiseptic similar to Merk's pyoktanin. It is a yellow, crystalline powder, slightly soluble in cold and hot water, soluble in alcohol, and difficultly soluble in ether. Heated it sublimes, charring at a higher temperature, and burning without ash. The water solution is neutral, and gives a precipitate with caustic potash, which is soluble in alcohol. The plain solution produces colors on the addition of hydrochloric acid or peroxide of hydrogen solution. We are without particulars of the therapeutics of this substance, which is made by Petit, of Paris.—*Chemist and Druggist.*

IRON SALTS—THEIR FATE AFTER ENTERING THE CIRCULATION.

Jacoby (*Archiv für Experimentelle Pathologie und Pharmakologie*, Vol. XXVIII.; p. 264.) recently investigated this subject by experiments on animals. He found that the iron salts, when injected into the blood, are eliminated in a few hours to but a very small extent (about 10 per cent.) with the urine, intestinal secretions, and bile; the greater part (about 50 per cent.) however, is deposited in the liver, and the remainder in other organs (spleen, kidneys, walls of the intestines. This deposition is ended in 2–3 hours, after which the blood is free from the metal introduction.—*Merck's Bulletin.*

IODIDES OF ANTIPYRIN.

M. Duroy reports (*Bulletin de l' Academie de Médicine*) that he has obtained several iodides of antipyrin, all of which are capable of being used in therapeutics. The method of preparing an iodide of antipyrin is very simple. One equivalent of iodide dissolved in alcohol of 90°, and brought into contact with an equivalent of antipyrin dissolved in five times its weight of distilled water, yields a brick-yellow precipitate which is antipyrin iodide. It is soluble in two-and-a-half times its weight of water at 25° C.

NEWS AND MISCELLANY.

FANCIFUL ANIMAL REMEDIES.

Edible birds' nests are, of course, in high repute as aphrodisiacs, but they are more food articles than medicines.

The shells of the mollusca are used medicinally, thus *clam shells* are cathartic; *oyster shells* administered for deafness. *Fossilized shells* are used as a powder in ophthalmia and in scabies; internally in fever and in syphilis. *Coral* is also applied in powder to opacities of the cornea, and as an astringent for epitaxis.

Seed Pearls are prescribed in affections of the heart and liver; in the form of a powder to ulcers, and opacities in the cornea; in deafness it is put into the interior of the ear, and is applied to pustules of small-pox. This remedy is, however, dear, being quoted at $160 the catty or pound.

Petrified crabs are applied to boils and sores, etc. Fragments of these fossil crabs crushed, powdered and finely levigated are used in opacities and other affections of the eyes, and sell at from $30 to $300 a picul in different localities.

If we pass to the lower order of insects, we find the skins of the *dung beetle* fetch £3 the cwt., for medicine. The flesh flies

(*Musca carnivora*) collected on putrid carcases are torrefied and employed as drugs. *Maggots* are prescribed in the delirium of fever and dysentery. *Silk-worms* in cystitis; after being burnt the ash is mixed with wine and drank, in order to cause the bursting of abscesses.

The larva of the *grasshopper*, torrefied and pulverized, made into pills, are considered anthelmantic and given to children in fevers.

Wood bugs (*Cimex*) are also torrefied and given as medicine. The bodies of *Cicada sanguinolinta*, with the wings and feet taken off, are considered a cure in hydrophobia.

Caterpillars are considered good for bronchial complaints; are given as a purgative and anti-spasmodic, and are apparently cheap, selling at $6 the picul. The cocoons of a caterpillar are applied in inflammation of the eyes.

A decoction of *centipedes* is used in gonorrhœa; powdered they are applied externally to venereal sores, but it costs $150 a picul.

Cantharides are used in hydrophobia.

Cuttle-fish bone, mixed with native wine, is given for cancer.

A species of green *mantis* and its nests are used in cases of incontinence of urine and spermatorrhœa. The *cricket* forms the basis of a medicine to throw out splinters which have entered into the skin. It is considered anti-hydropic. Three or four such crickets are administered in a wineglassful of Chinese rice wine. The drone or *wasp* is used in cases of bites by spiders, ulcers and leucorrhœa. It is said also to cure toothache.

But while we may smile at most of these Chinese remedies, it should be borne in mind that as great ignorance prevailed, and as much prejudice existed among ourselves in times not long passed, before chemical knowledge and scientific discoveries had made such rapid strides.

Take for instance the following asserted facts:

Had one of our ancestors a distressing toothache, there were ready at hand the *weevil* and the *lady-bird*, either of which would be crushed and applied to the afflicted part. Nay, did he wish to get rid of the offending organ altogether, he had but to touch it with the ashes of burnt "emmets or pismires," and straightway the tooth would drop from the gum. Had he the misfortune to sprain his leg or bruise his foot? Two at least of the beetles which dwell in the excrementitious matter, *Geotrupes* and *Aphodius*, were specifics held in high estimation. The yellow matter which exudes from the joints of the oil beetle was held to be as efficacious in dropsy or rheumatism as in hydrophobia, and no doubt was so. Another infallible remedy against the bite of a mad dog consisted of the fat white *maggots* generated in the putrid carcase of the dog itself. Truly a case of homœopathy run mad! That foul disease, leprosy, could not stand before the bruised body of a *meal-worm*. The great jaws of the *stag-beetle* when powdered, we are told, proved a certain cure in most of the maladies incidental to childhood. The different *tree bugs* were good against ague; the male cricket taken internally could drive away a cold. Was the cold accompanied by headache? There were plenty of remedies at hand, such as *earwigs* and *cockroaches*. This last insect was especially valuable, for according to Dioscorides (whose receipt was unhesitatingly reproduced by Mouffié in the 17th century), the fat of the cockroach, pounded with oil of roses, was singularly efficacious in earache, and the same insect boiled in oil removed warts. Snake poison, too was rendered perfectly harmless, if the patient could be induced to swallow one or two *bed-bugs!*

There was a time when three *gnats* were taken as a dose, just as three grains of calomel might be taken now; while three drops of *lady-bird's milk* were formerly prescribed as seriously as a small dose of some fashionable medicine at the present day.

It is even still alleged that the little insect known as the *golden cetonia*, found in considerable numbers on rose trees, when pounded to a powder and administered internally, produces in the person a sound sleep, which lasts sometimes thirty-six hours, and which has the effect, in many cases, of nullifying hydropic symptoms.

A kind of paste made from the cockroach, administered internally, was found one of the most powerful antispasmodics known, and particularly useful, when diluted with water, in the case of lock-jaw.

Considering the number of species (at least 150,000) and the varied properties they possess, it is astonishing how few insects have been pressed into man's service, either for curative or culinary purposes.—P. L. Simmonds, in *Amer. Jour. Pharm.*

It has been calculated that the electromotive force of a bolt of lightning is about 3,500,000 volts, the current about 14,000 amperes, and the time to be about 1–2000 part of a second. In such a bolt there is an energy of 2,450,000 watts, or 43, 28, 182 h. p.

PRELIMINARY PROGRAM OF THE FIRST ANNUAL MEETING OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

TO BE HELD AT PHILADELPHIA, PA., SEPTEMBER 24TH, 25TH AND 26TH, 1891, IN THE HALL OF THE COLLEGE OF PHYSICIANS, CORNER 13TH AND LOCUST STREETS.

FIRST DAY, THURSDAY, SEPTEMBER 24.

3 P. M.

1. President's address—Dr. G. Betton Massey, Philadelphia.
2. Electro-Therapeutics in America; An Historical Survey—Dr. A. D. Rockwell, New York.
3. The Action and Application of the Faradic Current in Gynæcology—Dr. Augustin H. Goelet, New York.
4. Alternative Currents—Dr. Horatio R. Bigelow, Philadelphia.
5. The Treatment of Corneal Opacities by Galvanism—Dr. C. A. W. Alleman, Brooklyn, N. Y.

SECOND DAY, FRIDAY, SEPTEMBER 25.

10 A. M.

6. Report of Seventy-five Cases of Uterine Myomata Treated by Electricity—Dr. J. H. Kellogg, Battle Creek, Mich.
7. Two cases of Fibroids where Electricity ceased to control Hæmorrhage after a time, although eminently satisfactory at first—Dr. H. E. Hayd, Buffalo, N. Y.
8. The Treatment of Fibroids by Electricity—Dr. W. H. Hutchison, Providence, Rhode Island.
9. Electro-Puncture in Uterine Fibroids—Dr. G. Betton Massey, Philadelphia.
10. Electricity in Chronic Parametritis—Dr. Von Raitz, New York.
11. Report of a case—Dr. A. H. Buckmaster, Brooklyn.

3 P. M.

12. Some New Applications of Electro-Therapeutics—Dr. Frederick Peterson, New York.
13. The Analgesic Effects of Galvanism—Dr. Landon Carter Gray, New York.
14. Electricity in Diseases of the Stomach, with Exhibition of Patient—Dr. Lawrence Wolff, Philadelphia.
15. Electricity in Carcinoma—Dr. Robt. Newman, N. Y.
16. Title not Received—Dr. W. J. Morton, New York.
17. Title not Received—Dr. Henry McClure, Cromer, England.
18. Some Points in the Technique of Electrolytic Epilation—Dr. Plym S. Hays, Chicago, Ill.

8.30 P. M.

BUSINESS MEETING.

THIRD DAY, SATURDAY, SEPTEMBER 26.

10 A. M.

19. A Rare Case of Twin Extra—and Intra-Uterine Pregnancy Treated by Electricity—Dr. G. H. Whitcomb, Greenwich, New York.
20. Electricity in the Treatment of Rheumatism—Dr. W. F. Robinson, Albany, New York.
21. The Treatment of Subacute Articular Rheumatism by Electricity—Dr. M. A. Cleaves, New York.
22. Electricity in Anchylosis—Dr. Von Raitz, New York.
23. Has Electricity any Action as a Germicide, or in Producing Poisonous Results in Food—Dr. W. R. D. Blackwood, Philadelphia.
24. Exhibition of a Rectal Electrode, with Remarks on its Application—Dr. Guy Hinsdale, Philadelphia.

3 P. M.

25. Abdominal Electro-Puncture in an Ovarian Tumor—Dr. G. Betton Massey, Philadelphia.
26. Eight Months' Work in the Dispensary for the Treatment of the Diseases of Women by Electricity—Dr. H. R. Bigelow, Philadelphia.

AN ADVERTISING DOCTOR.

That there is a great deal of humbug in the part of the medical code of ethics which prevents a doctor from advertising in the daily newspapers has once more been proved by an elaborate article from a rhinologist of Rochester, N. Y. This professional nose carpenter is in good standing in the medical profession, ranks well in the American Medical Association, and would probably resent in a way that could not be misunderstood any insinuation that he did not make his daily walk conform to the perpendicular rules of the medical code. The code, it seems, is in no way violated when in an elaborate four-column article copiously illus-

trated he describes in the New York *Medical Record* his success in the work of mending or straightening noses. The article is embellished with look-on-this-and-then-on-that cuts that show the before and after treatment, show noses once as crooked as a ram's horn that under this doctor's magic touch have grown as symmetrical as the face of Powers' Greek slave. All this is set forth in a way to catch the popular eye. It is not set down in these technical terms which tend to tickle the eye and ear of the Hippocratic elect. Though in a professional journal it is written and pictured in a style that he who runs may read and understand.

"But," say the sticklers for the code, "the article is in a medical journal, and not intended for the humble laity." If not for the laity, then why should photographs of homely faces, made handsome, be reproduced? Could not a generous use of the beloved technical terms have made the article as intelligible to the learned profession as pictures? Must the mature man of science be enlightened with object lessons? The facts are the article was prepared for the general public, and to this end will have general circulation. To be sure, the space it occupied was not paid for as an honorable merchant or manufacturer pays for space he occupies in a newspaper when he comes to announcing his ware, but the books of the *Record* will probably show that the author of the article ordered an unusual supply of copies the week his article appeared. Before this time those copies have probably been mailed from Rochester, not to professional men, but to the doctor's old patrons and to a crooked-nose generation.

The object of the article is as patent as is a "for sale" legend nailed to a dwelling house. There was but one object, and that one certainly was not to educate any of the regular *Record* subscribers. It was a case of advertising, pure and simple, a kind of advertising in which the same doctor has often indulged. It is free advertising at that. The code justifies it, and yet not long ago because a Chicago doctor tried precisely the same thing in the daily press, and paid for the same like an honorable man, by the terms of the code he was expelled from the medical profession."

We clipped the above article from one of our daily newspapers, and print it because several such editorials have appeared in this paper. It does not appear to call for an answer, because this whole subject of advertising has been thoroughly gone over, and settled to the satisfaction of the medical profession.

We are always pleased to know that our friends are interested in our welfare, and thankfully do we receive advice upon all subjects, but we believe that we are able to conduct our affairs without any assistance or dictation from "the Press."

Personally, we can see no harm in a man publishing an article in a medical journal and embellishing it with illustrations. Nor can we see the impropriety of ordering reprints of the article, to be distributed as the author may see fit.

It is quite pathetic to see the indignation expressed above, emanating from a business whose chief profit is derived from advertisements. We assure the editor that we are satisfied with the present method, and hope he will not allow himself to be disturbed by any failure upon our part to appreciate his unselfish efforts.—*Cinn. Lancet and Clin.*

THE TRANSFERRED MALADY (A CASE OF METASTASIS).

(IN AN OCULIST'S OFFICE.)

How sweet the girl! I saw her pass
  The waiting group, with dumb surprise;
A golden-haired, trim, willowy lass,
  With heaven's soft azure in her eyes.
What could there be in them to mend?
  Nothing, I stoutly should insist;
But still she asked to see my friend
  The bachelor—and oculist.

I saw her take the patient's chair
  (Venus and Science matched amain),
And, though his search found little there,
  He asked the girl to come again.
But while with his ophthalmoscope
  He sought the source of her distress,
In the next room, with rhyme and trope,
  I tried my rapture to express.

"Neuritis of mild type it is,"
  He said (whatever that may be);
"Here is a wash I use for this,
  But come each day and visit me."
I knew the doctor's ready skill;
  Yet while he battled with the case,
His eyes received from hers a thrill:
  A crimson flush suffused her face.

Daily, as she was bid, she came;
  Daily the doctor scanned her eyes.
A cardiac spasm, I need not name,
  At length he struggled to disguise;
For gazing in those orbs of blue

So close, transferred an aching smart.—
No "wash" he ever gave or knew
For ailing eyes could help his heart.

The girl was cured, the patient lost.
What now avails his utmost fees,
Or rapid skill, to be so tossed
About by Cupid's sharp caprice?
Those blue eyes, had *I* the case,
Should not have been for years dismissed.
To keep them always face to face
I'd die—a baffled oculist.

—Joel Benton in *Harper's Monthly.*

CULTIVATION OF THE LEPROSY BACILLUS IN SERUM.

Dr. Beaven Rake and Dr. G. A. Buckmaster, members of the Leprosy Commission, have during the last two months and a half been engaged in bacteriological work at Almora Leper Asylum and in the new laboratory which has been built at Simla by the Government of India for the use of the Commission. They have now succeeded in cultivating the leprosy bacillus in serum from a blister. The first series of experiments, begun on March 31st, proved negative. On April 14th a blister was raised over a tubercle on the face of a leper at Almora, and another over normal skin on the back of the same patient. Specimens of the fluid from these blisters were taken in a sterilized capillary tube, and allowed to mix. Previous examinations of blister fluid over a tubercle in this patient had shown leprosy bacilli. The capillary tube was kept at a constant temperature of 98° F., and was taken to Simla, where microscopic examination on May 2d showed some brightly stained leprosy bacilli and some turbidity of the liquid. On May 14th a tube of bouillon was inoculated from this tube of serum, and on May 26th there was an undoubted growth of leprosy bacilli on the surface of the bouillon. From this culture vigorous growths of leprosy bacilli were also obtained on gelatine and agar. Another capillary tube of serum prepared in the same way from another leper gave precisely similar results.

"TROPHIC CENTRES IN THE CORD."

Under this title M. Brissaud has contributed an important and suggestive paper, which appears in a recent number of the *Archives de Neurologie.* The paper deals primarily with the subject of alcoholic neuritis, and the subject discussed is whether associated with the changes, which are acknowledged to be present in the peripheral nerves, there may not coexist in the spinal cord some change in the cells of the anterior horns of the grey matter. It is not denied that the chief force of the poison seems to expend itself on the peripheral nerves in alcoholic paralysis, as in other forms of toxæmia in which weakness and muscular wasting are observed, such as lead palsy; but the author contends that as in some of those cases, there certainly are changes in the grey matter of the cord; so, it may be, similar or analogous may at times be recognizable in cases of multiple neuritis from alcohol. Changes of this nature have actually been described by d'Oettinger and Korsakoff, and by Finlay and Sharkey, and the author points out the probability of such changes occurring especially when the symptoms of muscular weakness and wasting with localized pain are confined to the region of distribution of a certain nerve or plexus of nerves. And even if changes in the cord are not recognized, it does not follow that they are not present, for it may be that changes do exist which by our present methods are still unrecognizable. A curious fact in this connection is that mentioned by M. Raymond, who produced artificially a slight degree of myelitis in animals, the symptoms of which soon disappeared. When the animals were killed a year or eighteen months later examination could reveal no trace of the original myelitis, but the nerves in connection with the injured segment of the cord were not unfrequently found to have undergone profound alteration.—*Lancet.*

A FIVE YEARS' MEDICAL COURSE.

The Medical Council of the College of Physicians and Surgeons of Ontario recently passed the following resolution: "On and after July 1, 1892, every student must spend a period of five years in actual professional studies, except as hereinafter provided, and the prescribed period of studies shall include four winter sessions of six months each and one summer session of ten weeks; the fifth year shall be devoted to clinical work, six months of which may be spent with a registered practitioner in Ontario and six months at one or more public hospitals, dispensaries or laboratories—Canadian, British or foreign—attended after being registered as a medical student in the register of the College of Physicians and Surgeons of Ontario; but any change in the curriculum of studies fixed by the Council shall not come into effect until one year after such change is made."

Clinical Lecture.

EXOPHTHALMIC GOITRE.—TWO CASES OF HEMIPLEGIA—RHEUMATOID ARTHRITIS.

BY JAMES TYSON, M. D.,
PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY OF PENNSYLVANIA.

Delivered at the Hospital of the University of Pennsylvania.

Gentlemen:—We have in the wards a case of exophthalmic goitre which presents the essential symptoms of this affection in such a typical manner that I am glad to have the opportunity of showing it to you. Even at a distance you will see the characteristic symptoms and those from which it derives its name. The exophthalmos is very striking and the goitre equally so. The patient was admitted to the Hospital two days ago. He is a married man, 38 years of age, and groceryman by occupation. When a child he had scarlet fever, chicken pox and mumps. When seven years of age he had mild attacks of chorea which recurred frequently until he was thirteen years old. This is an important point in his history. He states, that his arms twitched more than his legs and that the right arm twitched more than the left. His head did not shake at all. In other respects he was well and strong until the age of 32 years and for nineteen years was able to work daily. When 32 years old he had as a result of over-work, bad drinking-water during the summer, etc. an attack of diarrhœa. He had diarrhœa every alternate week for six weeks averaging five movements a day. During these six weeks, however, he worked as usual. Since then he has had frequent attacks of diarrhœa lasting from one to four weeks. For the past five years he has had a severe attack of vomiting each year. Now, every time that he has an attack of diarrhœa, it is accompanied with vomiting. From the age of 32 to 36 years, he was well, with the exception of the diarrhœa above noted. Ten years ago he had a severe cold lasting three months and with this had muscular rheumatism affecting the arms and legs.

The present illness began two and a half years ago, he thinks as the result of catching cold. He had severe pain in all his joints both large and small, but the hip and knee-joints were the worst. The joints were neither red nor swollen. He was in bed six months with this attack and during most of the time had high fever. Since then, he has had successive attacks of rheumatic troubles in the joints. He first noticed swelling of the neck after he had recovered from the attack of rheumatism two and a half years ago. He never noticed that the eyes protruded more than those of other persons and therefore we can not determine when this began.

There is one other essential symptom of exophthalmic goitre and that is frequency of the pulse. The patient's pulse at present is only 96 per minute. When I counted it in the ward a few minutes ago, it was in the neighborhood of 150. It was so frequent and so irregular that I at once ordered him fifteen drops of the tincture of digitalis. This has had the effect of bringing the pulse down to 96. He therefore has this third and characteristic symptom of exophthalmic goitre, the frequent pulse. You will observe also that the goitre is the seat of an impulse. This is quite common in this disease where the goitre is of large size but it is not peculiar to the goitre of exophthalmic goitre.

On previous occasions I have spoken to you of what is known as Graefe's sign which is put down as characteristic of exophthalmic goitre. In the last three cases that I have shown you, this sign has been absent and it therefore cannot be said to be essential. This sign as you know is a want of synchronism in the dropping of the eyelid and the ball as the latter is rotated downwards. Here the lid goes down as rapidly as the ball. Our

own experience then is that Graefe's sign is by no means constant.

The essential symptoms of this condition are exophthalmos, goitre and frequent pulse. We may, however, have other associated symptoms. These patients are often nervous and choreaic and there is certainly a close relation between chorea and exophthalmic goitre, that is, you often find that patients who have exophthalmic goitre have had chorea at some period. This is particularly so among women. The chorea sometimes continues in association with the exophthalmic goitre. At other times it disappears on the appearance of the latter affection.

There is often a cardiac murmur associated with this disease but I think that, as a rule, it may be regarded as a result of the same cause rather than a part of the symptomatology of the affection. We have in this case a soft but easily heard systolic murmur heard best at the apex but also faintly heard at the base.

I may now say a word as to the etiology of the affection. In two of three cases which we have recently seen there has been a history of rheumatism, and rheumatism is put down as one of the best recognized causes of exophthalmic goitre. There are other causes of the disease but not so well determined. One of these is simple fright, (especially in women) anxiety, unhappiness and long-continued wretchedness, are responsible for a certain number of cases of this condition. Furthermore, fatigue and overwork may lead to the same disease. Then as I have already said, chorea is liable to precede this disease, but I would not say that it is a cause, but rather that they are both the result of the same cause. Chorea is rather inexplicable in a large number of cases. It is more common in children and in females. We know very little of its pathology. It has been thought that in some of the uncontrollable, obstinate cases where the patient is in constant motion, that there was a lesion of the blood vessels of the brain, but the morbid anatomy is very imperfectly determined. In the mild cases, there is no morbid change noticeable. It would seem that the cause that brings about the chorea is more or less responsible for the exophthalmic goitre.

At a previous lecture I dwelt upon the explanation of the symptoms and it is not necessary to devote much time to this on this occasion. It is plain that there is something behind the eyes pushing them forward. The most reasonable cause is hyperæmia of the blood vessels as a result of which they become swollen and the eyes are pushed forward. This hyperæmia must be brought about by the action of the sympathetic as a result of which the tone of the blood vessels is relaxed. This most likely is of the nature of a paralysis. The same explanation would apply to the hyperæmia of the vessels of the thyroid gland. In addition to the increase in the quantity of blood there is a true hyperplasia of the connective tissue and probably of the gland tissue itself.

In the treatment of this affection one of the first indications is to remove the cause if that can be done. The debilitated condition of the patient must be relieved. He must be properly nourished and the blood renewed and for this iron and arsenic fill a useful purpose. In the next place the use of remedies to relieve the symptoms must be considered. One of the best of these is digitalis. You have seen in this case the good effect of even one dose of digitalis. Every case of exophthalmic goitre should receive more or less continuously, as indicated, digitalis. Let me here impress upon you one condition of its successful use and that is that it be intermitted from time to time. Digitalis loses its effect when long continued. I have no fear of the cumulative effect of digitalis and I am doubtful whether such a condition exists. However, to get the best results from digitalis we should suspend its administration from time to time. The dose should gradually be reduced to nothing and then stop it for a time. Strophanthus may be substituted. While this is not so reliable as digitalis, it is an excellent remedy. It must however be given in larger doses than were at first recommended. We may begin with five drops, soon increasing to ten. As these patients are often nervous and irritable, bromide of potassium is useful in connection with digitalis. Under the use of these remedies, in association with proper hygienic conditions, I have seen the prominent symptoms in the course of time disappear. While it is doubtful that the symptoms will ever disappear completely in a case like this, it is likely that they will cease to be so conspicuous and that the patient will not be annoyed. I think that in a short time I shall have the pleasure of showing him to you in a much improved condition.

TWO CASES OF HEMIPLEGIA.

About a month ago, I showed you two cases of hemiplegia and made some remarks upon the etiology of the condition. The most interesting feature was the distinction between the form in which the face is par-

alyzed on the opposite side from that of the limbs and that in which it is paralyzed on the same side. In the majority of cases, the paralysis of the face is on the same side. That was the condition in the two cases which I showed you. We therefore concluded that there was a lesion in the motor tract above the decussation of the motor fibres, but exactly what that lesion was we were not prepared to say, although we thought it probable that in both cases it was hæmorrhage. It might be a syphilitic tumor or some other morbid growth. From the suddenness with which the symptoms developed we were inclined to believe that it was of a hæmorrhagic character. I bring the two patients before you in order that you may note the progress. In both the paralysis was on the left side and about equally bad.

You will recall the treatment which we directed in the case of this colored man, 66 years of age. We put him on a purely expectant treatment, so far as drugs were concerned, with massage and electricity. There has been marked improvement in his case. He can now move his arm and leg which he could not do when admitted. He is still improving, but how much better he will get I cannot say. We conclude that the clot is being absorbed and that the pressure which it makes on the nerves of the motor tract is being lessened. In almost every case of paralysis from a clot, there is improvement in the motor symptoms if the patient lives more than a few hours. This results from contraction of the clot which always occurs within a few days. This has nothing to do with the improvement which occurs later from the absorption of the blood.

The second case is a woman, aged 44 years. She has not improved so much. We placed this woman also on massage and electricity, and in addition gave her iodide of potassium with the hope of promoting absorption of the clot. Notwithstanding we did more for her than for the man, there has been less improvement. The face is not drawn as much as it was at first and she can raise her head which she could not do before.

The obstinacy of the symptoms in a woman comparatively young, makes me think that the lesion may possibly be something other than a blood clot. The most likely one would be a gumma or syphilitic tumor. I must say, however, that there is nothing in the history pointing to specific disease, but in a woman of her social position the suspicion is warranted. In paralysis from a clot in a person of this age, we certainly should expect more improvement than has taken place. I shall therefore treat her with this idea in mind. I shall at once put her on large doses of iodide of potassium, gradually increasing until she takes one drachm three times a day.*

RHEUMATOID ARTHRITIS.

I have here another patient whom you have also seen. It is a young girl with rheumatoid arthritis, whom Dr. Pepper showed to you two months ago. It is encouraging to be able to show a case like this, in which there has been considerable improvement, for the prognosis is apt to be unfavorable. When before you two months ago she was anæmic, and emaciated with almost no power of movement of the legs. The ankles were much swollen and the feet somewhat involved. The joints of the fingers were particularly affected. They were swollen and their movements much restricted. The skin was glossy and rather red. The fingers are still swollen, but she has less pain. She is now able to walk about the wards. What we fear in these cases is anchylosis and fixation of the joints. This can, to a great extent, be guarded against by passive motion. The pain of the treatment is apt to interfere with its employment, but we should not be influenced too much by this consideration, but insist upon passive motion and massage. The results of such treatment is often astonishing.

The patient has been taking four grains of antipyrin, and six grains of sodium salicylate three times a day. She has had also five grains of carbonate of lithium three times a day. She has taken emulsion of cod liver oil, a drachm and a half three times a day. With this, she has had massage and a passive movements. Looking at the patient and wondering whether anything more can be done for her, I think that one can not fail to be struck by her pallor, which indicates the need of iron. I think, therefore, that it would be advisable to add iron to the treatment. I should be disposed to omit the antipyrin and salicylate to determine how much of the improvement is due to them, and substitute a preparation of iron. There is nothing more suitable than Basham's mixture. I have been in the habit of employing the following formula

*Under this treatment, which with intermissions was well borne, improvement was more rapid, and at this time, August, 1891, she is able, with a little assistance, to walk in the ward.

which is satisfactory and makes a clear mixture:

℞ Tr. ferri chloridi.....f℥ss.
Potassii acetatis.....℥ij.
Elix. simp., q. s. ad.....f℥iv.
Sig. A teaspoonful two or three times a day in water.

One grain of sulphate of strychnia might be added to this mixture with advantage.

COMMUNICATIONS.

A CASE OF SKIN GRAFTING.

BY HORACE M. DARLING, M. D., LL. D.
CORNING, N. Y.

In December, 1890, Mr. C., a brakeman of the Fall Brook R. R., had his hand entangled by his mitten in the bumpers of two freight cars while making a flying coupling, whereby the hand and forearm are crushed, necessitating amputation. My brother, Dr. Louis Darling, operated, excising the hand and about three-fifths of the forearm. He found the fleshy part of the flap considerably bruised, but was compelled to use it, or to amputate it above the elbow joint. This amputation, though protracting the healing, leaves a longer stump and materially facilitates the adjustment and utility of an artificial hand and forearm. As was anticipated, a portion of the flap sloughed and the muscles above the point of cutting also had suffered in the severe squeeze by the car bumpers, and suppurated beneath the skin. An incision let out the pus, and the parts under aseptic dressings and applications progressed slowly to healing. In due time all healed save one extensive corner of the stump. The skin had sloughed away and none was left wherewith to facilitate growth and covering of the end of the bone.

I had charge of the dressings after the operation, and we had concluded to excise the end of the bone, and thus get covering, but my patient was a jolly, hardy son of Erin, and, as one day I talked of grafting the open wound, he fell into rapport with the idea and submitted to the trials.

I intended first to try a piece of sheepskin, but the sheep spoken for didn't come, and when I arrived he and his friends were terribly disappointed, for they were tired of the delayed healing. Jokingly I asked for a chicken. Well, it was quickly caught, and then, of course, I was compelled to do something, and I did. I cleaned the wound, touched the surface with the point of the knife, and while slightly bleeding, I excised pieces of skin from under the wing of the chicken and applied it at three points on the raw flap. The wound was dressed and left for 24 hours. When I next saw it, the grafts had rolled up, and two had been swept off with the discharges; the one was still slightly adherent. I dressed the stump, leaving the one graft *in situ*. Two or three days afterwards, I again dressed the wound, but unfortunately the attendant had, in washing away the discharges, inadvertently removed the graft. These grafts had been cut from under the wing of a young chick, and were very delicate, too delicate, I thought, so I directed a full-grown hen to be caught and from under her wing I cut two grafts about the size of ten cent pieces, and accurately applied them to the open surface, allowing the upper one to touch the real skin, and placing the other one in the center of the raw surface, then dressed the wound antiseptically, and gave instructions to leave all as it might be until I saw it the next day. The following day I found the grafts adherent, seemingly agglutinated underneath to the wound. I cleansed the wound and dressed it antiseptically. The second day following I found the graft in the center had produced a point—a *nidus*—which appeared covered with a smooth something. The graft next the skin also appeared to be fast and the discharges much lessened around it. They were dressed as before, and on my next visit the center graft had disappeared, but a *nidus* remained. The graft close to the skin had partially gone but in its place there was a perceptible glossing over, the surface looking something like a collodion covering. The center spot, at a subsequent visit, had not developed but had entirely disappeared. The other graft, or the spot where it had been, progressed favorably and the skin—very thin at first—extended out into the raw surface. The discharge lessened and this point grew more and more in skin covering. I again grafted on other parts of the sore, fresh grafts cut from the hen, and again points formed, from which coverings spread. Thus this large raw surface, freely discharging, was covered with a new growth, the discharges lessened, and isolated scabs soon formed, which, when removed, left a *quasi* skin. The scabs formed from time to time and were removed. The surface I then dressed with vaseline and kept it lubricated until now it is entirely covered and has been covered without any discharges or scabbing for a month, the covering assuming more and

more the characteristics of skin. Once, since this skin formed, a small abrasion was produced by his shirt; this refused to heal for a time, but after repeated applications of the stick *argenti nitros* it has healed, and the entire stump is well covered. The covering is purplish, but day by day assumes more and more the appearance of the skin.

I can not say that the grafts adhered and grew, or were absorbed or discharged, but I can say that at and from the places where the grafts were placed there appeared a natural covering which remained and extended and became skin, while the places of the open surface, where the grafts were not put and around the graft's *nidus*, the surface was coverless and discharging. From day to day the *nide* could be seen extending out into raw places and the wound thus covering over.

I had before this often on large raw surfaces, or extensive ulcers, placed pieces of this or that animal's skin, cut from a tender part, and though not adhering or growing they frequently seemed to change the condition of the surface favorably, and promote the growth of covering, sometimes permanent and sometimes to break out again.

In this case there is no doubt that the grafts were of invaluable service in promoting the growth of skin on the stump.

BILATERAL FACIAL PARALYSIS, WITH REPORT OF A CASE.

BY M. IMOGENE BASSETTE, M. D.,

INSTRUCTOR IN NERVOUS DISEASES IN THE PHILADELPHIA POLYCLINIC.

Double facial paralysis, and all forms of bilateral cranial paralysis, are comparatively rare. In an experience of nearly four years in the department for nervous diseases at the Philadelphia Polyclinic, the case which will be reported in this paper is the first of double facial palsy that has come to the service, although unilateral cases have been common. A few cases of other types of bilateral cranial paralysis have been observed, but always as parts of more general affections, as of ophthalmoplegia, bulbar paralysis, or progressive muscular degeneration. Bilateral facial paralysis, and bilateral cranial palsies in general may be peripheral, nuclear or cerebral; and the differential diagnosis of these three forms, sometimes an important practical matter, will be considered after the presentation of the case.

S. G., aged 33, was married and had had three children, and also three miscarriages, but denied any knowledge of syphilitic infection. She followed washing, ironing, and house cleaning for a living, and therefore was much exposed to wet and cold. Four years ago she had a severe attack of sciatica for about six weeks. Three months before coming to the service, after becoming thoroughly drenched in a rain, she was attacked with pains and soreness, which were at first general, but finally settled in the muscles of the chest, and remained there about two weeks, then leaving appeared in the right side of the head, and in the ear and face. Two days before this she had constant twitching of the right corner of the mouth and of the right eyelid. She had a sensation as if her head was divided in the middle from the chin to the nape of the neck. As soon as the pain commenced in the head she had sensitive lumps or "kernels" behind her ears. A week later she was completely paralyzed on the right side of the face; she was unable to close her right eye or wrinkle her brow, and her mouth was drawn to the opposite side. Two weeks after the appearance of this paralysis she began to have pain of the same character, but more intense on the left side. She now had great difficulty in masticating her food, owing to the inability to close her mouth, and was obliged to use liquids chiefly. From the first she had some blunting of taste. Her hearing was not affected until the left ear became involved, when she soon had complete deafness on this side.

When she came under observation at the Polyclinic, about a month after the first attack of paralysis, she had almost complete bilateral facial paralysis. She still complained of pain on the left side, but it was not so severe as at first, and her hearing had in a measure returned but was still much impaired on the left side. She continued to have trouble in chewing on account of the inability to close her mouth; and speech was much affected owing to difficulty in moving her lips. She could protrude the tongue and move it in all directions. Careful testing showed complete loss of taste on the anterior surface of the tongue on both sides, and this was accompanied by great dryness of the mouth. Double lagophthalmus was marked; she could not wrinkle the forehead, dilate the nostrils, raise the lips, or draw the angles of the mouth upward or downward. She was obliged to

place her hands against and around her lower jaw and cheeks in eating so as to prevent the food from falling out of her mouth; she also had some difficulty in swallowing, and was obliged to throw her head far backwards to assist in this act. She was carefully tested for touch, pain and temperature on the tongue, face, and mucous membrane of the mouth, and these senses were found to be not impaired. Smell was impaired on both sides, but was not lost. She complained of noises in the left or partially deaf ear, which she compared to the falling or crunching of ice.

The muscles would not respond to the faradic current, but on careful testing with the galvanic, reactions of degeneration were found to be present on both sides, more advanced on the left.

The patient has continued to report at the Polyclinic service for nervous diseases, up to the time of writing, a period of two months. She has made considerable improvement, much more decided on the right than on the left side. At first small blisters were applied in front of and below the ears, and she was given small doses of mercury. After a few days salicylate of sodium and gaultheria were given, under which the pain subsided, and later her internal treatment was chiefly iodide of potassium, in doses of 10 to 20 grains. Strychnia and quinine have also been used, and the galvanic current has been applied three times a week.

When last examined, the deafness and tinnitus of the left ear had entirely disappeared. She could nearly close the right eye, and the left much better than at first; the right angle of the mouth could be well drawn upward, and on the right side the lips could be elevated and depressed. She had no difficulty in swallowing and but little in chewing. In general the improvement on the right side of the face might be set down as equal to one half of the loss, while on the left side the paralysis was still very decided but improving. Reactions of degeneration were marked on both sides.

The appearance of the face in this case, as in all cases of complete bilateral facial paralysis, was very striking. It presented an immobile, mask-like look, which was entirely uninfluenced by strong emotion.

The consideration of the nature and causes of cases of this kind is of practical interest, because both prognosis and treatment must depend upon the etiology and special pathology of the case. Speaking with reference to the location of the lesion we may have three forms of bilateral as well as of unilateral facial paralysis, namely, a peripheral, a nuclear, and a supra-nuclear or cerebral form. Under peripheral would be included all cases due to gross lesions affecting the portio dura or its branches, anywhere from the superficial origin of the nerve to its terminal expansions. These lesions may therefore be intra-cranial, intramural that is, within the Fallopian aqueduct, or entirely extra-cranial. The ma-jority of the peripheral cases reported have been due to lesions, in part at least, in the Fallopian canal. Not a few have been associated with disease of the middle ear, mastoid cells, or temporal bone. Several bilateral cases in patients suffering from double otitis have been reported. Cases have also been recorded due to intra-cranial tumors, as growths of the pons or in the floor of the skull, and also others dependent on localized basal meningitis.

The peripheral extra-cranial form of bilateral facial palsy is a rare variety of a rare affection, but Gairdner,[1] in the *Lancet*, has reported an interesting case of this kind. The case was apparently rheumatic, due to exposure. Although bilateral it was incomplete. It involved most, but not all the external branches of the portio dura; but the petrosal, the chorda tympani, the auditory, and the nerve of Jacobson, and all the branches connected with the sympathetic nerves were not involved, showing that the disease was entirely outside of the stylo-mastoid foramen. The patient had some power over the occipito-frontalis muscles, and even over some of the muscles of the ear which in health are not usually under the control of the will. The buccinators were almost completely paralyzed. Gairdner made some observations in connection with this case on the involvement of different muscles of articulation. The defect in articulation was almost entirely limited to the labials. Although formidable in appearance, this case was amenable to proper treatment, and made marked progress under the use of galvanism, exercise of the muscles, counter irritation, and iodide of potassium.

Bilateral nuclear facial paralysis as an isolated affection is extremely rare, and I have not been able to find the record of such a case. Congenital cases of bilateral paralysis of several cranial nerves, including the facial have been reported. These have been attributed to lack of development of the nuclei of various cranial nerves, and have

[1] Gairdner: *Lancet*, London, May 18, 1851.

been called by Schapringer[1] cases of "bilateral pleuroplegia." Such nuclear cases are not always congenital, but sometimes come on in progressive degenerative diseases which invade both the cranial and various spinal centres. Cases, for instance, have been reported associated with progressive muscular atrophy. The ordinary type of glosso-labio-pharyngeal paralysis, eventually becomes bilateral, but does not usually present at an early period striking bilateral phenomena. Cases of complete double oculo-motor paralysis, and of ophthalmoplegia both externa and interna, have been reported in considerable numbers, and in some of these spinal centres have been involved, although the cranial nuclei between the oculo-motor and cervical regions have escaped. Mills[2] has reported such a case of complete double oculo-motor paralysis associated with which was advanced paralysis and atrophy of both upper extremities.

The third form of double facial paralysis, the supra-nuclear or cerebral, is that which arises from double lesions situated above the nuclei in the pons and medulla oblongata, that is, in the facial centres of the cerebral cortex, in the great ganglia, or in the facial tracts connecting the cerebral centres with the cranial nuclei. Two lesions of considerable size must be present in similar locations one on each side of the brain, and this occurrence is not likely, but cases have been reported.

This case without doubt, belongs to the class of peripheral facial palsies, and the lesions are in part, at least, situated within the Fallopian aqueduct.

A peripheral facial paralysis, unilateral or bilateral, usually has a more or less acute onset, and a definite traceable cause. In the case here reported paralysis was preceded by what appears to have been an attack of diffuse muscular rheumatism, without any articular trouble. It is not impossible that syphilis may have been a factor in the case, but a specific history could not be obtained. The paralysis appeared upon the right side of the face, much as cases of rheumatic or syphilitic facial paralysis usually originate; the left sided paralysis followed the right within two weeks, and both presented similar characteristics, differing only in extent. That hearing on one side was lost and on the other retained, was in favor of peripheral as contrasted with nuclear disease, as the latter is usually uniformly bilateral. In favor of peripheral disease was also the occurrence of paralysis in the distribution of those nerves which are in contact with the portio dura, or form communications between it and other nerves, in other words, the chorda tympani, the petrosal, and the auditory. In a cerebral case these nerves are not involved, and in nuclear disease only when the lesion is extensive or multiple, including other centres than the facial.

A good practical point of distinction between a peripheral and a cerebral facial paralysis, especially when unilateral, is the completeness of the paralysis in the former. In a cerebral case the paralysis which remains prominent is usually of the muscles which are supplied by the branches of the lower part of the face; the frontal and orbiculo-palpebral muscles usually recover so fully that the palsy does not attract attention although a minute study of the movements of the muscles will show some weakness. Even in a double facial paralysis this distinction may be of some value, but probably, as in a case of double cerebral lesion, the psycho-motor centres or tracts for the face are destroyed on both sides, and one side is not left to act for both, some paralysis of all the muscles of the face will be present in the upper as well as the lower distribution of the portio dura.

The completeness of the paralysis—and the involvement of the upper as well as the lower fibres of the facial—is not against nuclear disease, but complete nuclear paralysis comes on late, after long-continued degenerative processes, and not suddenly or rapidly as in peripheral cases. Nuclear paralysis, which is usually bilateral—of the facial, abducens, oculo-motor, or other type—as a rule, if not congenital, comes on insidiously, the muscles gradually weakening and wasting, and commonly without a preceding history of rheumatism, injury, ear disease, tuberculosis, or other cause of gross lesion. As already stated, both sides are likely to be attacked uniformly, although this is not always the case. It is rare, but not unknown, to have nuclear disease confined to the cell-cluster connected with one set of nerves; it is especially rare to have the facial nuclei alone attacked.

In cases of extensive peripheral neuritis or peri-neuritis—the reflexes are abated or abolished, and in this patient the palpebral reflexes were diminished, and the muscles of the face and the uvula and soft palate were irresponsive. These tests would help

[1] Schapringer: *Medical News*, March 1, 1891.

[2] Mills: Trans. College of Physicians, Philada. Third Series, Vol. vi, 1883, p. 433.

to separate the case from both nuclear and central facial paralysis. In cerebral cases the reflexes are unaffected; in nuclear cases they may be increased until the disease has nearly destroyed the facial nucleus, or the curious phenomenon known as crossed reflex action may be present. With reference to this, Erb [1] speaks as follows: "Benedict has laid great stress upon the occurrence of unusual, and especially upon decussated reflex actions, as a means of diagnosticating the seat of the disease in the neighborhood of the facial nucleus; but reliance is only to be placed upon them when all precautions have been taken, especially to avoid diffusion of the current when electrical irritation is employed. If this be done, we are justified in admitting the presence of a disease of the gray substance in the neighborhood of the facial nucleus." Both the direct and the crossed reflex action were absent in this case.

The electrical examination is always of importance, and may at once settle the question of diagnosis, as between the peripheral, the nuclear, and the cerebral form. Most cases of peripheral facial paralysis give typical degeneration reactions. In the majority the paralysis is either complete or at least complete so far as the extra-Fallopian branches are concerned, and in these the nerve being completely compressed, all the changes, modal and serial, of typical reaction of degeneration will be present. In a few light forms, as Erb and de Watteville have pointed out, the reactions to both currents remain nearly or quite normal, and in a medium or middle form of the affection partial degeneration reaction may be present. These, however, are not common, and, as a rule, the presence of a partial degeneration reaction would point to a nuclear disease, and a normal electrical response to a cerebral lesion. Erb and de Watteville have shown that in the chronic degenerative diseases such as amyotrophic lateral sclerosis, progressive muscular atrophy, bulbar paralysis, and the more or less isolated nuclear affections, the partial degeneration reaction is the rule. The modal and serial changes in the present case indicated true peripheral disease.

Supra-nuclear facial paralysis, that is facial paralysis from disease of the cortex, the ganglia, or the cerebral tracts, would be most likely to be due to multiple lesions, as tumors, abscesses, hæmorrhages, or emboli sms, and would therefore probably have the general symptoms of these affections. Occasionally such cases originate from injuries to the head causing fracture or hæmorrhage on both sides of the head, or fracture on one side and hæmorrhage on the other. After a study of the history and general symptoms, and the special symptoms as detailed, the diagnosis would be completed by remembering that in cerebral cases all degeneration reactions are absent.

The exact site and extent of the lesion on each side in such a case, has some bearing on the prognosis and treatment. The lesions on both sides have undoubtedly invaded the Fallopian aqueduct. With reference to such lesions, Althaus [2] has divided this canal into three parts, 1, a first or external section, which is below the origin of chorda tympani; 2, a second or middle section, which includes the chorda tympani and the stapedian nerve, and 3, a third or internal section, which embraces the geniculate ganglion, where the large petrosal nerve is given off, and also near at hand the small and external petrosal. In addition to the nearly complete paralysis of all the muscles supplied by both facial nerves after their exit from the stylo-mastoid foramen, the patient had similar, but not exactly identical symptoms. She had complete abolition of taste on the anterior extremity and sides of the tongue, showing that the lesion on each side involved the second or middle section wherein runs the chorda tympani. The third or inner division of the canal was also probably reached on both sides. The uvula was not deflected, but the velum palati drooped on both sides, and the palate did not respond well to electrical or other excitation. The uvula did not deflect probably because the paralysis was on both sides. One symptom, deafness, indicated a more extensive lesion on the left side than on the right. This deafness, which improved, was associated with decided tinnitus. The most reasonable explanation for its presence is that the inflammation of the facial nerve and its sheath extended inwards on this side sufficiently far to involve the auditory nerve by contiguous inflammation or by pressure. The Fallopian aqueduct begins at the bottom of the short canal which leads inward from the internal auditory meatus, and in this canal the auditory and facial nerves are in company, so that a purulent or other inflammation extending backward along the facial might reach and involve the auditory. The patient had not on either side that hyper-sensitiveness of hearing which sometimes indicates paralysis of the nerve to the

[1] Erb: Ziemssee's Cycl. Pract Med. Am. ed., Vol. xi, p. 501.

[2] Althaus; Brain, vol. ii, 1879, p. 24.

stapedius, but this is generally absent or obscure when the lesion extends to all the sections of the Fallopian aqueduct.

Facial paralysis has afforded some interesting facts in connection with certain physiological problems. The anatomical relations and functions of the chorda tympani nerve have frequently been a subject of discussion, and cases of double facial paralysis in which by close study, the exact sites of the lesion has been fixed have assisted the final decision with reference to this nerve. In two papers by McDonnell [1] and Nixon, [2] which record interesting cases of double facial paralysis, the physiology of taste and the distribution of the chorda tympani have been discussed in connection with the phenomena presented.

The nerve supply to the tongue includes the trunks or branches of the hypo-glossal, the lingual or gustatory, which is a branch of the fifth, the chorda tympani, and the glosso-pharyngeal nerves. One question which has proved a fruitful subject of investigation is as to the measure in which certain of these nerves are concerned with taste. The hypo-glossal nerve is purely motor, but at a certain part of its course it communicates with the gustatory nerve. The glosso-pharyngeal nerve is a special nerve of taste to the tongue, but it is not distributed to all parts of this organ. The chorda tympani nerve is undoubtedly distributed to the tip of the tongue, but owing to its meandering course and complicated relations it has been difficult to decide as to its origin, its independence, or if not independent, of which great nerve it is a part.

In the present case the sense of taste was carefully tested, and was found to be totally abolished on the anterior extremity and sides of the tongue. She complained at first that everything she put into her mouth tasted like tallow; later the taste of articles improved, but at the time of the last examination, after a lapse of two months, taste was completely abolished on the distribution of the chorda tympani on the tongue.

As it is important to have a clear and precise method of studying the impaired functions in a case of this kind, it might be well to give the methods which were employed in testing for touch, temperature and taste, and for the secretion of saliva,—which were the same as those described in McDonnell's paper. The tongue was touched lightly with the finger, a feather, a camel's hair brush, and other light objects, and was tested with the double points of the æsthesiometer, the patient correctly and readily recognizing the impressions. The temperature was tested by touching the tongue with cups filled with water slightly differing in temperature; with her eyes closed the patient could at once distinguish a difference of only a few degrees. Solutions of sugar, citric acid, salt and quinine were made in gum mucilage, and "sweet" "sour," "bitter," and "cannot tell," were written on a slip of paper and the patient was directed after the solutions had been applied to the tongue to answer before withdrawing the tongue into the mouth. She could not perceive the electrical taste when the poles were applied to the tip of the tongue. The effect of testing for the secretion of saliva can be best described in the words of McDonnell in recording the experiments made upon his patient and upon a healthy individual, as the results were the same: "The secretion of saliva excited by the application of sapid substances to the forepart of the tongue was in abeyance. The comparative observations made on this point were very striking. The patient and one of the students were placed sitting with their mouths open and their tongues raised to the roof of their mouths, so that one could see in beneath the tongue within the incisor teeth; a camel's hair brush dipped in lemon juice was then passed over the tip and edges of the tongue; in the healthy individual in less than half a minute, the hollow beneath the tongue became filled with saliva, which dribbled over the lip, while in the patient no saliva could be seen welling up."

So far as the determinations with regard to taste in this patient were concerned, they were simply in confirmation of the facts which have been noted in the majority of cases both unilateral and bilateral in which the lesion reached the middle portion of the Fallopian aqueduct. No positive light is thrown by such cases on the question of the origin of the chorda tympani, either from the facial, glosso-pharyngeal or fifth nerve. They show, however, that this nerve is undoubtedly in contact with the facial in the canal.

One view with reference to the chorda tympani nerve which has much in its favor is that which has been held by Scarpa and others, that it is a distinct cranial nerve with a separate nucleus in the floor of the fourth ventricle. Nixon holds that in accordance with general analogy it is most likely that we have only one great nerve of taste, as of sight, smell, and hearing, and this is most

[1] McDonnell: *Med. Chir. Tr.*, London, 1875, 2. s, xl. 369–375.

[2] Nixon: *Dublin Jour. Med. Sci.*, 1876, l xi, 105–112.

likely the glosso-pharyngeal. He believes that the difference in taste as determined by the anterior and posterior areas of the tongue, depends upon the dissimilarity of the structures of the two regions and the closeness of the base of the tongue to the organ of smell, and that probably the chorda tympani nerve rises from the glosso-pharyngeal, joining or communicating with the facial in its course. The glosso-pharyngeal is well known to be connected with the facial by two or three routes, as by the tympanic plexus, or by the communicating nerve between the facial and glosso-pharyngeal.

As already stated observations on cases of peripheral bilateral facial paralysis, like the one here considered, show that the nerve in its course is in contact with the facial, but threw no light on the origin of the chorda tympani. Some of the nuclear bilateral cases, however, would seem to indicate that the chorda tympani is a distinct cranial nerve with its own nucleus, or that it is a part of the glosso-pharyngeal. Harlan[1] and Keen[2] have reported a case of congenital bilateral paralysis of the 6th and 7th nerves. The absolute bilateral and congenital absence of function of the 6th and 7th nerves, without, as was the case, any involvement of the chorda tympani, according to Keen, pointed clearly to defective development of the nucleus common to the 6th and 7th nerves, and tended to confirm the assertion of Sappolini that the chorda originated from a distinct nucleus as a thirteenth cranial nerve.

Severe as a case like the one reported here is, great improvement can be hoped for from judicious treatment. Those cases in which the lesion was situated beyond the stylo-mastoid foramen offer of course a more favorable prognosis, but the double as the unilateral cases of facial paralysis even when intra-Fallopian sometimes recover and when a complete cure is not effected may greatly improve. The behavior of the nerves and muscles in reference to electricity as the case progresses affords some basis for opinion as to complete or incomplete recovery. If the faradic and galvanic reactions show no sign of improvement after several weeks the case will only make a partial recovery. The best treatment is that which has already been indicated as having been followed in the present case: At an early period leeches or blisters behind, below or in front of the ear, small doses of mercury and sudorifics; a little later, the salicylates. Iodide of potassium may also be used, particularly if the case threatens to become chronic and to assist in nerve and muscle regeneration, strychnia and galvanism will probably prove most useful.

ACUTE INFECTIOUS JAUNDICE.[1]

BY STANLEY M. WARD, M. D.

SCRANTON, PA.

The existence of an acute systemic affection, having the characteristics of an essential fever with its usual accompaniments, attended likewise with marked and persistent jaundice, hæmorrhages from various mucous surfaces, more or less disturbance of the nervous system and of the gastro-intestinal tract, the pathology of which seems to be a catarrhal condition of the gall ducts with enlarged liver and spleen, is evidently not generally admitted. Having recently had occasion, because of a case of jaundice under my care presenting many anomalous symptoms—to look through such complete and recent works as Pepper's *System of Medicine*, and Keating's *Cyclopædia of Diseases of Children*, I could find nothing to enlighten me (the Annuals (Sajous) for 1889 and 1890 contained several pages beside references to Weil's disease—defined elsewhere as abortive typhus with jaundice"—). But beside these my search was unrewarded. My friend Dr. L. Wehlan, of Scranton, kindly put his library at my disposal, and I am greatly indebted to him for the copy of the *Sammlung Klinischer. Vorträgr* (September, 1890) containing the lecture of Dr. Hennig, of Königsberg, a translation of which constitutes a large part of this article. Dr. Wehlan also rendered me most efficient aid in the translating.

Case of the Author.—Fred. T., an inmate of the "Home," of this city, of healthy parentage, had not "seemed himself" for several days prior to my first visit on the morning of April 20th. He did not complain of anything particularly only of being tired. He had eaten no supper the night previous. Pulse 85, temperature 102½°, lungs and heart normal, throat within a little congested, tongue coated with a light fur, nothing known about his urine or fœcal discharges except that he was "cos-

[1] Read at the July meeting of Lack. Co. (Pa.) Medical Society.

tive." No diagnosis made. Ordered a "fever mixture" and small doses of calomel. The next day the symptoms were about the same, but he was nauseated and had vomited. Appeared utterly indifferent to everything. Jaundice appeared the next day and his temperature rose to 103°. Stools "pasty" and very offensive. Bowels constipated. In a few days a severe epitaxis took place. The buccal cavity became sore, and bleeding occurred often from the raw mucous surfaces. His breath had a sour odor and was very offensive. There was some nocturnal delirium. Liver and spleen were both enlarged. Urine contained bile-pigment and small quantities of albumen. Meantime the jaundice increased, though it never became that dark, greenish hue seen in malignant cases; he bled frequently from the nose and mouth, though I cannot state positively that the blood which came from the oral cavity was not from the posterior pharynx or at least from the mucous surfaces already mentioned, rather than from the stomach. Thus for over four weeks these symptoms continued. Jaundice fever of a remittent type—but twice during this time did I find a normal temperature—ranging from 100° to 103°, hæmorrhages, anuria, obstinate constipation, pasty stools, anorexia and malaise. Gradually the fever subsided, the jaundice decreased, the stools and urine regained their normal character and appearance, his appetite returned and convalescence ensued. Early in the boy's sickness he was taken away from the others, and but one child had access to him. I may state, whether there is a connection or not I will not say, that soon after Fred's recovery I saw the other child with what seemed to be an irritation of the gastro-intestinal tract. He was sick but a few days.

Dr. Hennig's Cases.—October 16th, 1889, I saw Erwin L., a strong boy, on account of a yellow discoloration of the conjunctivæ. The mother stated that the child had not been well since the ninth; and though he had been restless, tossing himself from one side of the bed to the other, had a poor appetite, was cross and had lost flesh, these symptoms had not alarmed her until on the 11th she noticed the yellow tint of the conjunctivæ. Examination revealed the following: Jaundice of the skin and conjunctivæ, tongue coated with a dirty fur, sickening odor of the breath, no eruption, lungs and heart normal, spleen not easily mapped out, slight increase of liver dulness, pressure on abdomen not painful, tympanitic abdomen painful on pressure, no tumor, sensation and motion normal, no cerebral symptoms, bowels a trifle constipated, stools a slightly bad odor and a little blue in color, urine somewhat scanty, of a dark brown color, s. q. 1023, traces of albumen only discoverable by the metaphosphoric and citric acid tests, bile-pigment, hyaline casts, epithelium, and a little pus likewise present. Temperature 101⅘°, pulse fairly good and rhythmical, 106 to the minute. Neither itching nor yellow vision present. He can distinguish colors and sees good at all times. The boy being affected with hereditary syphilis—the last outbreak occurring during the summer of 1889—I at first sought some connection between this and his present condition, although jaundice is rarely a symptom of hereditary syphilis (Furth). However, as there was no evidence of a new outbreak, not much enlargement of the liver and no roughness of the organ, I threw syphilis out and made a diagnosis of catarrhal jaundice instituting a suitable therapy. Having obtained excellent results from Henoch's prescription of HCL. acid, a suitable diet in "bilious" diseases and duodenal catarrh, I decided to use them in this case. The boy improved slowly under this treatment, sleep returned, he showed a disposition to play, and his appetite returned, nevertheless icterus of the skin and conjunctivæ continued, as did also bile-pigment, albumen and casts. Splenic dulness became more plain from day to day (no pain being complained of in that region), though not in proportion to that of the liver, (both organs being easily palpated). He bore these examinations impatiently and manifested pain where they were made. The only subjective symptom now remaining, was pain in the right hypochondrium and abdomen. On the 18th the stools were yellow, this being the first indication of an opening through the ductus choledocus. Jaundice now slowly disappeared, and on the 19th a polyuria occurred, urine sp. g. 1007. Pus and casts now disappeared and he was discharged on the 21st. Case 2.—Margaret, this boy's sister, aged 3½ years. She also had hereditary syphilis exhibiting the last symptoms during June, 1889. When brought to me, early in November, I found that she was disinclined to play, was the color of a "dried herring," had pains at the base of the brain, "bone breaking" pains in her lower limbs and tooth-ache which being worse at night caused her to sleep poorly. On the 7th, her urine was found to contain bile-pigment, pus, hyaline casts, pavement epithe-

lium, with white and red blood corpuscles, sp. g. 1021. She had icterus of the conjunctivæ and face. This little patient felt very bad. She wept and sobbed loudly, complained of the itching, pain in the back of the head, in the epigastrium and in the right hypochondrium. She winked a great deal,had trouble with her vision, photophobia and was much depressed. Her tongue was heavily coated, breath sour, diarrhœa, scanty, dark-brown urine, frequent pulse, 140, temperature 102½°, the fever attended with chills. Lungs normal excepting a slight catarrh of the right lower lobe, cardial dulness normal. The heart sounds could be heard distinctly alternately with the sounds from the large blood vessels. Liver dulness extended a finger's breadth below the edge of the ribs. Palpation of the organ was very difficult. It and the spleen were smooth. The slightest pressure on the tympanitic belly evoked screams of pain. Sensation and motion appeared to be normal. In this case also a diagnosis of catarrhal jaundice was made and a similar line of treatment pursued. But a few days afterwards, or on November 9th, I saw something which caused me to view this case from another stand-point and awakened in me a great degree of interest. It was that of a third child, three years of age, living up stairs in the same house, and said to be affected in the same way, with jaundice. The families being intimate, the mother, at my request, brought her child, Elsa, to me. Her skin and conjunctivæ were yellow,tongue coated white, pulse 128, respirations 24. She complained only of weariness. She had a good appetite, regular digestion with scanty, slightly whitish stool. Her sleep was normal. As happened, according to the report of my colleague, Dr. Herbst, in his cases, that the jaundice quickly disappeared under muriatic acid, suitable diet and purgatives, so it was in this little patient, who by the 23d, was restored to health, having, with one exception, spent but one day in bed. But in the second patient the disease pursued a different course, presenting the following symptoms: A high degree of jaundice remained in the skin until the 14th, the body was the color of a lemon, discharges from the bowels were scanty, bluish-gray in color and very offensive, the urine contained a great mass of bile-pigment, albumen over 1½ per mille, (Esberch's albuminometer,) quantities of casts and pus corpuscles. There was now and then anuria. The child had a severe fever, pulse full and very fast, remaining for some time at 140. As with all the cases observed, her delirium was worse at night. During the day the child sat here and there for a short time around the house or lay on the sofa, she complained and sobbed a great deal on account of the severe pain in her head and legs and on account of the intolerable itching. She was very unhappy and enjoyed absolutely nothing. Had severe thirst at times, winked a great deal, was extremely peevish and complained of pain in her eyes. She could see during the day, had the characteristic appearance of blue-blindness; in the twilight or at night she could not take a step, being unable to see at all. Ophthalmoscopic examination negative. November 15th, it was only by quite strong palpation that I was able to demonstrate the position of the liver. On the 16th, the discharges from the bowels lost their bluish cast and became of a lightish brown. On the next day the skin around the neck changed in color, the urine lost some of its bile-pigment, the disposition of the child was not so peevish and cross, and it began to take some interest in affairs going on in its room, the pulse fell to 120, stronger. The patient's appetite improved, she complained no more of pain in her abdomen and legs, and the pain in her head was also better.

With the permeability of the bile ducts the child's recovery proceeded uninterruptedly so that on November 20th further treatment was dispensed with. Case 3. During this girl's sickness, Kurst F., brother of Elsa, presented much the same symptoms as the other three children. For the particulars of this case I am indebted to my colleague, Dr. Herbst, whose account is as follows: Kurst F., five years old, was seen on November 14th, with a yellowish hue of the conjunctivæ. There was nothing complained of which pointed to indigestion as its cause. In a short time his skin likewise became jaundiced, fever was not present. He was around the house and cheerful all the time and had fully recovered by the 27th. Case 4. On November 1st, Mr. L., father of the first-mentioned children, was sick with fever and shaking chills, severe pain in the head, anorexia, soreness in his limbs and pain in the left hypochondrium and right epidymus. The scanty urine contained no gonnocci but was concentrated, had a sp. g. of 1023, and contained a mass of bile-pigment with albumen. Examination of the lungs showed a diffuse catarrh, splenic dulness increased, while the liver could easily be felt under the edge of the ribs. With rest in bed and ice to the inflamed scrotum, and purgatives, he was better the next day and on the fifth the whole scrotum was enveloped

in a mercurial plaster, and he left his bed to go on a journey with no feeling of weight or heaviness therein. During his entire illness there was very little jaundice, though on more than one occasion bile-pigment was found in his urine. The splenic dulness was normal on the third day but the liver was slightly enlarged at the last examination. Case 5. Finally, Mrs. L. was attacked on November 14th, with a shaking chill, great lassitude, dull pain in her abdomen and trifling hæmorrhage. She believed herself two months pregnant, though she was three months advanced. Although she was put to bed, on the 18th, she had a chill, heat and burning in her abdomen, with a severe hæmorrhage, which, during the course of the following day, became so severe that fears were entertained for the safety of the fœtus. Though the womb would admit the index finger and the fœtus could be felt it could not be seized. During the night bearing down pains came on, accompanied with hæmorrhage and the fœtus was passed during the act of urinating. The secundines were removed without hæmorrhage or trouble by manual expression, late the same night. The fœtus appeared normal, had no appearance of syphilis, and was not macerated. The placenta was large showing how far pregnancy had advanced. Sections of the child showed no pathological lesion. The membranes showed fresh ecchymoses. The lying-in was normal so that the patient was around by the end of November. Mrs. L. was slightly jaundiced the whole time but the discharges from her bowels did not have the characteristic color which marks an interference with the excretion of bile.

Dr. Theodore's Case.—On Nov. 11th, 1889, Kate, ten years old, the daughter of Professor D., was taken sick with catarrhal jaundice. Added to the jaundice there was fever, 102½°. The stools never dry, a little "costive" and light in color. Urine reddish-brown. After the second day the fever tended to become higher every other night. She was free from jaundice and dismissed from treatment on the seventh day. On the day of her dismissal, her sister Joanna, aged twelve, was attacked almost as she had been, except that the jaundice was more intense and the other symptoms less severe. She was under treatment twelve days. Three days after her dismissal, viz., December 3d, her brother George, aged eight, was taken sick with anorexia, fever, heavily coated tongue and constipation. My first idea that here was also a case of catarrhal jaundice proved correct, for he was jaundiced on the next day, his fæces became an ashen-gray, his urine reddish-brown and the skin yellow. On December 12th, this patient was convalescent. December 14th Ludwig, his two and a half year old brother was taken sick with high fever, coated tongue and diarrhœa. The hope that this too was a case of jaundice was frustrated. His temperature remained high while other symptoms were lacking. That this was a case of typhoid was soon proven by the appearance of the "spots." The course of the fever was free from any complication and he had fully recovered by the end of the seventh week. On December 24th his mother who had watched and nursed him for ten days and nights was attacked with typhoid and died early in January with intestinal hæmorrhage. But jaundice had not yet finished in this family for, on January 3rd, 1890, Martin, a six year old boy was taken sick in like manner and had the characteristic yellowish discoloration. He was sick but six days, his appetite and bowels remaining normal all of the time. Finally, Elsie, aged twenty-one, was taken sick January 20th with a mild attack of jaundice. Only one child Otto, aged four, and the father escaped. The treatment of all three cases consisted in the application of the faradic current to the gall bladder. No restrictions were placed on their diet and no medicines were used.

Epidemics of jaundice have occurred for many years in Europe, certain parts of Africa, in some of the Pacific islands and in America. Woodward, *Outlines of the Chief Camp Diseases of the U. S. Army*, mentions one during the year 1861 and 1862. The earliest one I found recorded occurred in Berlin in 1699 and Dr. Hennig records others as follows: Berlin, 1702, 1878; Paris, 1741, 1760, 1865, 1870, 1871 and 1872 with many more.

The cause of infectious jaundice seemed to be some agent developed outside the organism. Kelsch (Hennig) says its breeding places are marshes, earth rich in organic matter and similar localities. Hennig gives a summary of his views thus: Infectious icterus is always an acute specific—infectious, miasmatic, but not contagious disease.

It may be sporadic, endermic or epidemic.

It occupies a close relationship to abdominal typhus and bilious typhus.

It is always a disease with a favorable prognosis.

The infectious agent is always developed outside the human body.

It does not return.

As to treatment, complications must be met as they arise. Alkaline drinks and waters are recommended, so are lemonade, nitro-muriatic acid and hydrochloric as well, externally and internally. Calomel in small doses may be cautiously exhibited. Injections of cold water are recommended and finally the faradic-current. The diet should, in my opinion in most cases be restricted.

417 Adams Ave. July 21st, 1891.

ADDENDUM.

Permit me to epitomize an article which I find quoted from the *London Medical Record*, April 1885, in the *New York Medical Abstract* for May of the same year, which originally appeared in the *Berlin klin. Woch.* Dr. Lürman reports that in Bremen there occurred an epidemic of jaundice which lasted from October 1883 to April 1884. The epidemic was limited to between 1200 and 1500 ship-builders all employed by the same establishment. With the exception of being together during working hours they were separated. The soil was sandy, no extensive repairs had recently been made in any of the buildings, the water being repeatedly examined was found pure, no phosphorus was used around the building or in any connection with the men's work and no history of any former epidemic existed. Late in October 1883 the first case of jaundice presented itself, during November there were 33 cases, in December 137 more and to April 1884, 191 were recorded, though there were many that escaped observation. Masters, clerks and laborers were attacked indifferently. The attack began with a gastric or a gastro-intestinal catarrh which lasted a week or so when jaundice came on, "the symptoms were epigastric oppression and fulness, anorexia, vomiting, faintness, &c." Constipation generally present. "Yellow vision only occurred in a few cases." "Physical examination showed a prominent and tender epigastrium." There was no hepatic enlargement "nor was the gall bladder ever felt as a tumor. The whole process was a febrile; the pulse was often retarded," the fæces were but little changed from the normal. There was no albuminuria nor bile-acids but the "coloring matters were easily shown by Gmelin's test." Cerebral symptoms, general dropsy with anuria (cholæmia) occurred but once. There were no deaths. No cause can be assigned for this epidemic. "A neighboring factory of 600 persons entirely escaped." Bad or defective diet and impure water seem excluded as causes as in the one case the wives and children of the men were not attacked and in the other most of the men seldom drank of it, bringing coffee with them. "A curious connection," it is stated, was found to exist between the occurrence of the epidemic and the revaccination of the men. Out of 540 men in one lot revaccinated in August, 141 had jaundice subsequently, out of 466 in another lot 35 had it and of 283 in still another lot 14 were affected. Afterwards 50 more were revaccinated and but one was jaundiced. Another singular fact is that of 500 persons taken on afterward not one of whom was vaccinated not one was affected and of 87 persons revaccinated with other lymph and by another surgeon not one was attacked.

Dr. Lürman arrives at the following conclusion: The jaundice was evidently infectious, the "virus was strictly limited both as to time and place with a very long incubation period of from two to eight months and was casually connected with the revaccination in some way or other."

Society Reports.

PROCEEDINGS OF SECTION III OF THE SEVENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY. AUGUST 10 TO 17, 1891.

THE RELATIONS OF THE DISEASES OF ANIMALS TO THOSE OF MAN.

COL. SIR NIGEL KINGSCOTE, K. C. B.,
PRESIDENT.

PRESIDENTIAL ADDRESS.

The President said: My first duty, in taking the chair of this very important and interesting Section of the first meeting of the International Congress of Hygiene held in the United Kingdom is to offer you all, on behalf of the Organizing Committee and the Council of the Section, a cordial welcome to our meetings, and to express to you our sincere thanks for your presence and co-operation in the work that is before us. The subjects that we shall have to discuss are of the greatest and most immediate importance to all classes of the community in every country; and I think myself happy in having been honored with the presidency of the first assemblage of medical men, verterinarians and agriculturists that have ever met on

common ground to discuss questions of the profoundest interest to them all, and to the world at large.

The title of our Section is sufficiently indicative of its scope and object. The relations of the diseases of animals to those of man have been the subject of more or less vague speculation by observers from an early period of the world's history; but it is only of late years that such relations have been systematically and scientifically studied. It would be in the highest degree inappropriate for me—who owe my position here to the accident of being somewhat intimately associated with the business management of two important institutions, which devote much of their energies to the study of animal life and animal diseases—to attempt to summarize the stages of development of this great question, or to pass in review the various diseases which have shown to be intercommunicable between men and animals. As to some of these—as, for instance, rabies and anthrax—the evidence appears absolutely conclusive. A few others are, perhaps, still within the range of speculation, or at least can hardly claim to have been proved to demonstration. On all these diseases and disorders, and the consequences which they involve, we are fortunate in having some of the highest living authorities here to instruct us, and I shall not abuse your good nature by standing between you and the study of their researches and experience.

There can be no doubt that the anatomical and physiological relations between the lower animals and the human being are sufficiently close to justify the presumption that they are liable to the same class of diseases; and one important part of the subject which will be considered during the meetings of our Section is the question of susceptibility, without which it would seem that the individual ceases to be responsive to the attack of the malignant virus.

In short, as will probably appear in a very prominent form in the discusssion of the papers on parasitic diseases, the whole question seems to resolve itself into the survival of the fittest, and it must be for this Congress to consider and discuss the best ways of combating the invasions of the human body by the many varieties of self-multiplying alien germs and external morbific influences which prevent the individual life from completing its normal course.

THE PREVENTION OF HYDROPHOBIA.

Dr. E. Roux, of Paris, delivered an address on the prevention of hydrophobia after infection by the bite of a rabid animal, and gave an account of the results obtained at the Pasteur Institute.

THE PASTEUR TREATMENT.

It was, he said, little more than six years since M. Pasteur has made the first inoculation in man. Since then thousands of persons bitten by mad dogs had applied for treatment at the Institute. At the last Congress of Hygiene in Vienna (1887) M. Chamberland had given an account of the results obtained by the then recent discovery of M. Pasteur. At the present day the number of persons treated was large enough to enable a judgment as to the value of the Pasteurian method to be formed. The application of antirabic inoculation to man had been rendered justifiable by the observations which M. Pasteur had made that dogs could in this way be prevented from developing the disease after inoculation. This fact, which could be easily proved by any competent experimenter, had been verified by the special commission appointed by the Government of England. Encouraged by his success with fowl cholera, anthrax, and swine plague, M. Pasteur had endeavored to obtain the virus of rabies in an attenuated form. He had been defeated in his attempts to create virus by artificial media, but he had succeeded by inoculating rabbits in the brain. After a certain series of inoculations, the disease developed itself in rabbits after an interval which could be exactly fixed. In this way it was possible to have, on any given day, the central nervous system from these animals which contained pure cultures of the rabic virus. That this was so was shown, not as in ordinary cultivations, by the character of the culture, but by the fact that the disease developed with a regular course, and because the central nervous organs did not show any obvious lesion. So completely successful had this method of maintaining virus been that the inoculations had been carried on ever since the year 1883 without interruption by a single accident.

The spinal cord from an animal thus inoculated contained a virus of high but constant virulence. If exposed in a sterilized flask containing fragments of potash at a temperature of 23° C., the cords during the procees of drying gradually lost their virulence, until after fourteen days they had completely lost it. In the treatment of persons bitten by rabid dogs this cord dried for fourteen days was first used, then the cord dried for thirteen days, then for twelve days,

and so on, going from the weaker to the stronger virus, until the cord which had only been dried for three days was employed. In this way immunity was produced. For the purposes of injection the cords were rubbed down in some sterilized bouillion which had been rendered slightly alkaline. Some difficulty was at first found in ascertaining the exact quantity which should be used for injection in man. At the first the strongest virus was that from a cord dried for five days. The immunity thus conferred was sufficient in most cases, but was not adequate in the treatment where the bites were numerous and serious. The method of treatment had been varied several times in consequence, but for several years that adopted consisted in giving at first large quantities of emulsion of cords of feeble virulence followed by the injection of more active emulsion. The actual quantity used varied from 3 cubic centimetres for the weaker virus to 1 cubic centimetre for the stronger, the quantity of dried nervous substance employed corresponding pretty nearly to a centigramme for each injection. The duration of treatment varied slightly according to the severity of the bites.

In the case of ordinary bites the following scheme was followed:—

1st day. Cord of
14 days, dose 3 cc. of emulsion
13 " " "

2nd day. Cord of
12 days, dose 3 cc. of emulsion
11 " " "

3rd day. Cord of
10 days, dose 3 cc. of emulsion
9 " " "

4th day. Cord of
8 days, dose 3 cc. of emulsion
7 " " "

5th day. Cord of
6 days, dose 2 cc. "
6 " " "

6th day. Cord of
5 days, dose 2 cc. of emulsion

7th day. Cord of
5 days, dose 2 cc. of emulsion

8th day. Cord of
4 days, dose 2 cc. of emulsion

9th day. Cord of
3 days, dose 1 cc. of emulsion

10th day. Cord of
5 days, dose 2 cc. of emulsion

11th day. Cord of
5 days, dose 2 cc. of emulsion

12th day. Cord of
4 days, dose 2 cc. of emulsion

13th day. Cord of
4 days, dose 2 cc. of emulsion

14th day. Cord of
3 days, dose 2 cc. of emulsion

15th day. Cord of
3 days, dose 2 cc. of emulsion

In bites about the head the incubation period was often very short; it was therefore necessary to act with promptitude, and to increase the number of injections in the earliest days, in order to save time. Further, the treatment was prolonged for twenty-one days, according to the following table:—

1st day—morning
Cord of 14 days, dose 3 cc. of emulsion
" 13 " " "

1st day—evening
Cord of 12 days, dose 3 cc. of emulsion
" 11 " " "

2nd day—morning
Cord of 10 days, dose 3 cc. of emulsion
" 9 " " "

2nd day—evening
Cord of 8 days, dose 3 cc. of emulsion
" 7 " " "

3rd day—morning
Cord of 6 days, dose 2 cc. of emulsion

3rd day—evening
Cord of 6 days, dose 2 cc. of emulsion

4th day
Cord of 5 days, dose 2 cc. of emulsion

5th day
Cord of 5 days, dose 2 cc. of emulsion

6th day
Cord of 4 days, dose 2 cc. of emulsion

7th day
Cord of 3 days, dose 1 cc. of emulsion

8th day
Cord of 4 days, dose 2 cc. of emulsion

9th day
Cord of 3 days, dose 1.5 cc. of emulsion

10th day
Cord of 5 days, dose 2 cc. of emulsion

11th day
Cord of 5 days, dose 2 cc. of emulsion

12th day
Cord of 4 days, dose 2 cc. of emulsion

13th day
Cord of 4 days, dose 2 cc. of emulsion

14th day
Cord of 3 days, dose 2 cc. of emulsion

15th day
Cord of 3 days, dose 2 cc. of emulsion
16th day
Cord of 5 days, dose 2 cc. of emulsion
17th day
Cord of 4 days, dose 2 cc. of emulsion
18th day
Cord of 3 days, dose 2 cc. of emulsion
19th day
Cord of 5 days, dose 2 cc. of emulsion
20th day
Cord of 4 days, dose 2 cc. of emulsion
21st day
Cord of 3 days, dose 2 cc. of emulsion

The large quantities of spinal cords of feeble virus injected during the first three days had the effect of bringing the patient quickly into a fit condition for being inoculated with the more active cord. The two schemes described above could of course be altered to suit varying circumstances; for instance in numerous and deep bites on the limbs a line of treatment was adopted intermediate between the two above named schemes. Persons treated at the Pasteur Institute were divisable into three categories. The first included those persons bitten by animals which were proved by experiment to be suffering from rabies; the second class included those persons bitten by animals recognized to be rabid by verterinary surgeons; while the third class consisted of those bitten by animals only suspected of suffering from rabies.

The following is the result of the antirabic vaccinations of each category for the five years 1886–90. The results of the present year were not stated, because sufficient time had not yet alapsed:

Classes A and B:—Treated, 7,925; deaths, 73; mortality, 0.92. Class C:— Treated, 1,540; deaths, 17; mortality, 1.1. Total.—Treated, 9,465; deaths, 90; mortality, 0.95.

It would be seen that the general mortality among these 9,465 persons was 0.95 per cent. as compared with 12 or 14 per cent., which was the mortality of persons not treated. These figures included all the cases which died after treatment: but to be absolutely just, the persons who had died a few days after the treatment ought to be excluded, for in them the disease had broken out before the preventive inoculations had had time to produce their effect. If these deductions were made, the mortality would be reduced to 0.61 per cent.

In order, however, to study more exactly the efficacy of the treatment it was desirable to exclude patients bitten by animals only suspected of being rabid, and to confine attention to classes A and B. Further, he would take out of these those patients who had been bitten on the head. The gravity of bites in this situation was well known; it produced among patients not treated a mortality of 80 per cent.; 710 persons bitten about the head had been treated at the Pasteur Institute, and 24 had died—that is to say, there had been a mortality of only 3.38 per cent. Further, it should be remembered that in this proportion of 3.38 per cent. were included those cases in which the disease broke out immediately after the inoculation had been made, and which might very properly be excluded from the list.[1] Was it possible to give a more convincing proof of the efficacy of the antirabic treatment? What one among all the methods of treatment known to medicine could claim to have fewer failures? Pasteur might therefore reply to his detractors by asking them another question: Have you anything better to propose? Among the 9,465 persons treated 1,551 were not French; 24 had died, a proportion of 1.29 per cent. The somewhat higher mortality among those patients had to be attributed to the longer period which had elapsed before they came under treatment. The number of English patients treated had been 389, and the mortality among them was 1.8 per cent. This high rate was due to the considerable number of patients who had been severely bitten, but who had only presented themselves for treatment several days after the injury. It was most important to remember that the shorter the interval the greater was the prospect of success.

The nature of the change produced in the cords by the process of drying was questionable. It was certainly due to combined action of the air and of the desiccation, for cords kept at the same temperature in a moist atmosphere of carbonic acid or hydrogen, retained their virulence for a long time. The change was probably not a true attenuation such as was observed in anthrax vaccine. It was more probable that the vitality of the rabid virus was first modified and then destroyed. Since the process of desiccation affected the various parts of the cord unequally, it was desirable always to employ rabbits of the same weight, those used being of the weight of 2 kilogrammes. M. Pasteur believed that, in addition to the living virus

[1] Nine persons had died of hydrophobia within 15 days after treatment. If this number was deducted the rate of mortality would be 2.14.

in the cords, special chemical bodies were formed by the rabid microbe, which bodies probably had some part in producing immunity. In certain cases which had been treated at the Pasteur Institute a long time after the infliction of the bites, it was thought that the earliest symptoms of hydrophobia were already developing, and in certain of these cases these symptoms, such as pain along the course of the nerves and hyperæsthesia, had disappeared under treatment. In certain cases also in dogs it appeared probable that rabies had been aborted by vaccination after inoculation. A point to which much importance ought to be attached was that during the process of preparation a cord should be kept absolutely pure and free from contamination by microbes. This could only be ascertained by inoculating with particles two days before the cords were inoculated for vaccination. By taking these precautions, the danger of producing an abscess at the point of inoculation was almost completely avoided.

Since the method of treatment was first adopted the rate of mortality had declined: thus, in 1886 it was 1.34, but in 1889 it had fallen to 0.54, and in 1890 to 0.71. It might be asked whether even this mortality might not disappear. He feared, however, that this could not be. In the first place, most of the deaths were among persons who died within a fortnight after the completion of the inoculations, that is, persons who were already developing the disease when the treatment was commenced. Another reason why success could never be absolutely complete was that the virus might remain latent in the system for months or even for years. The condition of immunity produced by the preventive inoculations might in fact disappear before the virus itself had perished, and in this way the cases of development of hydrophobia at a very late period would continue to occur.

THE PREVENTION OF RABIES IN DOGS.

Dr. George Fleming, C.B., F.R.C.V.S., said that it was now generally accepted by those who had most carefully studied the subject, that rabies was a purely contagious disease, due to a virulent principle or specific agent.

Of all the domesticated animals, the dog was certainly the one which was by far the most frequently attacked, and perpetuated the malady. In the interests of mankind, no less than in those of the domesticated animals, and particularly of the dog itself, this very alarming, most painful, and always fatal disorder should be suppressed.

The measures necessary for the extinction of the disease must be based on the fact that the dog was the chief, in fact the sole, propagator of rabies; that the contagium or infecting material was conveyed from the diseased to the healthy by means of bites (other means being so exceedingly rare that they might be left out of consideration;) and that to free a country from it, all rapid and suspected dogs should be destroyed, certain restrictions maintained for a limited period, and only dogs from other countries exempt from rabies allowed admission.

That the disease could be limited, or altogether suppressed by the enforcement of proper measures, there was an abundance of evidence to prove. Sweden, Norway, Switzerland, Baden, Prussia, Bavaria, Würtemberg, and other countries have been freed from it by such measures; while countries in which it had never been seen, such as Australia and New Zealand, were preserved from its invasion by such precautionary measures as quarantine of imported dogs, or, as in Sweden, total prohibition of importation of dogs.

That the dog was the sole propagator of the disease was well seen from recent English statistics. In 1888 and 1889, 90 and 91 per cent. of the animals reported as rabid were dogs, and in 1890 the percentage was more than 96. The animals other than dogs were infected by rabid dogs, and these infected each other.

He then proceeded to discuss the preventive measures which should be adopted, taking them in the order of importance, in the following terms:

1. *Destruction of Rabid Dogs.*—The necessity for the destruction of all rabid dogs is so self evident that it need not be further insisted upon. The disease is incurable, causes much suffering, and the affected dog is, so long as it lives, so great a danger to other creatures that its speedy destruction is imperative. Dogs which are suspected of being rabid, or of becoming so through contact with those which have been affected, must always be a source of grave apprehension and danger, and unless they can be kept under close and safe observation for a considerable time, should also be destroyed, seeing the risks incurred in allowing them to live. A suspected dog may be defined to be one that presents symptoms resembling those of rabies, or which has been in conditions that have rendered infection probable or possible.

2. *The Control of Ownerless Dogs.*—Wandering dogs are the chief agents in the propagation of rabies, for the reason that they are more exposed to contamination than those which are properly cared for, and also because rabid dogs, even when carefully guarded, seek to wander from home. In proportion as wandering dogs abound in infected countries, so is the disease prevalent. This is a well established fact. In England in 1888, of 160 rabid dogs, 64, or 40 per cent., were returned as stray ones; in 1889, of the 312 rabid dogs reported, 121, or more than 38 per cent., were evidently ownerless; while in 1890, 64 out of 129, or more than 51 per cent., were so returned. Therefore, in order to limit the propagation of rabies, all wandering dogs should be secured, and, if not claimed within a certain period, destroyed.

3. *Muzzling.*—The value of the muzzle in suppressing rabies has been demonstrated on many occasions; and in serious outbreaks of the disease its introduction has always coincided with a diminution in the number of cases and the eventual extinction of the scourge. Its use is also coincident with a decrease in the number of cases of hydrophobia occurring among people during such outbreaks and their ultimate cessation. The evidence in support of this statement is so voluminous and explicit that anyone examining it must be convinced as to the certainty of the fact. After referring to the experience of Berlin since the severe outbreak in 1852, which led to the issue of a degree that all dogs should be provided with a wire muzzle positively preventing the animal from biting, and empowering special persons appointed by the police for that purpose to seize and destroy all dogs not so muzzled, Dr. Fleming continued:

In Vienna we are informed that rabies was entirely suppressed by 18 months of stringent muzzling, but in the summer of 1886 the muzzling order was recinded and badges had to be worn on dogs' collars instead. In the following half-year there was only one case of the disease, but in the next half year rabies became epizootic and the muzzle had again to be worn, with the result that the malady soon subsided and disappeared. Consequently the muzzling order is still rigidly and most beneficially enforced in Vienna.

In Holland, before 1875, rabies were prevalent to a very serious extent; but in June of that year the use of the muzzle was ordered with the result that in the autumn the number of cases fell to 41; in the next whole year they were 55; in 1877 they were 14, in 1878 they were 4, and in 1879 they were 3.

These, and the cases which have since been reported, only occurred on or near the frontier of Belgium, in which country the muzzle is not in use though rabies is always prevalent. To such a degree, indeed, does the disease exist in Belgium that in 1889 there were brought to the Veterinary School at Brussels no fewer than 94 really rabid dogs, 49 having been admitted during the winter quarter and 45 during the summer quarter; and from January 1st to April 24th, 1890, 16 were taken there.

In the Grand Duchy of Baden, during the years 1871, 1872, 1873, 1874, and 1875, the number of cases of rabies was respectively 18, 37, 37, 50, and 43. Then the muzzle was rigorously applied, and in 1876 there were 28 cases; in 1877, 3; in 1878 4; in 1879, 2; in 1880, 2; in 1881, 2; in 1882, 3; in 1883, 2; in 1884, 2. Since that year only one case has been observed and that was a dog from Metz, where there were no proper regulations and which had been contaminated before its arrival at Baden.

In Sweden rabies was at one time a somewhat common disease, and from 8 to 10 people died annually of hydrophobia, but on muzzling being enforced and the importation of dogs prevented, rabies have been unknown for many years, and no deaths from hydrophobia have occurred since 1870.

In England the value of the muzzle has been as well exemplified as elsewhere, though its application has always been extremely partial, being only employed in towns or districts when rabies has increased to such an extent as to create alarm, and removed immediately when the disease had for the time disappeared. No effective action has at any time been taken to suppress it in England or Ireland; in the latter country it is always more or less prevalent, and ever since it was first legislated for in England it has maintained a permanent existence in the following 14 counties, namely, Chester, Derby, Essex, Hants, Kent, Lancaster, London, Middlesex, Notts, Surrey, Sussex (East), Sussex (West), Warwick, and York (W. R.) During the past year cases of rabies were reported for the first time in three counties previously free from it; these were Bucks, Norfolk, and York (E. R.;) and it was reintroduced into Leicester after an absence of two years, and into Stafford, which had been free for one year.

The extent to which rabies has prevailed in this country may be judged from the loss of human life through bites from rabid dogs.

It is stated that in England (including Wales), there have been 939 deaths from hydrophobia recorded during the past thirty-eight years, the yearly average for the first sixteen years being 8, for the next sixteen years 15, and for the remaining period, ending in 1885, 45. Thus, the mortality has steadily advanced through more than 400 per cent. On the other hand, the Prussian preventive measures have reduced deaths from hydrophobia to a remarkable degree; for while in the decade ending in 1819 there was a yearly average of 166 deaths, in a similar period ending in 1886 there was a yearly average of 4½.

The value of the muzzle in suppressing rabies, has been, perhaps, best demonstrated in London, on several occasions, and especially in 1885. In the previous years hydrophobia had increased to a very alarming extent, as has just been mentioned, in England, and no steps worthy of note had been taken to check the mortality. For London alone in that year no fewer than 27 deaths of people were reported as due to the bites of rabid dogs. A muzzling order was then enforced, and at the end of 1886 not a death was recorded. Unfortunately, the order prescribing the use of the muzzle was then rescinded, and in a few months a case of hydrophobia occurred in the south of London, soon to be followed by others, and in 1889, 10 deaths were registered. In July of that year the muzzling order was again issued and stringently carried out, and rabies and hydrophobia once more disappeared.

In other countries where rabies prevails and dogs are not muzzled, though other measures—as the dog tax, medal on the collar, leading by a leash, etc—are enacted, the malady continuously manifests itself, and numbers of people perish from hydrophobia every year. We may give Belgium and France as examples. In the latter country the monthly sanitary bulletin shows to what an extent it is prevalent, and I need only refer to the last two which I have to hand those for March and April of the present year. In March, 132 dogs and 8 cats were destroyed as rabid, besides those sacrificed as a preventive measure; while 32 persons were bitten by mad dogs, as well as cattle and pigs. In April, 151 dogs and 4 cats were destroyed because of being rabid, and a large number were killed because they had been bitten by mad dogs or were wanderers; and 47 persons were wounded by mad dogs. The reports of the Pasteur Institute show that by far the largest proportion of persons protectively inoculated are French. There can be no doubt that if the use of the muzzle were enforced generally and strictly throughout France rabies would quickly vanish from the sanitary bulletins.

Belgium has tried all the other recognized measures except the muzzle, and yet the malady is as rife and deadly as ever. A Royal Commission was recently appointed to inquire into the subject, and the report addressed to the Superior Council of Hygiene in April last states that the regulations in force are insufficient, and, while not contesting the value of Pasteur's preventive inoculations with regard to people bitten by rabid dogs, it is urged that there is something far more desirable, and that is the extinction of the disease in the canine species. For this object the Commission insists upon the immediate adoption of the muzzle.

4. *Dog Tax and Registration.*—The imposition of a dog tax and registration is necessary to limit the number of dogs and to ensure that every one has an owner, who should be held responsible for any damage it inflicts. From this measure no dog owner should be exempt. If an entire country is infected with rabies then suppressive measures should be applied to the whole area, uniformly and energetically, until the malady is perfectly extinct. If only a portion of a country is visited by it, then it is questionable whether such measures should be limited to that portion only. If it were possible to keep all the dogs it contains within its boundaries, then such a step would suffice, if a certain zone around it were established beyond which no infected animals should pass. But it would be extremely difficult, if not impossible, to establish such a barrier; and, to effectively rid a country of rabies, though only partially infected, the sanitary police measures should be applied to the whole. That such a result is possible has been proved by the experience of the countries I have named, and, from these examples and what we know of the disease, it may certainly be affirmed that rabies need only exist in a country which does not desire to get rid of it.

Dr. J. Bardach (Odessa) gave the results of the Pasteur method of treatment in the bacteriological institute of that town during four years. Between 1887 and 1890, 2,243 patients had been treated, and of these only 16 had died, giving a mortality of 0.72 per cent; and if, following the statistics of the Pasteur Institute, they collected only those that died after the treatment had been carried on for two weeks, they obtained the

following figures: 2,238 treated, 11 of which died, giving a mortality of 0.49. He gave a number of statistics of the more severe injuries of the head, etc., from which it might be gathered that in these cases the results were not so favorable, especially where the wound was such as to implicate the brain or central nervous symptom, or the tissues closely associated with them, the mortality in these cases rising as high as 1.51 per cent. Where the hands were affected it was as low as 0.69 per cent., and where the lower limbs and trunk were affected it fell to 0.61 per cent. These results, he thought, might be considered exceedingly satisfactory, and would compare favorably with any other statistics.

Dr. Hime (Bradford) said all who had studied the Pasteur method were satisfied that it was established on a scientific basis; and he gave an example in the case of a dog of his own of the efficiency of the remedy. He thought, however, that it would be an advantage, in spite of what Dr. Fleming had said, to have the name and address of the owner of a dog on its collar, as at any rate it would enable the veterinary surgeon to ascertain the district from which any dog had come, and would enable him to grapple more readily with the disease at its source. He thought that the law might be made more stringent as regards owners of dogs, and that it should be possible to proceed against them more readily than at present; the onus should be placed on the owner, and not upon the bitten person. The present system of muzzling dogs in certain areas only was radically bad, and was manifestly useless and absurd; it was not only stray dogs that required muzzles, for all dogs were liable to become rabid. It had been demonstrated by MM. Roux and Nocard that even three days before the slightest symptom of rabies showed themselves in an infected dog under careful observation, its saliva was infective, and, when inoculated, would cause rabies in other dogs and other animals; this showed how very important it was to know whence a rabid dog came, so that extra precautions might be taken throughout the area. That rabies could be entirely eradicated was indubitable, and that it was still existing among us was characteristic of our apathy. As pithily said by His Royal Highness in his opening address, "If preventable, why not prevented?" Dr. Hime asked, in conclusion, whether there were any facts available as to the question of how far the dogs of Australia, where rabies was unknown, were less susceptible to rabies than the dogs of other countries, or whether the fortunate immunity of Australian dogs was due entirely to the measures of quarantine of three months carried out there against all imported dogs?

M. Nocard (Alfort) mentioned a prophylactic treatment which was applicable to domestic animals, at least to herbivores. M. Galtier had some time ago announced that the injection of rabic virus into the veins of the sheep and the goat did not produce hydrophobia, but rather conferred immunity. He himself had quite recently made a number of experiments, by which he had been able to show (1) that the extravenous injection of rabic virus would not produce rabies in horses; (2) that if the quantity of virus injected was sufficient, these inoculated equines acquired an immunity against rabies; (3) that it was possible to protect equines inoculated by intraocular injection when there were introduced into the veins certain quantities of dilute rabid nervous material. From these experiments he thought it might be hoped that a prophylactic treatment might arise out of the labors of M. Galtier. Upon the question of the prophylaxis of canine hydrophobia, he was in principle entirely at one with Professor Fleming, and he considered that muzzling would be exceedingly useful; but it must be remembered that no muzzle would prevent a mad dog from biting. Anyone who had seen a foaming mad dog tearing at the bars of his cage would understand how useless the muzzle would be. The muzzle, however, would indicate that a dog had a place in which to live and was well looked after, and that if all others were destroyed the greater number of candidates for madness would be exterminated. Of course a leash would serve equally well, and he gave examples of how these would work. The truth was, there was no necessity for new sanitary measures for the suppression of rabies; it would be quite sufficient to determine and to apply exactly and rigorously the most simple measures that were already actually prescribed in all civilized countries.

Dr. C. R. Drysdale (London) said that, having frequently attended the inoculations at the Institute Pasteur, he could speak with the very greatest admiration of the immense care and intelligence shown in the carrying out of the treatment. As to the issues of Pasteur's plan, he considered it now clearly proved that, when only 0.92 per cent. of deaths had occurred after this treatment, as compared with probably more than 20 per

cent. in similar cases, it was an indulgence in an improper amount of scepticism to deny it any longer. Consequently, he thought it was high time that a Pasteur Institute should be formed in London, for it was not fair for English people to send over all their patients to Paris and then to abuse Pasteur and his noble-minded assistants. As to the prevention of rabies, a muzzling law could be applied in England better than any other European country because it was surrounded by the sea, and, if muzzling were attended to for a year, the disease might be stamped out of the United Kingdom, and when once stamped out it might, as in Australia and New Zealand, be kept out by means of quarantine. There was no doubt that rabies was an eminently preventable disease, and being so, it was extremely immoral in anyone to refuse to help forward such a salutary law in this and other countries as the muzzle law of Prussia.

Professor Redfern (Belfast) agreed that muzzling in certain areas only was so ridiculous that it was wonderful how it could be thought of as being likely to bring about useful results. He thought that this matter was one that should be brought officially before the Congress, and that no uncertain voice should be given by a vote of the whole Section, if necessary. They would then go to members of both Houses with their hands strengthened, and be able to place the matter in a very strong light, so that they might obtain satisfactory legislation, but he wished it to be understood that, as the matter had been brought up, a very great responsibility rested on every member of the Section, and he hoped that both publicly and privately they would do all in their power to put this question on a satisfactory basis.

Dr. Ostertag said it had been suggested that the muzzle was ineffectual because cats and wolves carried the disease as well as dogs, but that cases of this sort were rare was proved by the experience of Germany. Since the passage of the laws regulating the contagious diseases of animals rabies had become a rare disease and only occurred along the French and Russian borders. These laws provided that all mad dogs, and those suspected of rabies, or even of having bitten, were to be killed, and all dogs and cats within a radius of fifteen miles must be kept in confinement during three months each year. In Berlin all dogs wore muzzles, and a case of hydrophobia had not been reported for ten years. As a result of these laws a Pasteur Institute in Germany was unnecessary.

Sir Henry Simpson (Windsor) said that no doubt they would all agree with Dr. Fleming that muzzling was an efficient remedy. He wished to call attention to the practical carrying out of a muzzling order, and to warn the Section if they made a recommendation to the Legislature to endeavor to make some exemptions, or they were likely to recommend in vain. He would say exempt sporting dogs, because for seven or eight months in the year these were used for hunting purposes. Hunting and sporting led to the employment of many persons, many horses, and expenditure of money. If men of wealth were asked to sacrifice their hunting for a couple of years they would not do it, and the country would not sanction a measure which would result in such a loss of revenue to the trade of the country. Considering that sporting dogs were well cared for, and that their owners were true lovers of dogs, it appeared to him that they need not be muzzled, but that it should be a recommendation that they be kept in charge of competent persons, and that any deviation from health should be at once noted, and an inspection made by a properly qualified veterinary surgeon, and, if necessary, the animals kept in quarantine.

Dr. Elizabeth Blackwell begged to call attention to the suffering of dogs made to produce virus; she herself had visited the Pasteur Institute and seen a series of dogs in the various stages of induced madness.

Professor Brown said that as the head of the department which was charged with the duty of checking the progress of contagious diseases of animals, he wished to refer to some of the questions which had been dealt with in the course of the discussion. He agreed with every word which Dr. Roux had uttered as to the value of M. Pasteur's method, and with all that Dr. Fleming had urged in favor of preventive measures, but he wished to emphasize the difficulties which arose from the sentimental objections of owners of animals, who, as Dr. Roux had remarked, were quite incapable of realizing that their dogs might become mad, although they were keenly alive to the risk incurred by their neighbors' dogs, and believed in the necessity of imposing restrictions on them. He could assure the meeting that if they by a strong expression of opinion induced the Legislature to insist that all the dogs in the United Kingdom should be muzzled for a certain time, every one in his

department would be gratified; but he need hardly remark that an order to that effect emanating from the Board of Agriculture, even if they had power to pass one, would excite unusual opposition.

Professor Perroncito indicated that in the municipality of Turin they had a laboratory for the Pasteur antirabic treatment that gave exceedingly good results, as published by the director, and he also mentioned that an experimental inquiry upon the same method of treatment had been commenced in connection with such animals as oxen, horses, etc., with most encouraging results.

DEMONSTRATION OF ANIMAL PARASITES.

Professor Brown gave an exceedingly interesting demonstration of animal parasites, first treating the subject generally, and taking up the questions of symbiosis, mutualism, commensualism, and parasitism. That the subject was not quite as simple as might at first sight appear was evidenced when he stated that Van Beneden had described no fewer than 400 species of strongules. He then gave a demonstration of the developmental stages of certain of the fluke or trematodes and of the cystic worms or cestodes.

ACTINOMYCOSIS.

Professor Perroncito, after mentioning some cases of direct infection of the skin with actinomycosis, said that he should reserve the greater part of what he had to say until Friday.

PARASITES TRANSMISSIBLE FROM ANIMALS TO MAN.

Professor Ralliet (Alfort) observed that the parasites transmissible from animals to man were either vegetable or animal. The vegetable parasites included besides the bacteriaciæ or microbes and divers saprophytes that were only accidentally parastic, the fungi (*tricophyta*) which caused the several affections designated by the name of "tinea." The animal parasites might be divided into external and internal parasites.

Of the internal parasites some were common to man and animals, or, living more especially in animals, might develop accidentally in man; they were often transmitted indirectly, while others must necessarily penetrate into the human organism in order to complete their evolution, and hence their transmission was always direct (*Tænia solium, Tænia saginata.*)

Indirect transmission took place very generally through the medium of drink or food, polluted or infected by the deposition of ova or embryos.

Direct transmission was brought about by the consumption of the flesh of infected animals. In this case the parasites living in the larval state in animals attained their complete development in man (*Tœnia solium, Tœnia saginata, Bothriocephalusl atus, Trichina spiralis.*

Prophylaxis must be regulated by the indications furnished by the preceding data: 1. So far as concerned external parasites, man ought, as far as possible, to avoid contact with animals suffering from parasitic affections transmissible to his species; he ought to endeavor to destroy the parasites and their progeny, not only in those animals themselves but also in all spots which might have been infected. 2. Since internal parasites were introduced generally through the medium of food or drink, it was expedient only to consume these substances after a careful examination and after having purified them, were necessary, boiling filtration, or other means. 3. Certain sanitary measures might contribute effectively to the completion of the protection.

TRICHINOSIS IN THE NETHERLANDS.

Dr. B. Carsten said that the first trace of trichinosis in the Netherlands was discovered in 1883, at Jerseke, a village near Goes, in South Beveland, one of the islands forming the province of Zeeland, whence by means of the pigs kept at and the rats infesting a tannery and storage for offal, the disease spread till 140 persons in 7 different parishes on the island were affected, one succumbing. The disease, which threatened to become enzootic in this district, was stamped out, thanks to the energetic measures adopted. A royal decree was issued prohibiting the removal of pigs and pig manure from an infected district, and a special verterinary inspector was stationed temporarily in the neighborhood as supervisor; the local authorities instituted a strict search for for trichinæ, ordering that all pork before consumption should be submitted for inspection to a competent committee appointed for that purpose, that all pig yards should be overhauled, and that whenever any trace of trichinæ was found the infected swine and all vermin found in the neighborhood thereof should be killed and, together with the offal, consumed by fire. The only other appearances of trichinosis in the Netherlands were in 1888, at Leyden and Noordwyk, two places in close proximity in the province of South Holland, where prompt action stopped its

spread. Since 1889 there had been no return of the disease in the Netherlands. In March, 1888, trichinosis was included among infectious cattle diseases, and consequently all infected pork became liable to seizure and destruction by order of the local verterinary official. That trichinosis, now a thing of the past in the Netherlands, was due to the thorough organization and the persistent enforcement of precautionary measures.

SELECTED FORMULÆ

WHOOPING COUGH.

The following treatment is used very largely by certain leading specialists in diseases of children in Paris. The treatment is divided into three periods. The patient should remain in one room or in bed. The following prescription is given:

℞ Tincture of aconite
Tincture of belladonna } aa.....3j.
Camphorated tinct. opium

M. Sig. Two to five drops once or twice a day, according to the age of the child.

If there is no febrile movement the amount of aconite may be much decreased, and if constipation is present the opium should not be used. In the second period, or when vomiting comes on, ipecac may be given in small amounts to allay gastric irritation; and in the third period, when convalescence is established, cod-liver oil, tonics and Fowler's solution will be found of service.—*Medical News.*

ZINC SULPHYDRATE AS A DERMATIC.

Zinc sulphydrate is a white precipitate—$Zn(SH)_2$—which must be preserved under water, as it is prone to decompose in the dry state. It was employed by Barduzzi, internally as well externally, in Chronic Eczemas, Psoriasis, and Vegeto-parasitic Dermatoses, with favorable results. According to Barduzzi, the desirable action of this salt is based on the sulphur being made absorbable and its irritating properties being lessened. For its administration, he gives the following formulas:

INTERNAL.

℞ Zinc sulphydrate, washed...grammes 0.5 [gr. 7½].
Extract gentian.....*sufficient to make* 50 pills.

3--12 pills daily.

EXTERNAL.

℞ Zinc sulphydrate.....grammes 5.0 [ʒ 1¼].
Lanolin.....grammes 20.0 [ʒ 5].
Lard.....grammes 30.0 [ʒ 7½].

Make ointment.

—*Merck's Bulletin.*

FERRATED CODLIVER OIL.

C. Neuss, in the *Pharmaceutische Zeitschrift für Russland*, recommends the following process for ferrated codliver oil:

℞ Codliver oil.....parts 20.
Alcohol of 90 per cent.....parts 15.
Liquor potassæ (s. g., 1.120 to 1.130) parts 33.

Mix and saponify by the aid of heat, in a spacious vessel of iron or enameled ware, stirring continuously. Then add

℞ Liquor ferri perchloridi.....parts 27.
Water.....parts 50.

and continue the heat and agitation until the iron soap is precipitated in the shape of a brown mass. Let cool, and, after carefully decanting the aqueous liquid so far as possible, and, if necessary, evaporating all watery residue, add to the iron soap five times its volume of codliver oil, and again raise the temperature until the soap is entirely dissolved. Add codliver oil sufficient to bring the whole up to 270 parts. The product is a ferrated codliver oil containing 1 per cent. of iron, of a pleasant flavor, and of a fine Malaga brown color. It keeps well.

PRURITUS.

Dr. Brubaker recommends the use of the following preparation for pruritus:

℞ Acid. hydrocyanic. dilut.....fʒ ij.
Sodii borat.....ʒ j.
Aquæ rosæ.....fʒ viij.

M. Sig. Use as a lotion.

MERCURY FOR GLANDERS.

Gold (*Lancet*) reports two cases of glanders cured by inunctions of mercurial ointment, twice a day for a month, the patient being kept at the point of salivation. The effect on the mouth was combated with chlorate of potash gargles, and on the body suppurating spots were treated by poulticing, incisions, washing out with solutions of perchloride of mercury, and dressed with iodoform gauze.

REMEDY AGAINST CHILBLAINS.

A very effectual treatment of chilblains consists in rubbing the parts twice daily with

℞ Baume de fioraventi.....grammes 100.
Acidi hydrochlorici dil.....grammes 15.

—*Journal des Maladies Cutanées.*

THE

MEDICAL AND SURGICAL REPORTER.

ISSUED EVERY SATURDAY.

EDWARD T. REICHERT, M. D.,

PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF PENNA.,

EDITOR AND MANAGER.

Nos. 518-520 MINOR STREET,

P. O. Box 843. Philadelphia, Pa.

THE MEDICAL AND SURGICAL REPORTER.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

At the termination of the period of subscription, we will promptly discontinue sending THE REPORTER unless directed to the contrary by the subscriber.

Remittances should be made by draft, check, postal note, or money order payable to Edward T. Reichert.

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy." Unless this is done, newspapers are not looked at.

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

POPULAR HYGIENE AND CRIMINAL IGNORANCE.

In the issue of the REPORTER for September 5, 1891, we published a paragraph, quoted from the *Lancet*, which stated that the Devonshire County Council, co-operating with the National Health Society, is sending trained teachers and lecturers through Devonshire, with the view of extending among the poorer population the knowledge and means of preventing common ailments, and the selection and preparation of wholesome food. "We do not doubt," says the *Lancet*, "that good will result from this effort to educate the people. It is impossible to overestimate the mischief which now results from ignorance, but if the ordinary means of prevention of disease, and the laws of health can be made of general knowledge, a great advance will be made."

The above paragraph affords us much food for thought and, at the same time, calls forcibly to our minds the crying need for a more general knowledge of the fundamental principles of hygiene by the people at large, and the absolute criminality of an entire ignorance of or disregard of them. It is high time that the profession, as well as local Boards of Health, should be stirred up to greater activity on this matter.

The highest possible aim of the physician must be the prevention of, rather than the cure of disease, and it might be well if the Chinese method of remunerating the family physician only while he maintains health in the household were adopted in this country.

It is generally appreciated by every member of our profession, that a disregard of sanitary precautions in a single case of contagious disease occurring in childhood, may be a greater menace to life than a misplaced switch before a crowded passenger train. While ignorance on the part of the switchman would be a poor defense, yet if clearly proven, the fault of his superiors in not giving proper or adequate instructions surely only increases the criminality of their

neglect; and again, if it were clearly shown that their superiors practiced a continual disregard of public safety, would it not be time indeed for the local authorities to set about, with all speed, to see that proper instructions *were* given and their observance *enforced*?

The two cases are parallel, and need no further elucidation. In the first instance, the ignorant public can only look toward their "sanitary superiors"—their physicians—for instruction, and these failing, the local Health Boards must act with prompt decisiveness. These facts are universally granted, and utterance here may seem superfluous, while the object lesson cited may be considered more fit for school children than thinking physicians. Granted, and if so the criminality of our profession in failing to properly instruct the masses in the simplest rules of public health, is so much the greater, and the importance of the step taken by the Devonshire County Council, incidently mentioned by our English contemporary, cannot be overestimated.

It is now an indisputed fact that the infectious diseases of childhood can only be occasioned by direct infection or contagion, as their name implies, and also, that such infection and contagion are unlikely to occur if proper preventive (hygienic) means are employed. It is impossible for either the physician or the Board of Health to enforce the employment of these without the entire co-operation of the public. The prevention of these diseases, or in other words, the preservation of public health and the lessening of our death rate must devolve upon the action of the public at large.

Yet, how can we, with reason, expect an *ignorant* public to perform so important a duty? Is it not more than time, in the face of these facts, that the profession should bestir themselves to find some means of accomplishing this object?

The writer recently rode in a crowded street car in which beside many healthy children, there was one with whooping cough, another infant but barely convalescing from scarlet fever, while a consumptive sat in the corner, and coughed and expectorated on the floor of the car despite the printed notice requesting him not to do so. Yet the jostling crowd was content!

It was an undoubted case of "blissful ignorance," and yet our minds reverted forcibly, and not too kindly, to the fact that each of these person's health was probably looked after by some reputable physician.

The proper observance of hygienic principles, the isolation of cases of contagious diseases, the removal of all possible causes of infection, and above all the careful and proper instruction of the public in these matters, are duties the performance of which every member of our profession should hasten to accomplish.

Let, therefore, the action of the Devonshire Council in this matter serve as an incentive. If criminal fault there be, let not the fault rest upon our shoulders. The knowledge is ours, and ours the duty to disseminate this knowledge. Let us not, therefore, hide the light of advanced science "under a bushel."

Book Reviews.

MINOR SURGERY AND BANDAGING, INCLUDING THE TREATMENT. By Henry R. Wharton, M. D., Phila. Lea Bros. & Co., 1891. p. 497.

The author has in this work endeavored to present, in as concise a manner as possible, a description of the bandages, surgical dressings, and minor surgical procedures which are employed in the practice of surgery at the present time, together with the preparation and application of antiseptic dressings, the dressing of fractures and dislocations, and short articles upon trache, otomy, intubation of the larynx, ligation of the arteries, and amputation. The author's positions and long experience as lecturers demonstrator, and hospital surgeon enable him to write authoritatively upon all these subjects.

The book is so uniformly excellent from cover to cover, that it is difficult to particularize, but the preparation and application of antiseptic dressings is especially well written and modern, and the articles upon tracheotomy and intubation of the larynx,

are clear and practical, upon both of which operations the author is an accepted authority in the surgical world.

The work is profusely illustrated with cuts, mostly new, and taken from photographs, the illustrations of the bandages and dressings for fractures being the finest that have ever been used in any work upon the subject.

It is no exaggeration to say that it is one of the most satisfactory books published upon this subject, and one that can be unreservedly recommended to students of medicine everywhere. It will also prove useful as a work of reference for the busy practitioner.

THERAPEUTICS.

THE ABORTIVE TREATMENT OF ERYSIPELAS.

Dr. Natale Amici's (*Gazetta Medica di Roma*) method consists in sterilizing the streptococcus of erysipelas in the shortest time possible. Infection is not always limited to the reddened portion of the skin, but is often found beyond this in the latent state, even at the distance of thirty-five to forty centimetres, as the author has been able to undoubtedly prove in erysipelas of the extremities. It is not always easy to decide whether the infection be limited to the reddened skin alone, as is especially the case when the disease is met with at its beginning, or is beyond the boundaries of the inflamed spot. In general one may suspect that the infection has overleaped the apparent limits, if from the first there be symptoms of any gravity, as high fever, headache, burning thirst, and vomiting. Besides these phenomena in such cases the apparently normal skin will be found on a pressure to be painful, which pain will be more striking if pressure be made upon the inflamed focus. In other cases isolated inflamed spots, of the size of a franc piece, will be discovered scattered here and there on the surface of the normal skin; these are also sensitive to pressure and already foci of infection. As one withdraws from the central infected and inflamed spot the cutaneous painfulness on pressure decreases gradually until where it ceases one may assume that healthy skin is reached. Hence, if one would stay the progress of the disease these outrunning points of infection must be sterilized. Therefore this method of abortive treatment consists in carefully recognizing latent infection in order to combat it as quickly as possible. Any suitable antiseptic may be used. The writer employed solutions of carbolic acid and alcohol, carbolic acid and glycerin in equal parts and finally, in those cases where this remedy is not well borne, he recommends the following:

℞ Hydrarg. chlor. corrosiv., ... 0.03 grams.
Glycerin . . . . . 30.00 "
For external use.

All these three solutions are to be applied locally by means of a small brush. This same treatment is also useful in lymphangeitis.

QUININE ALBUMINATE.

A preparation described as being a homogeneous compound of egg albumen with quinine, possessing the remarkable property of not being decomposed by the strongest alkalies, has recently been introduced by M. Tarozyi (*Union Pharm.* May, p. 196). It is claimed that the preparation is easily absorbable by the mucous membrane of the stomach and passes into the circulation, where it exercises its therapeutic properties without undergoing decomposition, under conditions in which the ordinary salts of quinine are broken up by the alkaline liquids of the system. This "albuminate of quinine" is stated to be prepared by double decomposition between sulphate of quinine and albuminate of soda, but the manner of operating is not indicated. The product is a white amorphous bitter substance, said to contain fifty-six per cent. of quinine; it is alkaline in reaction, dissolves more readily in hot water or alcohol than in cold, and more freely still in water acidulated with lactic or hydrochloric acid. It may be distinguished from other salts of quinine by treating it with water, acidulated with sulphuric acid, which forms with the quinine soluble acid sulphate, the albumen being precipitated after standing.—*Pharmaceutical Journal and Transactions.*

CARBOLIC-ACID SPRAY IN LYMPHANGEITIS.

"Dr. E. Schwartz reports two cases of very severe lymphangeitis with diffuse cellutis of the lower limbs, which he treated successfully by Verneuil's method of keeping the parts under prolonged and frequently repeated applications of carbolic spray. The following is the mode of procedure: The limb is placed on some impermeable material in

such a manner that the spray can run easily off the part; the rest of the body and the bed are protected with mackintosh. One or two spray producers, filled with a watery solution of carbolic acid from 1 to 40 to 1 to 80, are then placed at a distance of about a yard from the part to be acted on, and allowed to play on it for an hour or an hour and a half, two or three times a day. Signs of carbolic poisoning must be carefully looked for, and in any case the strength of the solution and the length and frequency of the applications must be diminished as the inflammation subsides. This treatment should be combined with free incision and with wet antiseptic dressings. The patient's strength must, of course, be supported by the proper constitutional treatment. Used in this way, M. Schwartz says the method has an excellent effect, rapidly checking and modifying serious septic processes. He compares the action of the spray to that of a prolonged antiseptic bath, and he thinks it indicated in all cases in which continued local immersion is impracticable."—*British and Colonial Druggist.*

DIURETIN AS A DIURETIC.

Dr. Robt. H. Babcock, in a paper in the *N. Y. Med. Jour.* reaches the following conclusions:

1. Diuretin (Knoll) is a diuretic of great power and promptitude, suitable to all forms of dropsy.
2. Not increasing arterial tension, it is likely to succeed where digitalis, caffeine, and their congeners fail.
3. In cases of cardiac dropsy, with great feebleness of the pulse and arrhythmia, it will strengthen and regulate, rather than depress, the heart's action.
4. It appears to cause no irritation of the stomach or kidneys.
5. It requires to be given to the extent of from ninety to one hundred and twenty grains daily, and preferably in small doses frequently repeated.
6. It is best administered either in solution in warm water or in gelatin-coated pills, since, if exposed to the air in powders, it undergoes change, with a precipitation of much of the insoluble theobromine.

FUMES OF THE BROMOHYDRATE OF AMMONIUM IN ASTHMA.

Being familiar with the favorable action of the fumes of ammonium chloride in some forms of bronchitis and naso-pharyngeal catarrh, the idea suggested itself to Dr. Maxwell to test the fumes of the bromide of ammonium in asthma (*Journal de Médecine de Paris*, May 31, 1891).

To obtain these fumes he employed bromohydric acid of a specific gravity of 1.7, and it is stated that but few inhalations are required to cause the immediate disappearance of the dyspnœa, while sometimes, he writes, by causing the inhalations to be used at the time a dyspnœic attack is threatened the asthmatic seizure has been entirely prevented. In order that the fumes should have a neutral reaction they should be passed through a wash-bottle.

PARALDEHYDE IN TETANUS.

Dr. V. E. Ignatieff (*Gazzetta Medica di Roma*) proceeding from the experience of Russmant, Nopoff and Cervello, according to whom paraldehyde acts upon the nerve centres as well as upon the peripheric nerves, the writer prescribed it in two cases of tetanus (a boy of fourteen years and a woman of twenty-nine). Chloral had already been given in large doses without result. Paraldehyde was administered by the mouth and rectum, in daily doses of 3.75 to 9.40 grammes in the former (95.68 grammes in nineteen days), and 15 grammes in the latter case (450 grammes in thirty days). Both patients recovered completely. No disagreeable secondary action of the drug was observed, which occur so frequently after the administration of chloral in large doses. Dr. Tchervinsky communicated a case of tetanus to the writer which was also successfully treated with paraldehyde. Therefore, the author warmly recommends this method of treatment. The drug not only causes the convulsions to disappear, but also at the same time diminishes the pain, quiets the patient, combats the insomnia and permits the patient to be fed, thus giving the organism the possibility of eliminating the virus produced by the pathogenic microörganism circulating in the blood.—*Jour. Nerv. Ment. Dis.*

ERUPTIONS DUE TO SALICYLATE MERCURY.

At a meeting of the Russian Syphilidological and Dermatological Society, Dr. Flitner of St. Petersburg communicated five cases, referring to syphilitic women in whom intragluteal injections of Salicylate of mercury (1½ grain ever fourth day) caused more or less intense cutaneous lesions. Drug eruptions of late having attracted consider-

able attention, the following condensed account may be of interest:—In one of the patients, aged 28, the first injection was rapidly followed by rigor and fever, with a bright confluent erythema over the flexor aspect of the upper limbs, and the whole circumference of the lower. On the next day the chest and epigastrium became involved, while over the whole affected surface there cropped out numberless vesicles, closely resembling miliaria crystallina. On the fourth day, the erythema assumed everywhere the shape of "almost regular geometrical figures," such as aces of diamonds (on the forearms), oblique crosses (on the chest), &c. On the fifth, there appeared erythematous patches on the face, abdomen, back and buttocks, while the older rash became livid, and here and there brownish, the vesicles at the same disappearing. On the eighth day, the eruption began to subside; on the twelfth, a furfuraceous desquamation set in, being especially pronounced on the limbs.

In another woman, aged 18, on the day following the first injection, the back, chest and abdomen were found studded with dark, dusky, and bluish-brown, circular and rhomboid spots, varying in size from a small pea to a large almond. A few days after the second injection, there supervened rigor and fever, headache and giddiness, accompanied by the eruption of rose and red lenticular papules over the upper and right lower extremities, most of the patches presenting on their summits two or three vesicles with a serous discharge. In the course of the subsequent eight days, fresh papules continued to come out (mainly on the right limbs), while the old ones gradually disappeared, leaving no trace. The primary pigmentary rash left some discoloration.

In a third patient, aged 26, on the day following the second injection, there was observed bright erythema (with minute vesicles) on the back, which was followed by the appearance of slightly itching, sharply circumscribed, particularly bright red patches on the limbs and buttocks. The rash disappeared on the fifteenth day.

In a fourth woman, 22 years old, on the following day after the first injection the whole body became covered with regular oval erythematous patches, the exanthem lasting only two or three days. No rash occurred after subsequent injections.

In the fifth patient, aged 20, the first injection was similarly followed by the development of erythematous patches, which, however, were limited to the lower half of the back, inner surface of the forearms, and face, the skin returning to normal condition in about six days.

In the course of discussion, Dr. Usass said that he had also seen several cases of erythema following mercurial injections. In one of his patients, the whole body turned red within six days, the integument showing areas of serous infiltration. In a fortnight a profuse desquamation ensued, the cuticle being shed in large sheets. The rash was accompanied by high fever (up to 40° C.) the patient's general state remaining rather grave for some time. Ultimately (in about four weeks), however, he made good recovery.

Dr. Stepanoff similarly adduced two cases of mercurial erythema, the rash lasting in one for two months, in the other a fortnight. In the former it disappeared spontaneously after discontinuing the treatment; in the latter it was cured by iodide of potassium.

Dr. Telistiakoff related a case of mercurial exanthum resembling erythema exudativum multiforme, and chiefly involving the forearms, chest, abdomen, and lower limbs. It re-appeared after each of the first three injections of the salicylate, lasting each time for about two and a half days. Subsequent injections did not produce any eruptions. —*Jour. Cut. Dis.*

MEDICINE.

CHRONIC INTERSTITIAL MYOCARDITIS.

After reviewing the history of this subject, MM. Bard and Philippe discuss (*Revue de Médecine*, May, 1891) its pathological anatomy, pathogeny, and etiology. Moderate hypertrophy of the heart is a constant phenomenon, with dilation of its cavities, particularly of the left ventricle. On section, the color varies according to the degeneration of the muscle. The thickness of the ventricular wall is not uniform; it is more especially thin at the apex. The interstitial change is visible to the naked eye in lines or *plaques*. The papillary muscles are particularly affected. Whenever cardiac hypertrophy is present with no valvular disease, myocarditis should be thought of. Microscopically, the patches of sclerosis are made up of bands of fibrous tissue, and the muscular elements are atrophied. If the process is rapid, cellular elements predominate. In the *plaques*, the vessels show a periarteritis; elsewhere there is no constant change found in them. The authors do not believe the disease to be of

vascular origin, for the inner coat of the vessel is healthy. In the other viscera the effects of chronic congestion are seen. Many confound this interstitial myocarditis with the sclerosis set up by vascular disease. In the senile heart like changes arise, due to progressive obliteration of the small arteries. As to atheroma affecting the large branches of the arteries of the heart, most often one of the chief trunks near its origin is involved, from which a true angina pectoris may result. Rarely a branch may be completely obliterated, giving rise to necrotic foci. This interstitial myocarditis is not due to hypertrophy the result of valvular disease, for the latter is seldom present. Nor is it the outcome of renal disease, for in purely primary forms of nephritis this diffuse interstitial myocarditis is never seen. Nor is it due to diseases of the lungs, for then the right side of the heart would be chiefly affected. It is really a primary myocarditis. The changes in the muscular fibres are degenerative, without any signs of inflammation, whereas those in the interstititial tissue are active. Thus the changes in the latter are primary. In the course of infective diseases inflammatory lesions are apt to take place in the interstitial tissue, and these may become chronic. Two sets of agents may set up this inflammatory sclerosis of the myocardium: (1) intoxications from alcohol, lead, gout, etc., and (2) infective diseases—enteric fever, diphtheria, pyæmia, eruptive fevers, syphilis, though here the pure interstitial myocarditis must be distinguished from the sclerosis due to syphilitic endarteritis and tubercle. Rheumatism, which may in any of its forms set up myocarditis, occupies as it were an intermediate position between these two classes of diseases.—*Brit. Med. Jour.*

EPILEPSY OCCASIONED BY AN IMPERFORATE HYMEN.

Dr. Somers reported in the *Lancet* an interesting case, re-capitulated in *La Revue des Sciences Medicales*. It occurred in a patient who had already suffered with epileptic attacks for three years. They had been preceded for a year by malaise, headache, anorexia, pain in the belly recurring each month. At first they occurred at intervals; afterward, toward the close they returned with increasing frequency. All the characteristics were those of ordinary epilepsy, and Somers, considering the age of the patient (twenty one years) and the absence of catamenia, at first thought it was a case of pregnancy in an epileptic, but an examination made by him detected an imperforate hymen. An incision of it permitted the escape of thick and sanious pus. Afterward the catamenia were re-established and her general condition was good. No recurrence of the attacks had taken place fourteen months thereafter.

ALBUMINURIA IN DIABETES.

The occurrence of albuminuria in diabetes has been known for a long time, but its frequency is a point authorities differ upon. Sir Alfred Garrod found it in about 10 per cent. of the cases; Von Duich in nearly 25 per cent.; Dr. R. Schmitz, of Neuenahr, in a recent paper puts it at a much higher figure. Of twelve hundred cases of diabetes in which the urine was examined as to the presence of albumen, in no fewer than 824 was it found in quantity varying from a trace to as much as 0.9 per cent. There is as much difference regarding its significance. The opinion was once current that the appearance of albumen in the urine gave to the prognosis a most grave aspect, and even now the view that the prolonged polyuria and continuous irritation of the kidneys may develop a parenchymatous nephritis is held to some extent. Frerichs doubted this, and was inclined to look upon the existence of complications such as tubercle, cardiac disease, and arterio-sclerosis as the cause. Both Frerichs and Senator regarded the occasional œdema of the ankles and face as an expression of the general exhaustion, not the result of nephritis; and the latter thought that the condition produced by diabetes re-acted upon the renal epithelium, which allowed the percolation of albumen. Schmitz does not regard albuminuria as of grave significance, provided there are no other signs of organic disease of the kidneys and no complications are present. Should nephritis be ascertained to exist, he thinks, it is most probably the result of some complication. He has seen patients live for many years who were known to have diabetes and albuminuria; one case going on for fourteen years and in good health still. Dropsy is rarely observed, and cases described as dying of uræmia are probably confounded with diabetic coma. Of 206 patients suffering from diabetes of more than two years' standing, only four had albumen absent ftom the urine. With regard to the origin of the albumen, Schmitz holds that the long continued ingestion of large quantities of albumen plays a very important part, and added to this may be vesical catarrh, which occurs readily from the decom-

position of saccharine urine.—*Berlin Klin. Wochenschr.*

THE ACTION OF ANTISEPTICS UPON THE PERITONEUM.

Delbet, Grandmaison, and Bresset (*Annales de Gynecologie et d' Obstetrique*, 1891) as a result of their united experiments and observations, arrive at the following conclusions:

1. The strong antiseptics, such as carbolic and salicylic acids, corrosive sublimate and biniodide of mercury, present more disadvantages than advantages, since they irritate a healthy peritoneum and thus favor the formations of adhesions.

2. The most useful solutions to be employed in laparotomy are one of sodium chloride (six or seven parts to one thousand), and of boric acid (three parts to one hundred).

3. Iodoform and salol exert but little action upon the peritoneum, and it is a question if they have any antiseptic effect.—*Amer. Jour. Med. Sci.*

INFLUENCE OF SEX IN EAR DISEASE.

Dr. Loewenberg, of the city of Paris, discusses the influence of sex in what he calls the "laterilization" of ear disease. After referring to the view generally held by otologists that the left ear is more liable to be attacked alone, or to be attacked first and to suffer more severely when both ears are affected, he says that he has for a long time past been struck with the fact that, while deafness is more common on the left side in men, the same does not hold good in the case of women. From statistics of 3,000 cases (not including diseases of the concha and external meatus) which have come under his own notice, he shows, in the first place, that the male sex is more subject to ear disease than the female, there having been 1,790 of the former to 1,210 of the latter. Among those in whom only one ear was affected there were 478 men and 311 women. The right ear alone was affected in 212 men and 167 women; the left alone in 266 men and 144 women. Deafness existed in both ears in 1,074 men and 737 women. Among this number the right ear was the more deaf of the two in 427 men and 340 women, the left in 647 men and 397 women. Deafness was equal on both sides in 238 men and 162 women.—*Brit. Med. Jour.*

ACUTE ŒDEMA OF THE SKIN.

Barduzzi (*Giorn. Ital. delle mal. ven. e della pelle*, 1890, No. 3) considers that there is not sufficient reason to separate acute œdema of the skin from urticaria. Of three cases of acute œdema which he relates, the third was the subject, after an acute gastralgia, of diffuse papular urticaria. After the second gastralgic attack she had acute œdema of the face and hands. In the latter condition he recognized what he considered to be an atypic urticaria œdematosa.—*Brit. Med. Jour.*

REGENERATION OF HAIRS AFTER EXTRACTION.

Giovannini *Giorn. Ital. delle mal. ven. e della pelle*, 1891, No. 1, 1891) found that usually when a hair is extracted the external root sheath is not removed, and a considerable part even of the inner root sheath remains in the follicle. The formation of new hair begins about the forty-first and seventy-second day after depilation, and takes place from the epithelial cells, which had been retained in the follicle.—*Brit. Med. Journ.*

SENSORY AND VASO-MOTOR DISTURBANCES IN CASES OF RHEUMATIC FACIAL PARALYSIS.

In the K. K. Gesellschaft der Aerzte in Wien, on 19th April, Hr. v. Frankl-Hochwart gave an account of twenty cases of facial paralysis which he had had under his observation. In ten cases there were neither sensory nor vaso-motor disturbances; in two there were both; in five there were sensory; and in three there were vaso-motor. The altered sensibility was in many cases complained of by the patients themselves, and confirmed by examination, including testing of the appreciation of heat and cold. It was never great, and sometimes involved not only the skin, but also the buccal and lingual mucous membrane. The sense of taste was in a few cases likewise diminished. The vaso-motor disturbances gave rise not only to alterations in the color of the affected side of the face, but also to raising of the temperature of the part.

These disturbances usually manifested themselves with the paralysis, but disappeared after a week or two, the paralysis persisting longer; in one case, however, in which the paralysis was of several years' standing, the loss of sensibility continued.

In explanation of such cases it is assumed that the facial nerve contains vaso-motor and sensory fibres; and, in support of this theory, cases in which herpes accompanies facial paralysis are alluded to as implying

that the nerve is supplied with trophic fibres.—*Deut. Med. Zeitung*, 30th April, 1891.

THE RISE OF TEMPERATURE IN THE EPILEPTIC ATTACK.

In his wide experience of epilepsy at the Bicetre, M. Bourneville has spent much time in the study of its effects on the temperature, and has come to the conclusion that it always raises the temperature a little at the time of the attack. In the case of single isolated fits the rise was always clearly perceptible—on an average of about 1° F., and sometimes as much as 3° F.; in a series of ten or twenty fits it was on an average larger, about 1·5° F.; and in cases of *status epilepticus* there was frequently a temperature of 105° and sometimes 108°. M. Duflocq has recently published a few cases of "partial epilepsy of subcortical origin" (*Revue de Med.*, February, 1891), in which only a few observations showed any rise of temperature, which was claimed abnormal. These have led M. Bourneville to repeat some of his previous lengthy and careful observations. Selecting sixty-seven patients in whom there were single isolated epileptic attacks, he has taken the temperature in each: (*a*) during the stertor immediately succeeding the convulsions; (*b*) a quarter of an hour later; and (*c*) two hours later. There is a uniformity in his results which is remarkable. In none of the cases is the temperature at the time of the attack as low as normal, and in none is the temperature not lower two hours later. The average (*a*) in the period of stertor is 100·5°, (*b*) a quarter of an hour later is 100°, and (*c*) two hours later is 99·3°. In nine other cases the rise of temperature culminates at (*b*) 100·5° rather than at (*a*) 99·8, but sinks at (*c*) to 99·4°. In that second class of cases in which there are series of attacks with short periods of consciousness between each, M. Bourneville's old observations are found to repeat themselves in four new cases. The temperature after the series of attacks rose on an average to 102·1°, and then fell after eighteen hours to 100·3°. In the third class, consisting of four cases of *status epilepticus* which all ended fatally, the rise of temperature was not quite regular during the three or four days that the condition lasted, but rose in all cases over 105°, and in one case touched 108·4° just before death.—*Revue de Med.*

SURGERY.

EFFECT OF QUININE ON THE HEALING OF WOUNDS.

Dr. Sokoloff has recently published in the *Lancet* some interesting observations on the effect of quinine administered to a wounded animal on the granulation and cicatrization of the wound. The experiments were conducted on rabbits. The fur was shaved from a portion of the paw, and an incision made through the skin and into the muscular tissue, the external wound being then sewn up and the whole dressed antiseptically. Subsequently microscopical observations were made on sections including the wound. Twenty-four rabbits which were experimented on in this way were treated with hydrochlorate of quinine, half a grain of which was given per diem for each kilogramme of body weight. A similar number of control rabbits were operated upon in precisely the same manner, but were not given quinine. The author gives a detailed description of the microscopical appearances observed each day for eight days in the two sets of cases. The effusion of blood was much the same in both, but there was a marked difference in the condition of the muscular tissue. In the control animals this lost its striped character, the portions in the immediate vicinity of the wound presenting the appearance of an amorphous homogeneous substance containing here and there a few muscular fibres or breaking up into separate pieces as in coagulation necrosis. Besides this, the muscular tissue gradually disappeared, leaving sheaths of sarcolemma either empty or filled with cells. In contrast to this state of things sections taken from the animals treated with quinine presented little or no sign of muscular degeneration, the fibres preserving their proper structure. With regard to the cellular elements in the control animals, two forms were found in the neighborhood of the wound—a large number of multinuclear leucocytes, and a much smaller number of large round or oval cells with a single large nucleus. During this period the nuclei presented various karyokinetic figures. In animals treated with quinine there was no multinuclear cells, all being oval, with a single nucleus and smaller than the corresponding cells in the control animals. The cells were, moreover, more numerous than in the control observations. In the quinine-treated animals the karyokinetic process commenced and finished

earlier than in the others, the chromatin filaments being also less numerous but thicker. Altogether there was less inflammation with quinine than without; in short, without quinine there was Zenker's degeneration, with quinine, none.

TREATMENT OF ORCHITIS BY REFRIGERATION.

In his inaugural thesis Dr. De la Valle reports the results of the treatment of orchitis employed in the service of Dr. Du Castel (*Journal de Médecine*, April 10, 1891). This process consists in painting the scrotum with a camel's-hair pencil dipped in the chloride of methyl, the operation to be repeated twice daily. It is stated that immediate and considerable relief ordinarily follows the very first application, even in cases where the inflammation is violent, and where the patients hitherto have been confined to the bed. The average duration of the treatment was seven and a half days; the average time the patients remained in the Hospital eleven and a half days. This treatment is extremely simple, and does not necessitate the employment of any other medical treatment whether internally or by external application.

A HUNDRED CASES OF ENTIRE EXCISION OF THE TONGUE.

A valuable paper by Whitehead on excision of the tongue appears in the *British Medical Journal* for May 2, 1891.

In the last twenty years the writer has operated for cancer of the tongue in 139 cases. Of these 104 were complete excisions, and 25 were partial operations, the mortality in the former being 19.21 per cent., while in the total number of cases it was 14.3 per cent. When the tongue alone was excised the death-rate was 4.5 per cent., and when glands and jaw were also removed it was 77 and 57 per cent. respectively.

He has not selected his cases, and has never allowed the extent of the disease or the emaciated condition of the patient to deter him from operation when there was any prospect of either prolonging life, or of affording even but temporary relief.

The essential details of Whitehead's operation are: 1. That complete anæsthesia during the first stage of the operation, but afterward only partial insensibility, is to be maintained. 2. The mouth must be securely gagged, and kept fully open. 3. The head should be supported in such a position as will afford the best light, and at the same time favor the gravitation of blood out of the mouth rather than into the pharynx. 4. A firm ligature must be passed through the tip of the tongue for the purpose of traction. 5. The division of the reflection of mucous membrane between the tongue and jaw and the anterior pillars of the fauces. 6. Rapid separation of the anterior portion of the tongue from the floor of the mouth. 7. Securing, if possible, the lingual arteries prior to division. 8. Passing a ligature through the glosso-epiglottidean fold, before finally separating the tongue. 9. The application of a mercurial solution to the floor of the mouth, followed by painting the surface with an iodoform styptic varnish. The cutting part of the operation is done entirely with scissors.

The writer does not advocate preliminary tracheotomy, and believes that it is possible to guard against the entrance of blood into the lungs by means involving much less risk than either tracheotomy or laryngotomy. He thinks it important that the patients should be made to sit up from the first and not kept in bed. The average time of convalescence he has found, under these circumstances, to be seven days.

In regard to the predisposing and exciting causes of the disease, it was found that in 104 cases a family history of cancer could be definitely traced in but six, and in seven others it was doubtful. In sixteen instances the disease was attributed to injury; 61 of the patients were smokers, and in the majority of these the disease began on the side on which the pipe was habitually held. Irritation from teeth was the exciting cause in 33. One patient had never smoked, and had not possessed a tooth for twenty years.

As to the duration of life after the operation, information was obtained in 61 cases. Fifteen lived for one year; four two years; two three years; four five years; one six years, and one patient survived the operation for fourteen years, although 62 years old at the time it was performed.

In conclusion, Whitehead lays great stress on the importance of the removal of the disease at the earliest possible moment after its discovery.—*Univ. Med. Mag.*

SHOCK.

Dr. Hunts, in the *Med. Record*, says: In the treatment of shock we must keep constantly before us the condition of the pulse, respiration, and temperature, and our efforts to be directed toward their improvement. Warmth,

in the form of a hot bath, or of hot plates, bottles, irons, etc., applied to the chest, abdomen, and extremities, is of prime importance. Even when life seems to be extinct, as in the case of a boy whom I had trephined for a crushed skull, reaction may sometimes be brought about by wrapping the patient from head to foot in a flannel blanket wrung out of water as hot as the hands can tolerate.

Stimulants are indicated from the start and should be persisted in until reaction has begun, when they must be diminished or administered in conjunction with nourishment either by the stomach, or when this will not retain it, by the rectum. I believe that the danger of over-stimulation is genuine, not on account of any fever which may ensue, but rather lest the enfeebled heart may succumb to the excessive demand made upon it. Of all the stimulants recommeded the greatest hope is to be placed in brandy or whisky, then digitalis, and then strychnine, all to be given hypodermically or by the rectum. Brandy and whisky can be given in syringeful doses repeated very frequently, digitalis in ten-minim doses of the tincture or one-sixtieth grain of the alkaloid and strychnine in one-thirtieth or one-fifteenth grain doses, though not repeated so often.

Verneuil recommends injections of ether at times an excellent stimulant. Carbonate of ammonia is valuable and may be given subcutaneously. Morphia and atropia are of great value when restlessness of delirium is present and should never be withheld in such cases.

Artificial respiration will often prolong and sometimes restore life and should be resorted to in suitable cases. Bleeding from the external jugular has been recommeded, where that vessel is found distended with blood, with the hope of relieving the engorgment of the heart and thus stimulating it to action, but it must be remembered that the paralysis of the heart is not due to its engorgement, but that this condition is rather dependent upon the paralysis, making the operation one of doubtful expediency.

Transfusion may, possibly, be of service when there has been loss of blood, in which case a weak saline solution will be quite as efficient as blood itself.

But little can be done to relieve the excessive irritability of the stomach, except to withhold absolutely everything from it. The patient's lips may be moistened, but nothing must be swallowed, and the extreme thirst may be slightly relieved by rectal injections of milk or water. A mustard plaster applied over the stomach sometimes seems to give relief.

ON THE PRESENCE IN URINE OF A SUBSTANCE RESEMBLING SUGAR IN ITS REACTION.

Dr. Cleghorn says that during the last two years he has come across three cases in which for a short time the urine contained a substance which reduced cupric sulphate, and produced the usual re-action of sugar with liq. potassæ and picric acid. The specific gravity of the urine in these three cases varied from 1024 to 1030; in each case the breath had the peculiar odor which can be noticed when patients are taking medicine flavored with chloroform. In the first case the patient was suffering from exophthalmic goitre, aged about 27, and earned her living as a printer in a newspaper office. In her case the substance was present in the urine for a fortnight. She had been suffering from exophthalmic goitre for four months, gradually going from bad to worse. At that time she was very ill, and almost confined to bed. Soon after she began to improve, and six months later was able to resume work. He does not think treatment influenced the progress of the disease in her case. The other two cases occurred in little boys aged 3 and 5 respectively, and in both the symptoms were very much alike. They were both suffering from what seemed rather severe attacks of gastric disturbance, and in both the substance was only found in the urine for three days. They were more than usually prostrated after the attacks passed off, but in a fortnight had returned to their usual standard of health. Some cases of this nature were reported in the *British Medical Journal*, vol. i., p. 169 (1890), by Dr. Ashdown, who says this substance can only be distinguished from sugar by the fermentation test. He proposed to call the substance glycuronic acid. As Dr. Cleghorn has come across these three cases in so short a time as two years, the condition must be far from rare, and its recognition may make the prognosis more guarded in cases of supposed glycosuria with urine of a comparatively low specific gravity.—*New Zealand Med. Journ.*

GYNÆCOLOGY.

THE TREATMENT OF AMENORRHŒA BY SWEDISH MOVEMENTS.

Thure Brandt treats this affection by

Swedish movements, without massage or any local treatment whatsoever, the exercises being of the kind called "congestive" to the pelvic organs. Of these there are two varieties, the one consisting of movements performed by the patient alone, the other requiring an assistant. There are ten of the first variety, which are to be practiced once a day in regular order, a rest of five minutes being taken between each movement. The exercises are as follows:

1. Elevation of the arms, and deep respiration in a walking position. To be done five or six times.
2. Rotary movements of the feet in a semi-prone position.
3. Lateral flexion of the trunk, in standing position, feet far apart, arms uplifted.
4. Bending and unbending of the knee in a standing position.
5. Flexion of the body forward and back, standing position, feet apart, arms lifted.
6. Circular movement of thigh in an upright position.
7. Running movement without leaving the spot, knees lifted high.
8. Circular motion of the trunk in upright position, feet apart.
9. Abrupt backward motion of the trunk in a kneeling position, the knees apart.
10. No. 7 done very slowly.

The movements requiring an assistant are divided into the feebly and the strongly congestive. There are nine of the first class, consisting of motions of head and arms, flexion of leg and foot against the resistance of the assistant, percussion of back, circulatory motions of trunk, torsion of the body in the sitting and kneeling positions, elevation of the chest by the assistant, the patient lying down.

The strongly congestive movements include five of the first list in a little different order, and three new movements, viz., lateral movement of the uplifted arms by the assistant, the patient resisting, followed by action on the part of the patient, the assistant resisting; bending and straightening the knee in an upright position against the resistance of the assistant, and a circular movement of the thighs. The ideal treatment for amenorrhœa would be the execution of these movements, one after the other, without fatiguing the patient. As this is usually impossible, a judicious choice should be made, adapting the movements to the condition of the patient. Feeble and anæmic subjects should perform the easiest exercises only, and begin with a few at a time.

OBSERVATIONS ON THE CHANGES IN SIZE AND CONSISTENCE OF THE FEMALE PELVIC ORGANS.

Lindblom (*Ctrlbl. für Gyn.*, No. 3, 1891), who employs pelvic massage extensively, has observed almost constantly during the séances changes in the pelvic organs, especially in the uteri.

In the most marked cases the uterus at the beginning of the séance is small, lax, and soft; it then increases in size, grows harder, and assumes a spherical form. These changes are noticed principally in the body and supravaginal cervix. The author attributes them to changes in the blood-supply of the organs and compares them to erections. The woman, however, experiences no sensations from these changes. The author has also observed that the swollen uterus just before the menstrual period diminishes in size as soon as the blood begins to flow, and the uterus grows flaccid and soft, the decrease in size and flaccidity being in direct ratio to the abundance of the flow. The ovaries decrease in size also on the appearance of the menstrual discharge.

NOTE ON THE VALUE OF PEROXIDE OF HYDROGEN IN GYNÆCOLOGY.

The value of peroxide of hydrogen as a detergent and purifier has long been known, and when applied to dressing foul ulcers (syphilitic or otherwise) has given good results. Some time since, Dr. Alexander Duke, while treating a case of sepsis in which pus was freely discharging from abraded surface on vaginal wall, thought he would try the effect of peroxide. He had previously had the part twice daily syringed with weak solutions of carbolic acid, iodine, sanitas, and Condy's fluid without much effect. He found the solution of peroxide act as a charm in checking the secretion gradually, cleansing and healing the abraded surface, and producing no irritation; and he ventures to suggest it as a suitable application, more especially to the female genital tract. One teaspoonful added to half a pint of warm water gradually increased in strength will, he feels sure, be found a valuable addition to the many antiseptics used in such cases. He also suggests that in all cases where there are symptoms denoting septic absorption during the lying-in period a close examination of the vaginal walls and cervix uteri for tear or abrasion should be made, and, when discovered, the part thor-

oughly cleansed and cauterized with strong carbolic acid. He believes he can attribute the recovery of more than one patient, whom he had been called to see in consultation, to the adoption of this plan. But he much prefers the prevention of such accident by flushing the uterus with hot water directly after labor, examining at the same time for any tear or injury, and cauterizing or suturing the surface then and there.—*Lancet.*

CLOSURE OF CERVICO-VESICO-VAGINAL FISTULA FROM THE SIDE OF THE BLADDER.

Baumm (*Archiv. für Gynäkoligie*, Bd. xxxix. Heft 3) reports an interesting case in which he followed Trendelenburg's suggestion to close complicated fistulæ by exposing and incising the bladder, as in epicystotomy, and suturing the edges of the fistula from within. The patient had had extensive sloughing after a tedious labor, as a result of which there was a large cervico-vesical fistula with extensive cicatrization involving the entire vaginal fornix, so that it was impossible to expect a successful result from a plastic operation. The patient was placed in Trendelenburg's posture. A median incision was made just above the symphysis, the pre-vesical space was exposed, and the bladder was opened by a transverse incision two inches and a half in extent, through which the interior of the viscus could be thoroughly inspected. The mouths of the ureters were surrounded by the cicatricial tissue at the edge of the fistula, but were located by passing a probe into them. The borders of the fistula were denuded, an assistant aiding by making pressure upon them *per vaginam*. Eight silk sutures (having a needle on each end) were passed down into the vagina, where they were drawn through by the left hand of the operator, and subsequently tied with the aid of a Simon's speculum. The upper wound in the bladder was closed with a double row of sutures, muscular and sero-serous, a T-shaped drainage-tube being inserted. After tamponing the pre-vesical space with iodoform gauze, the abdominal wound was closed. The patient had a tedious convalescence, and six weeks after the operation there remained a large fistula at the site of the abdominal wound which never closed. It was necessary to perform a slight secondary operation in order to completely close a small cervico-vesical fistula.—*Amer. Jour. Med. Sci.*

OBSTETRICS.

A CASE OF INTRA-UTERINE FRACTURE OF BOTH THIGHS—TREATMENT.

Dr. P. J. Farnsworth, reports in the *Annals of Gynæcology and Pædiatrics* an interesting case of this character: Mrs. S., aged 25 years, in fair health and of good constitution, was taken with her first labor August 19, at 4 A. M. Dr. G. A. Smith was called. Labor progressed favorably until 7 A. M., when dilatation had taken place sufficiently for examination. At first he was unable to make out the presentation, but a severe pain coming on the membrane ruptured, and he found it was the breech. Soon, in the midst of a strong pain, a distinct crackling sound was heard, like the breaking of a large twig, and in a few seconds it was repeated. The noise was easily heard by all in the room. Mrs. S. was very much frightened, became faint, and all pain ceased. I was then called in; an hour had elapsed and no symptoms of pain. Made an examination and found the breech engaged with the sacrum to the left acetabulum. After administering some stimulants and assuring the patient that everything was all right, the pains returned and proceeded regularly but slowly. Soon the body was born, and with a little delay the head was extracted. There was only a flutter of the heart and no respiration. Chloroform had been administered pretty freely during the last stages. The cord was tied and means used to resuscitate the child, which after some time was accomplished.

The child was a female of fair size, but thin and wrinkled as if it had been plump and then had fallen away. It weighed nearly seven pounds. On examination we found both thighs fractured, the right one in two places near the lower third, the left one above the upper third. The child was washed and laid on a pillow until afternoon, when we found her breathing well and making an attempt to nurse. We cut three pieces of paste-board from a paper-box cover; two as long as the legs from the foot to the perinæum; the third a little wider, reaching well up to the body. Wrapping the extended legs in several folds of cotton we put the roller bandage around them pretty firmly, carrying it around the abdomen so as to catch the upper ends of the outside splints. The dressing was found very loose after two days and was removed. We now found that the muscles resisted extension with no little force, which was overcome by ele-

vating the legs at a right angle with the body. Again applying the folds of cotton, we put on a plaster-of-Paris bandage, covering the legs with several thicknesses and placing them against a cushion to keep them up.

The mother had a full supply of milk, and the babe grew rapidly, apparently paying little attention to its unusual condition, being less fretful than many other children of that age generally are. On the 26th we found the feet showing some signs of constriction and removed the dressing. The shrunken, flabby look had given place to a full plump appearance, the bones were united, with very decided callus. We brought the limbs down carefully, made extension and then reapplied the plaster bandages, putting them again in the upright position, soles toward the ceiling. At the end of three days there was some irritation around the top of the dressing and the circulation a little languid in the feet. The bandages were taken off, the union was firm, with large callus. There was still muscular resistance to extension. We procured a thin board as long as the child, cut it into a fork at the lower part, padded it well and laid the child on it, drawing down the legs and bandaging them to it from toes to hips, and a wide band around the abdomen and stomach. It resembled an Indian papoose in full dress. This was done partly to get full and equal extension of the limbs, and partly for the convenience of the mother, whose circumstances rendered it necessary to make a journey of fifty or sixty miles on the river. The mother and nurse are willing to testify as to the ease and safety of this aboriginal means of dressing a baby when a journey is required.

On their return on the twelfth day we removed the last dressing, and found firm union with considerable lateral curvature. We next applied a firm felt splint, curved partly round the legs, but not covering them. These we fastened on with a roller bandage with considerable force, removing them each day and applying compresses of cotton where we wished to remedy a crook. On the eighteenth or twentieth day we removed all the dressings and allowed the nurse to put on "baby's long clothes." To all appearance the limbs were of a length and without deformity, except the rings of callus at the points of injury. Motion in all the joints perfect and of fair proportions. At this writing, five months from birth, no signs of injury can be detected,—a plump, well-formed baby as can be found anywhere.

I have given this case with more detail, inasmuch as we could find no mention of any treatment for such a case, and only mention that intra-uterine fracture did sometimes take place. We notice how quickly infantile lesions are repaired, also how easily deformities may be corrected, and observe in passing that many bow-legged people may have been made so by thick diapers and faulty dressing during the first weeks of life.

A NEW METHOD OF INDUCING PREMATURE LABOR.

Dr. Schrader, of Hamburg, has published a new method of inducing premature labor based on his observations that cold is a greater excitant of the nervous, and consequently also of the muscular system than warmth. Continuous irrigation at the temperature of 45° Fahrenheit is impracticable on account of the pain it causes, but a cold douche alternating with a warm one can be borne. Dr. Schrader connects a vaginal glass tube by means of a T-shaped piece and the necessary india-rubber tubes to two irrigators, one of which contains the cold and the other the warm water. By allowing now one instrument and now the other to work, cold or warm water may be sent through the vaginal tube into the vagina. Two people are required—the one to fill the irrigators, the other to work the douche. For each sitting about twenty-four litres of cold and half the quantity of warm water at 112° Fahrenheit are required, and the douche has a fall of about one metre and a half. The irrigation begins with the warm current, and before the cold water is turned on pressure is made on the perineum with the vaginal tube, so as to allow all the warm water to run away from the vagina. The same plan is observed before the change from cold to warm, by which means the alteration in the temperature as felt by the patient is always sudden. Each time about two litres of cold and half the quantity of warm water are used. The douche is generally repeated about every hour and a half until labor is active enough to make its continuance probable. Of eighteen women treated by this method exclusively, and four others who were partly so treated, one died of eclampsia twelve hours after delivery, but all the others made a good recovery. The eighteen women who were treated by the douche exclusively had twenty children, of whom fifteen, that is, seventy-five per cent., were alive. These cases required on the average ten douches

and a half; in half the number three douches and a half were sufficient.—*Centralblatt fur Gynakologie—Medical Record.*

PÆDIATRICS.

TREATMENT OF WHOOPING-COUGH BY ATOMIZATION.

Dr. H. Ernest Schmid, of White Plains, N. Y., in the *Medical Record* of June 13, gives his experience as follows:

I rely entirely, no matter what stage of the disease, on spraying my patients with a solution of carbolic acid, menthol, cocaine, glycerine, and cherry-laurel water, generally in some such proportion:

℞

Acid carbolic	grs. vj.
Menthol, 4 per cent. solution	ʒ iv.
Cocaine, 3 per cent. solution	ʒ iij.
Glycerine	ʒ j.
Aquæ laurocerasi, ad	℥ ij.

This I direct to be used by the atomizer every three hours—but I mean a thorough use, a brutal one, if necessary. I have the child held forcibly by one or more persons, and disregard any apparent strangling of the little one during a vigorous atomization. The nozzle of the instrument must be directed as far into the mouth of the patient as possible. During the struggling and sputtering and strangling some deep respirations will ere long be made, and the object is accomplished. At first, of course, in most cases, violent paroxysms of coughing may result from the spraying, especially if much force has to be used with the child, but these soon cease and palpable effects are speedily noticed by the parents. The great point is to be able to impress them with the importance of perseverance.

I have seen the whoop arrested by this means after one thorough spraying, coughing without the whoop still going on for a while, and I have been gratified with inducing perfect recovery in one and in two weeks. A few cases in illustration might not be out of place.

A young lady, while on a visit in New York, was attacked by the cough. An excellent physician attended her, but the violence of her attack was terrible, and only excessive doses of anodynes gave her any rest at all. After two weeks she concluded to return home and arrived here perfectly stupefied, with her eyes starting out of their sockets from the dreadful straining accompanying the whoop. I stopped internal medication at once, put her on my spray, and in one week she was well.

I was called to see two children, one three years, the other not quite a year old, brought home by their mother from a visit to some distant place, and sick with whooping-cough. Both whooped badly. After the first spraying the baby ceased whooping altogether, and both were entirely well in two weeks.

A gentleman sent for me to consult me about his two-year-old boy who had the whooping-cough. The family had come from Europe a short time before on a visit merely, and were booked for their return to France two weeks later on. Mother and child had gone to North Carolina, to some relatives, and there the latter was taken with the cough. I expressed the belief that the little one might be cured in time for the sailing of the steamer if it were here. The father at once telegraphed the family to come. It was very hot weather. The little one almost perished on the trip, and I feared he would not live through the first night following his arrival, for bronchitis complicated the pertussis, and a highly febrile condition prevailed. However, he rallied very much by morning, and the spraying was then begun. The struggles of the determined little fellow were very great, but the treatment was carried out mercilessly. In consequence of this I ceased my attendance in eight days, and the family sailed for Europe on the day previously appointed, with a perfectly recovered child.

A short time ago I found in one of my families three children sick with pertussis. The two older ones, after considerable persuasion and coaxing, permitted the use of the spray, but the youngest refused it. The two elder ones recovered in two weeks, while the youngest is going through the slow, protracted course of internal treatment, the mother not being willing to use force.

From my repeatedly successful employment of this treatment, I feel justified in claiming that it promises to be one of the most efficient methods yet devised, provided it be used intelligently, thoroughly, and, if necessary, energetically.

HYGIENE.

RECEIPTS FOR SPECIAL FORMS OF DIET.

Boiled Flour or Flour Boil.—Take one quart of good flour; tie it up in a pudding-bag so tightly as to get a firm, solid mass; put it into a pot of boiling water early in the morning, and let it boil until bed-time. Then

take it out and let it dry. In the morning peel off from the surface and throw away the thin rind of dough, and with a nutmeg grater grate down the hard dry mass into a powder. Of this, from one to three teaspoonfuls may be used, by first rubbing it into a paste with a little milk, then adding to it about a pint of milk, and, finally, by bringing the whole to just the boiling point. It must be given through a nursing-bottle.

An excellent food for children who are costive in their bowels may be made by using bran-meal or unbolted flour instead of the white flour, preparing it as above directed.

Rice Water.—Wash four tablespoonfuls of rice; put it into two quarts of water, which boil down to one, and then add sugar and a little nutmeg. This makes a pleasant drink.

A half-pint or a pint of milk added to this just before taking it from the fire, and allowed to come to a boil, gives a nourishing food suitable for cases of diarrhœa.

Sago, tapioca, barley, and cracked-corn can be prepared in the same manner.

Beef Tea.—Take one pound of juicy, lean beef—say a piece off the shoulder or the round—and mince it up with a sharp knife on a board or a mincing-block. Then put it with its juice into an *earthen* vessel containing a pint of tepid water, and let it stand for two hours. Strain off the liquid through a clean cloth, squeezing well the meat, and add a little salt. Place the whole of the juice thus obtained over the fire, but remove it as soon as it has become browned. Never let it boil; otherwise most of the nutritious matter of the beef will be thrown down as a sediment. Prepared in this way the whole nourishment of the beef is retained in the tea, making a pleasant and palatable food. A little pepper or allspice may be added if preferred.

Mutton Tea.—May be prepared in the same way. It makes an agreeable change when the patient becomes tired of beef tea.

Raw Beef for Children.—Take half a pound of juicy beef, free from any fat; mince it up very finely; then rub it up in a smooth pulp either in a mortar or with an ordinary potato-masher. Spread a little out upon a plate and sprinkle over it some salt, or some sugar if the child prefers. Give it with a teaspoon or upon a buttered slice of stale bread. It makes an excellent food for children with dysentery.— *Annals of Hygiene.*

THE INFLUENCE OF DIET ON THE GROWTH OF HAIR.

Several cases of shedding of hair after influenza has confirmed the opinion of Dr. E. C. Mapother that diet has much to do with the production and with the cure of symptomatic alopecia. Hair contains 5 per cent. of sulphur, and its ash 20 per cent. of silicon and 10 per cent of iron and maganese. Solutions of beef, or rather, part of it, starchy mixtures, and even milk which constitute the diet of patients with influenza and other fevers, cannot supply these elements, and atrophy at the root and falling of hair results. The color and strength of hair in young mammals is not attained so long as milk is their sole food. As to drugs, iron has prompt influence. The foods which most abundantly contain the above-named elements are the various albuminoids and the oat, the ash of that grain yielding 22 per cent of silicon. With care these foods are admissible in the course of febrile diseases, when albumen is the constituent suffering most by the increased metabolism. Dr. Mapother has often found a dietary largely composed of oatmeal and brown bread greatly promote the growth of hair, especially when the baldness was preceded by constipation and sluggish capillary circulation.

Those races of men who consume most meat are the most hirsute. Again, it is well-known in the Zoological Gardens that carnivorous mammals, birds and serpents, keep their hair, feathers, or cuticle in bad condition unless fed with whole animals and the egesta contain the cuticular appendages of their prey in a digested or partly digested state. It is also an old well proven fact that a closely restricted diet, cheese for instance, soon produces in dogs a loss of hair.

In treating fevers a long course of non-nitrogenous diet may promote seborrhœa, which is so often a concomitant of the alopecia. When the special nutritive supply is secure, the depressed condition of the vasomotor and trophic nerves proceeding from the cervical ganglia to the scalp may be stimulated by blisters and liniments at the back of the neck. Dr. Mapother has always found that friction of the scalp with pomades and lotions dislodges many hairs which might otherwise remain, and that cold or tepid baths with salt added and rough rubbing of the rest of the body will flush the capillaries of the affected part more effectually. Besides, when pomades are used, frequent washing becomes necessary, and this is conducive to baldness.—*Brit. Med. Journ.*

MEDICAL CHEMISTRY.

TIMBOINE, A NEW AND INTENSELY POISONOUS ALKALOID.

Dr. Plaff reports from Brazil (*Pharmaceutische Post*) that he has succeeded in isolating from the crushed roots of a leguminous plant called *timbo* by the aborigines of Brazil, a new and exceedingly toxic alkaloid, to which he has given the name timboine. The Indians have long used a decoction of the timbo roots for the purpose of killing fish by poisoning the waters, just as *cocculus indicus* is used in other countries. A small amount of the decoction is said to suffice for a very large volume of water.

TONQUINOL.

Tonquinol, the new artificial musk, occurs as a snow-white crystalline powder with which needle-shaped crystals are interspersed. The odor appears to be due to the presence of a nitro-terpene and nitro-sulpho-xylol. It is soluble in alcohol, water, fats, oils, ether, and chloroform. The alcoholic solution (1 in 50), on considerable dilution with water, is very agreeable in odor, and the perfume is not precipitated. At present tonquinol is sold by the manufacturers at the rate of 1½ pence per grain.

NEWS AND MISCELLANY.

A PARISIAN DINNER.

ANOTHER PLACE THAT NEEDS A PURE FOOD "HEALTHERY."

According to *Le Cosmos* the following is the agreeable *menu* of a Parisian dinner:

As aperitive, a vermouth, which is rendered agreeable by the addition of sulphuric acid.

The diner then attacks his potage of tapioca—made of potato starch to which copper has been added.

His butter is made of calf's fat colored with lead.

His roast, of inferior quality, has been improved with saltpetre; he discovers a few truffles made of pressed clay.

The vinegar of the salad is seasoned with vitriol.

The peas—a little too green—taste of the copper which has given them their color.

Dessert: A chocolate cream; the chocolate is made of glucose, red oxide of mercury and red ochre.

For coffee he is given a mixture made of horse-liver roasted in the oven, black walnut sawdust, and caramel.

His small glass of kirschwasser, which terminates the dinner, contains as high as twenty two centigrammes of prussic acid to the litre.

After such a meal the Parisian has a terrible thirst; he wishes to drink beer, and he drinks it. It is a decoction of poppy-heads, elder, belladonna, datura stramonium, soda, tan-bark and picric acid!

MOTOR NERVES OF THE BLADDER.

Nawrocki (*Pfluger's Archiv*, xlviii, p. 335) has investigated the course of the motor nerves of the bladder of the cat. The animal was slightly curarised, and the effect on the bladder observed when the lower spinal nerves were stimulated. The bladder in this animal receives its motor nerves through two channels: (1) some motor fibres leave the spinal cord in the anterior roots of the fourth and fifth lumbar nerves, pass through the rami communicants into the lumbar part of the sympathetic chain, and then into the superior middle and inferior mesenteric nerves to the inferior mesenteric ganglion, and thence by the hypogastric nerves and hypogastric plexus into the vesical plexus; (2) other fibres pass along the second and third anterior sacral roots into the sacral nerves, and thence to the hypogastric plexus and vesical plexus.—*Brit. Med. Journ.*

A SPANISH FASTING WOMAN.

Dr. Vergara, of Villacienzo, in the province of Burgos, states that there is in that village a married woman, aged 48, who for the last seventeen years has taken no nourishment of any kind; in fact, we are asked to believe that nothing whatever has passed her lips except a small amount of water, which she takes every three or four days. During all that time she has not left her bed for a single moment; she lies there in a state of lethargy, which might be mistaken for death but for occasional slight movements of her body and a feeble moan which she utters when disturbed, as by light falling on her face. There seems to be no question of making the case a paying exhibition, as the husband resolutely shuts his door against mere sightseers.

Clinical Lecture.

CORTICAL MYELITIS.

BY WILLIAM PEPPER, M. D.,

PROVOST OF, AND PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN, THE UNIVERSITY OF PENNSYLVANIA.

Gentlemen: The history of the patient now before you is as follows, he is 21 years of age, a brakeman by occupation. Jan. 3d while on a coal train going down grade at twenty miles an hour, he jumped from a height of about four feet, striking on his feet with great force on a rail-road tie, but was not thrown down. At the time he did not seem to have received any injury and kept at his regular work until January 24th. In the evening of January 24th he began to have pain in the stomach and bowels and this was followed by an attack of diarrhœa lasting four days. Although this made him weak, he still kept at his work. The evening of January 29 he had an attack of headache and vomiting. The headache lasted for thirty-six hours. In the evening of Jan. 30th, that is four weeks ago he noticed weakness in both legs. The next morning the arms were also weak. The head was drawn back somewhat. The feet, hands and face were swollen and the feet pitted on pressure. At this time (Feb. 28th) the diarrhœa had stopped and he had been constipated for several days. He states that micturition was neither frequent nor difficult. The swollen condition of the face, hands and feet continued about one week and then passed away, but the loss of power in the arms and legs has continued until the present time. His voice also is somewhat hesitating but he says that this has always been the case. I was recently in Princeton in consultation with Dr. McDonald in regard to another case. He told me about this young man and we discussed the nature of the case. He afterwards wrote to me stating that the paralysis was increasing, I then advised that the patient be sent here as he could not be properly treated at his home. He arrived three days ago and I want to carefully examine him with you.

With the history that has been given us, it is difficult to avoid the notion that the violent shock which he received by jumping from the train had some effect in disposing to the symptoms that came afterward, yet it is curious that from January the 4th when the injury occurred to January 24, when the first marked symptoms appeared, the man should be able to continue at his work and as he states feel as well as usual. If there were a marked concussion of the spine produced at the time of the accident, there were no symptoms of it, we must at least admit that this established predisposition to the spinal trouble. From the fact that he worked three weeks after the accident it seems doubtful that there was actual disease started at that time. The fact that as soon as he was attacked with diarrhœa, weakness quickly developed in the arms and legs and has progressed until it has reached a high state of paralysis, shows that the spinal cord must have been in a morbid state at that time, and that being in this condition some subsequent exposure or some fatigue was sufficient to bring on the spinal disease from which he is suffering. If we say that the railroad injury was not the direct cause of the trouble, I should consider it contributory to it, in an important degree.

The present condition of the man is as follows: He can rotate the head from side to side but there is stiffness of the muscles at the back of the neck. At first there was retraction of the head with tenderness of the muscles. As you have heard there was at first weakness in the legs to which was added in a day or two weakness of the arms. There was headache and vomiting in the

beginning, but not much fever. He then had a curious condition which is described by him as a general œdema of the entire body. I did not see this and I do not know that his attending physician saw it, but the patient describes it as a general swelling of the face, arm and legs with pitting on pressure. There was evidently real œdema.

The retraction of the head is lessened but the muscles are not soft. He can rotate the head. By means of the shoulder muscles he is able to communicate a movement to the arms. He, however, is unable to flex or extend the fingers and can not move the arm. The right arm and the left leg are the most markedly affected. There is almost complete paralysis of both legs. In other words, the man is paralyzed from his shoulders down. There is no paralysis of the muscles of the face, and no affection of the special senses. The brain is not involved and the paralysis is evidently due to disease of the spinal cord not extending above the upper dorsal or lower cervical region. It seems to have been an ascending lesion. The legs first became affected and then the arms, but the arms were involved so soon after the legs that we may say that the cord was affected simultaneously in almost its entire length.

Now in regard to the lesion in this case. A hæmorrhage high up in the cord above the origin of the spinal acessory nerve would cause paralysis of the arms and legs. This would cause a sudden paralysis, but here the paralysis occurred gradually, first appearing in the legs. A rapidly spreading myelitis, that is, an acute inflammation of the substance of the cord might produce symptoms of this kind. What portion of the cord would need to be involved to produce the symptoms that we have here? In order to determine this we should have to study the sensation and the condition of the bladder and bowels as well as the state of the reflexes. We learn that he passes water naturally four or five times in the twenty-four hours, and that he has had no trouble with the bowels. There is, therefore, no paralysis of the bladder or rectum, and this has an important bearing on the case. Sensation has been tested and found good everywhere. He feels pin pricks and light touches, and can measure the distance between points close together. His power of localization is also perfect. The reflexes on the other hand are absent. Tickling the soles of the feet causes no response, and the patellar reflex is wanting.

Taking the history of the case with the symptoms present, it is clear that we have to deal with a primary spinal trouble; that this spinal trouble involves a considerable extent of the cord, that it is not a destructive lesion occurring high up. If it had been such a lesion, the symptoms would have developed suddenly and would have affected the arms at the same time as the legs, but the history indicates that the lesion began below and extended upwards. We have here a choice between two lesions, one is spinal meningitis extending along the cord producing exudation and causing pressure, and the other a lesion of a part of the antero-lateral column, a deep congestion or a myelitis extending up in the line of the afferent fibres that compose the antero-lateral columns. I have no doubt that at the beginning of the case there was some meningitis. The retraction of the head is extremely significant, but it appears quite clear to me that the case can not be regarded altogether as one of meningitis. In spinal meningitis, the paralysis does not become complete as rapidly as it did here. Usually, at most, it is partial, a paresis, not a complete paralysis. In the second place, in meningitis, there is, as a rule, much more pain complained of than here. Pain radiates through the affected nerves, and the flesh is more or less tender, and there is a tendency to spasmodic twitching of the limbs and the reflex irritability, instead of being lost is often increased, at least in the earlier stages. I think therefore, that these considerations are sufficient to make us fear that this has not been a simple case of meningitis although in all probability as is often the case in acute affections of the cord, the membrane is more or less involved. Nor can we believe that a simple congestion would keep up such grave symptoms. As I have told you on other occasions, spinal congestion which is not rare, sometimes causes almost complete paralysis which lasts for four or five days or a week and then passes away. It does not deepen as this has done until it becomes almost absolute paralysis of all four extremities. We are therefore compelled to assume that there has been a myelitis—an inflammation of the substance of the cord.

What I believe has happened here is that the shock this man received produced some sensitiveness or weakness of the spinal cord and then as the result of some exposure there was an intense congestion of the spinal cord and also of the gastro-intestinal tract as shown by the vomiting and purging which continued for four days. These symptoms

are not connected with the spinal affection, but simply indicate the violence of the exposure. Note also that even after the occurrence of this attack he kept at his work, that of a brakeman of a freight train, for four days during this time he was still further exposed and in his weakened state he was more easily affected by such exposure. It is probable that what began as a simple gastro-intestinal catarrh was succeeded by a myelitis because the man continued to expose himself to these morbid influences and this inflammation being predisposed to by the fact that the spinal cord was in a state of unusual weakness as a result of the accident three weeks previously. Whether or not there was at the same time some renal congestion and the œdema of the face and hands was connected with some temporary albuminuria, I cannot say. We would not regard this œdema as a direct symptom of the spinal trouble. The myelitis which was established was not a transverse myelitis, that is an inflammation that stretches across the cord involving white and gray matter; when a cross-section of the cord is involved we have paralysis of the bladder. The nerves which supply the bladder appear to arise from the deeper portion of the cord. We may have a cortical myelitis or a myelitis of one fasciculus and the bladder escape as here. The same is true in regard to the rectum. Again, in transverse myelitis the sensation is involved. It affects the gray matter of the posterior columns and the patient complains of numbness, a sense of tingling, a girdle sensation around the waist, and anæsthesia is found. Such marked distubances of sensation indicate that the posterior columns are affected and if associated with paralysis of motion, that the inflammation has been transverse and the entire thickness of the cord is involved. In this case there has been no affection of the sensation and we may safely say that the posterior columns are not affected and that the deeper portions of the cord also have escaped.

Lastly, there has been no marked rise in the temperature of this case, nor have there been marked trophic changes. It often happens in acute transverse myelitis that there occur trophic changes, as gangrenous bed-sores appearing with great rapidity upon the back or buttocks, too rapidly to be attributed to the effect of pressure. I have seen bed-sores in myelitis begin on the third day in a person absolutely healthy up to the moment of the attack, showing that there was a loss of the trophic influence of those nervous cells in the anterior columns of the gray matter which we know exert so powerful a control over the nutrition of the parts. This patient has shown no disposition to bed-sores. The absence of loss of sensation, the absence of paralysis of the bladder or rectum, and the absence of a tendency to bed-sores, make it clear that the myelitis has not been a transverse myelitis involving all the tissues of the cord. The lesion therefore has been either a cortical myelitis which is sometimes met with, or a fascicular myelitis ascending in a single column. Taking into consideration that there was in the beginning evidences of meningitis, and the slight irregularity in the disposition of the paralysis more marked in one member than in another I am disposed to regard this as a cortical myelitis with leptomeningitis of the cord, that is a meningitis of the pia and arachnoid with inflammation of the periphery of the cord. It is either that or an inflammation of the ascending fibres in the antero-lateral column, excluding, I think, the direct cerebellar fasciculus lying on the outside of the antero-lateral column nearest the posterior horn of gray matter. The other fibres of the cord cross, partly high up below the medulla and partly as they go down the cord. The decussation is not complete high up. Although the majority of the fibres decussate at this point, some of the fibres go down the cord and decussate at different levels. This fact would serve to explain the difference in the degrees of paralysis in the different members. The fact that the right arm and the left leg are the most affected would indicate that the inflammation is more marked on the right side. I think, therefore, that the diagnosis lies between cortical myelitis with slight meningitis or myelitis involving the antero-lateral columns and affecting the right side more than the left.

This is of course a serious condition. Myelitis rarely terminates in complete recovery. The main danger is due to the fact that lesions of the spinal column tend to be propogated in the line of the normal action of the fibres. If this were a lesion of the posterior column beginning high up it would descend. As it is a lesion involving ascending fibres, its tendency is to ascend. There is danger that in these cases the lesion will continue to ascend until it involves the base of the brain. We have noted here a peculiarity of the speech which almost suggest that the glosso-pharyngeal nerve has been reached. The patient, however, states that his voice has not changed.

What is to be done? The case is now more than four weeks old. The nutrition is

fairly kept up. He can take food well. We shall continue to keep up the nutrition with a carefully selected diet. We shall give a mixed diet excluding indigestible, rich or heavy, sweet articles. Attention will be paid to the bowels. If they are not opened twice a week, a laxative enema will be given. I am disposed to put him on the use of iodide of potassium with ergot and belladonna. The only hesitation that I have in adopting this treatment is because I know that his physician has used these remedies from an early period. He has been judiciously treated, and that is one of the worst elements in the prognosis. I shall, however, give him for a while five grains of iodide potassium with twenty drops of fluid extract of ergot and ten drops of tincture of belladonna three times a day. There are no remedies which exert a better influence over the blood vessels of the cord than do ergot and belladonna. I give the iodide in the hope that it will favor the absorption of any exudate that may be present. In addition we shall have massage with passive motion of all the joints practised in order to prevent wasting and contractures. The time has now arrived when we may safely use Faradic electricity over the lines of the nerves of the arms and legs. We shall also employ counter-irritation to the spine.

Two weeks later this patient was again presented showing some improvement. He had gained some power over the larger muscles of the left arm and could move the legs better. There was no improvement in the right arm. The treatment was continued and cupping along the spine twice a week added.

COMMUNICATIONS.

BOWEL TROUBLES OF CHILDREN.*

BY I. L. VAN ZANDT, M. D.,
FT. WORTH, TEX.

It is not intended that this paper shall be exhaustive of the subject treated. I purpose giving only some of the results of my observations during the twenty-five years of my practice.

I will premise by saying that either this class of cases has become very much milder or I have become much more proficient in its treatment, for while in former years death was not uncommon, I cannot now recall such a result in one of these cases in the last six or eight years.

Observation has led me to divide the ordinary bowel troubles of children into three classes, according to the character of the discharges. Experience has taught me that each of these classes requires and is amenable to its own special, I might almost say specific, treatment. My division of these discharges is as follows:

1st. Those composed largely of blood and mucus.

2d. Those composed of a green or greenish material frequently associated with shreds of coagulated milk. This class will embrace also those cases in which the matter is passed yellow and becomes green afterwards. Green actions are generally almost odorless.

3d. Those with very offensive smelling actions, of various colors, shades and consistences.

Do not understand me to say that all cases will typically come under one of these heads, but I do say that a very large proportion, perhaps 90 per cent., will show a close approximation to one or a blending of the characteristics of the two, not often of more than two of them.

As to the cause for the first, the dysenteric, I can say nothing. It seems to affect both children living entirely at the breast and those fed wholly or in part by hand; the latter class being the greater sufferers. I will say, without having kept a record, that, as with adults, May is the month of greatest prevalence in central Texas.

From "West on Diseases of Children," I learned a long time ago to rely mainly on castor oil and laudanum when we have to deal with mucus, blood and tenesmus, the laudanum varied according to frequency of action. These are my staple but not my only remedies. I give most cases a prescription something like this:

℞

Ol. Ricini	℥j.
Tr. Opii	gtt. x.
Ol. Anisi	gr. ij.
Pulv. Acacia	q. s
Syr. Simplicis	ad. ℥j.

M. Sig. Teaspoonful every three or more hours. This for a child one year old.

To this I may add Ol. Terebinth if there is a tendency to the formation of gas; pepsin or papoid if undigested food is passing; bismuth if the actions are particularly offensive to the smell; hyposulphite of soda when the associated fœcal matter is green. In some cases which were stubborn and disposed to

* Paper read before the North Texas Medical Ass. at McKinney, Tex., June 16th, 1891.

become chronic, I have had marked improvement follow the use of bichloride of mercury in 1–240 grain doses, repeated every three or four hours, with the oil and laudanum mixture or with an opiate alone.

For many years I had felt the need of a satisfactory prescription for the green diarrhœa of children, when about two years ago I had occasion to prescribe hyposulphite of soda for a child having green discharges, not, however, having in view the correction of this particular feature, but the correction came, though unlooked for. Acting on this hint I worked out the following prescription, which has had a very happy effect in a large percentage of cases:

℞ Sodii hyposulph .....gr. xx.
Ess. pepsin (Fairchild's).....ʒ ij.
Tr. opii..... .....gtt. oo to xxx.
Syr. aurant, q. s. ad.....ʒ j.
M. Sig. Half teaspoonful every three hours, preferably after eating.

The opiate is varied according to ferquency of the actions. If these do not occur more than two or three times in twenty-four hours, none is given, its use being intended only to retard peritalsis to such an extent that the digestive juices may have time to act on the food.

This character of trouble I think occurs most frequently among children at the breast; frequently among those having no artificial food, resulting, probably, from some ill condition of the mother, causing a deterioration of her milk. One case I now recall, having come on soon after the babe was nursed by the mother overheated and fatigued by a long walk. This mother tells me that such a thing occurred several times.

I come now to my third and most numerous class, perhaps outnumbering both of the others together. The subjects of this we find almost exclusively among children wholly or in part fed by hand. The large majority will be found between the ages of ten months and two years. The pathognomonic symptom of this is the exceedingly offensive odor of the discharges, which are generally of a dirty brown, varying in consistence from that of mush to a dirty water which runs through the napkin, leaving only a stain; in frequency from two or three to a dozen or more in twenty-four hours.

In 1873 I got from J. Lewis Smith's book on "Diseases of Children" a prescription which after some experiment I made to read as follows:

℞ Pulv. opii.....gr. j
Hydrarg. chlor mitis,.....gr. ij.
Cretæ prep.....ʒj.
Bismuth subnit.....ʒj.
Sacchari alb.....ʒij.
Ol. anisi.....gtt. iv.
M. div. in part .....xii.
Sig. One every three or more hours.

In this as in other prescriptions the amount of opium varies with the frequency of the actions.

This prescription has served me so well that I almost think there is no better. On account of its bulk and inconvenience of administration I have often tried to find a substitute, but have generally been forced to fall back to the old and tried servant, just as most of us have probably done when we have been induced by the oversanguine praise of some enthusiast, to try a substitute for quinine in malarial fevers.

In all of these classes, rise of temperature must be combated on general principles.

Special attention should be paid to diet, studying the peculiarities of each case and adapting thereto its proper diet, for all cases do not require the same. I will mention only one article of artificial food. It is not patented. It has served me well both in my practice and at home, my last baby having been raised on it. It is oatmeal water one part, sweet milk two parts. The water is made by boiling oat meal in a surplus of water, setting aside till the meal has settled to the bottom, and then decanting the supernatant liquid. This should not be mixed till just before using, as the mixture does not keep well. The "water" should be prepared once or twice a day as may be necessary to keep it fresh.

It will perhaps be observed that I have said nothing about cutting gums. I have been in the habit of saying that the best preventative for "teething diarrhoea" is to teach the mothers that teething has nothing to do with it, so that they may look elsewhere for a cause. Get them to understand that improper feeding is responsible for nine-tenths, filthy surroundings for nine-tenths of the balance, leaving one case in a hundred for undefined causes, among which may be teething.

I repeat I do not expect every case to present a typical exemplification of one of my classes, but that nine out of ten will do so or show a blending of the characteristics of two of them.

It may be said that I am a routinist. So might a physician of a non-malarial country, when making his rounds with his friend the "swamp doctor," on seeing the uniformity with which he gave quinine, accuse him of routinism. His ready response would be, these these cases are all the same and need the same treatment. So I say the cases of each class are of a like character and require like treatment.

SOME OF THE RECENT ADDITIONS TO OUR MATERIA MEDICA AND THEIR THERAPEUTICS. *

BY ROBERT R. LAWRENCE, M. D.,

HARTFORD, MICH.

The great number of, so-called, new remedies which have been introduced during the last decade and a-half, is truly marvelous, and the therapeutists of to-day must have a thorough knowledge of these recent additions to our materia medica, combined with the power to discern the conditions whereby their application to the treatment of disease will assure the prescriber more definite and favorable results, than those with which we are more familiar, and which have proven to be of inestimable value in many emergencies.

It is quite impossible in the time allotted to the reading of a paper before this section, to give even a passing notice to all the new remedies possessing merit, and a full consideration of any one of them, which I shall name, would form an exhaustive article. A goodly number of these remedies have been properly classified in accordance with their medicinal action, and have been assigned their respective places beside those which have borne the test of years, while others have so far been noticed only in the journals and trade circulars, pending more thorough investigation. To make use of a social phrase, the "bringing out" of a new remedy is attended with many misgivings, and subjects the author to severe criticism by his professional brethren, both far and near. The vegetable kingdom has been very generous in contributing its productions for the benefit of the science of medicine, especially is this true for the period above referred to. Undoubtedly you are all familiar with the botanical history and medicinal properties of the drugs which I shall name, hence I will not weary you with a reviewal.

We are frequently disappointed in the action of medicines and diligently watch for relief that never comes.

Individually, we are verv prone to look at their effects differently, or in other words, convince ourselves that our experience with a given preparation, is directly opposite to that of Dr. B., who has called our attention to it in such glowing terms.

Belonging to the list, and which have gained great favor with the majority of practitioners I will enumerate a few of the most prominent and favorably known, to wit: cascara sagrada, yerba reuma, yerba santa, jamaica dogwood, eucalyptus, strophanthus, quebracho, cocaine; and a score of others whose properties are as well defined as these. We were taught that the fl. ext. of rhamnus purshiana, was the remedy *par excellence* to overcome constipation, regardless of the primary cause. At first, given indiscriminately, failure was the rule, then it was claimed by the discoverer, that it had a tonic effect on the muscular coat of the intestinal tract, stimulating peristalsis; that the active principle was similar in its effects on the human economy to strychnia, and that in order to obtain definite results it should be administered in small doses, and continued for a length of time, *i. e.* until the habit was overcome.

To administer a single dose sufficiently large to act as a cathartic would not best serve the object in view, in fact it would not be preferable to many of our more palatable laxatives.

The rule with this amendment has possibly been followed to the letter, and just so long as the patient perseveres in its use so long is he or she relieved and no longer.

How many of my colleagues present ever cured, or relieved permanently, a case of habitual constipation and traced that cure solely to the administration of cascara sagrada.

The mere habit of giving nature an opportunity at regular intervals, in connection with a proper diet, is in my judgment of more value than the exhibition of this highly extolled remedy. The well defined action of this drug as a cathartic, precludes any comments derogatory to this medicinal property.

Tyro prescribes it with the same amount of assurance, as to the results, as he would opium to allay pain, which is very proper, as the prescriber must necessarily have confidence in his prescription if he expects to inspire his patient with this same property so essential in combating disease.

Do not assume that I am opposed or a foe to this very worthy drug. I prescribe it frequently in the manner before stated, but when considered as a *specific*—pardon the term—for that which it has been so highly lauded, I must needs take exceptions, as my experience has been diametrically the opposite, and the conclusion is arrived at without prejudice.

Yebra reuma possesses properties well worthy our attention. As an alterative to inflamed mucous membranes of long stand-

* Read by title before the Michigan State Medical Society, June 12, 1891.

ing, topically applied, I consider it without a peer.

In ozœna with that most fœtid of all orders, I have found it very useful, and in chronic inflammation of the Schneiderian membranes it is even more effective, and a few patients have claimed that they have received permanent benefit in chronic nasal catarrh, by the insufflation of this preparation, properly diluted. I do not wish to be placed on record as claiming curative properties for this drug in chronic nasal catarrh, as I attribute the exciting cause largely due to climatic influences, over which medication has no control.

Yerba santa in laryngeal troubles, strophanthus as a cardiac stimulant, and tonic, Jamaica dogwood, and sulfonal, as sporifics, these we will pass by, with many others, and consider antipyrin, the most popular derivative of the coal oil series, a remedy that gained a world-wide reputation in the treatment of that protracted and serious epidemic, la grippe.

The discoverer, Dr. Knorr, prepares it synthetically from the constituents of coal tar, and places it at our disposal as an infalliable antipyretic, although devoid of anti periodic properties. From large doses collapse may occur, and 50 grs. given at one dose is said to have caused death in 32 hours.

This potent remedy has unquestionably been productive of great harm, during the prevalence of Russian influenza.

The intense cephalalgia, which is so prominent a symptom in this disease, was relieved very soon after the administration of a full dose of antipyrin, and this promptness in alleviating pain has proven a great incentive for its use in many paroxysmal troubles. It has formed the base of a large number of the prescriptions which have been compounded for the treatment of this malady. Given in maximum doses, and continued for an indefinite period, must now be considered a misuse of the remedy.

A patient already prostrated by the ravages of this grave disease, with the heart's action weakened to such an extent as to favor local congestions is literally fed on this mere depressant, thus adding fuel to the flame; still not having a thorough knowledge of its physicological action, we adhered to the routine practice,and persevered in its use, which in many instances, I fear, actually retarded the patient's convalescence.

I have in mind a case, the history of which will illustrate the point I wish to impress upon you. Dr. R——æt 37 years, a practitioner, had been intemperate for years, though capable at most times of attending to business, was attacked with the grippe and to relieve the excruciating pain in the head, was forced to take large, and repeated doses of this preparation, and at the same time, abstained from his accustomed stimulus. When I saw him he was an object of pity, and in a most deplorable condition mentally, bordering on imbecility, although articulation was very indistinct, and his muttering delirium, alternating with sopor, or mild coma, from which the patient when aroused, would again revert to this uncontrollable delirium, formed a chain of symptoms not duplicated in most of the neuroses. Then is it not plausible to assume, that the indiscriminate, and injudicious use of this drug by its depressing effect on the heart's action, induced stasis, deposits &c? Particularly of the brain, which being burdened by alcoholism, and thereby developed this condition of the nerve centre referred to, and which in all probability will result in a structural change of the brain tissue, and a consequent cerebral softening. After giving king alcohol due credit for his part in this case, there remains sufficient evidence to warrant us in believing, that the excessive use of this preparation, should be interdicted, as the above case narrated would justify us in arriving at the conclusion that there is danger of forming the habit of taking antipyrin, as well as opium, chloral hydrate, cocaine, &c. with an equally disastrous and sad ending. This is but one of several instances differing only in intensity.

I will call your attention to but one other remedy and that is resorcin. It has not sustained its reputation as an antipyretic, was formerly used as an alterative through its caustic properties in chronic skin diseases.

Prescribed internally almost solely in those conditions of the stomach, and bowels attended with an excessive formation of gas, as the result of a fermentative process.

It is a favorite remedy with the venerable Dr. N. S. Davis of Chicago in the class of cases referred to. It undoubtedly possesses virtues of this character, as do many others.

In considering the relative values of the newer and older remedies, what have we to offer in favor of the former? When are we guardians of the public health, justifiable in making this attempt at empiricism, when their supposed therapeutical actions are identical? Should we refrain from prescribing the newer remedies until the list of older ones are exhausted? . Administer them to the moribund patients expecting thereby to

reach the pinnacle of fame in the estimation of our patrons and generate the feeling of enviousness with our professional brethren by thwarting death? Such a course would be very unjust to say the least, and the unfairness of which would be preceptible to all.

What is the object in making the change? Having prescribed a medicine with which we are very familiar, and which has not disappointed us in the majority of instances, notice the confidence with which it is administered to a patient in a critical condition; how eagerly we watch that life intrusted to our care, believing in, and expecting to observe some characteristic effect, whereby our patient is to be benefited. Are they more reliable or specific in their action? No, but a goodly number of these new additions have their medicinal action defined by their manufacturers with a mercenery object in view. Consider for a moment the extensive collection of printed advertising matter, that finds its way upon your office desk in a very limited time, issued by unscrupulous manufacturers, and equally unscrupulous dealers. This does not apply to all, but to the list considered as a whole. Too much credit can not be given to the worthy, as they form an essential part of our profession, and without them we could not succeed. Proprietors of these fraudulent pharmaceutical preparations, are not wholly to blame for the exaggerated, and supposed merits of this class of medicines.

Charlatans take an active part in this drama. To illustrate; Drs. R. and B. had, or claimed to have, a typical case of that human pest, typhoid fever. Patient was pronounced by them to be in a critical condition, and the case a hopeless one. Owing to the supernatural power possessed by the junior member, he was informed by some *innate prompter* that there was, obtainable in Chicago, a new remedy, a specific for this fever. He visited the city, hurriedly procured this wonderful compound, returned to his patient, barely in time to save life.

Patient's convalescence dated from the giving of the first dose, and thus a life *was saved.* This proves the assertion, that many new preparations, standard, semi-secret and proprietary, afford a new device for the mountebank, or pretender, to control his patrons by claiming to have knowledge not attainable in the regular way.

We may ask the question; if the application of remedial measures to the treatment of disease is an exact science, why are we so frequently disappointed in the results obtained?

Why is it that Dr. B. has such unparalleled success in the treatment of laryngeal troubles, through the exhibition of yerba santa or Dr. J. with cascara sagrada affords his patient permanent relief from constipation.

To be more expressive, must we take it for granted, contrary to our experience, that such wonderful cures are performed by a few physicians, while the great majority of equally well qualified practitioners proclaim that their trials have proven the reverse, when given in similar doses and under identical circumstances. We are all more or less inclined to be routinists, to have favorite formulæ, and strive to have our cases conform to them, in lieu of vice versa.

In most instances the selection of a remedy, or the formation of a prescription, is not so difficult as the true naming of the disease. And he, who is the ablest diagnostician, is, *the most successful practitioner* irrespective of individual "hobbies" the important question is not what are you giving, but what are you giving it for?

To summarize.

The number of unreliable remedies is far too great. That it is impossible for the active practitioner, to devote sufficient time to their investigation as to render himself, or herself a competent judge as to their merits. That in consequence we are forced to accept the word of unfair dealers.

That unless they possess some properties not found in the older there is no reason for substituting the new, for the old.

That when the pathological condition is clearly defined, there is enough to give. We are all in favor of progressive medicine but, *not in favor of progressive quackery.*

To conclude, remedies like men, must stand, or fall upon their merits, and upon this basis, the motive for this paper is founded, and presented to you for your consideration.

THE TYPES AND TREATMENT OF INTERMITTENT FEVER.*

BY ROBERT C. KENNER, A. M., M. D.

Within the last thirteen years I have treated more than three thousand cases of all forms of intermittent fever. These were seen in the most malarious portions of Kentucky and Arkansas.

*Read before the Hardin County Medical Society, September 3, 1891.

I have taken careful notes of these cases and have arrived at the conclusion that there exist several types of this disease which I shall briefly describe.

It is not my intention to give an extended review of the therapeutics of intermittent fever. This would be most interesting and would acquaint one who had not read medical literature with many curious facts and practices. But the limit of this paper forbids this altogether, and I shall therefore confine myself to those remedies which I have found of the most substantial value.

In this paper I shall only consider the means of intercepting future paroxysms, leaving the treatment of the issues of the paroxysms, itself untouched.

While the paroxysms may be essentially alike and have their origin immediately or remotely in the same cause, the practitioner is confronted daily in practice with *several distinct types of this fever.*

In other words, we constantly meet cases in which, while they are alike as to form, there are symptoms and conditions of the system accompanying the one that are wanting in the other, and measures that will speedily cure in one case will utterly fail in another. It is one of the primary objects of this article to define as clearly as possible symptoms and conditions which constitute and differentiate these types. My experience leads me to look upon intermittents of the quotidian, quartan, or any variety, as assuming according to the state of the system four different types, and the treatment to be largely successful in warding off future paroxysms must be adjusted on the basis of this differentiation of the types. Intermittent fever is no more necessarily the same in two or three cases in practice than so many cases of pneumonia or typhoid or scarlet fever.

The types of intermittent fever met with in practice may be classed in this order: (1) That which is attended with that condition known as "biliousness" in its most marked form. Plus the fact that the patient has had an intermittent paroxysm, "the complexion is muddy, the conjunctivæ are yellow, the tongue is heavily coated with a yellowish-white fur, a bitter taste persists in the mouth, the breath is heavy in odor, even fetid."* There is generally a disgust with food and more or less obstinate constipation. If the bowels have acted, they have generally done so imperfectly, and the dejections are clayey or yellow in color. There is frequently retching and vomiting. Vomiting is very often an annoying symptom. This type I have observed occurs *only* in those patients who have resided in *very* malarial districts, those who live close to stagnant streams or pools, or near the banks of a river which is low or overflows and inundates the adjacent lands. It seems that malaria formed in a locality of this kind is necessary to the production of this type. This type of intermittent fever formed ten per cent. of the cases of which I have notes. (2) The second type is that one in which the accompanying symptoms of "biliousness" may be present, but to a much less extent, or even, as they often are, entirely absent. The tongue is usually more or less coated, though it is many times perfectly clean. The bowels are generally constipated, but frequently it is only to a slight extent, and sometimes there is diarrhœa with a red "beefy" tongue. The muddy complexion and other symptoms of the preceding type may be present in a less marked manner. The patient generally gives a history of malarial exposure, though he is often unable to make it out, and as a rule he has not been subjected to as virulent a degree of poison as the class who present cases of the first named type. The febrile action in the hot stage will run as high, and the other stages will present no distinctive differences from ordinary intermittent fever, only that the first-named type may be attended with more gastric irritability and other symptoms of "biliousness." This type is the one ordinarily met with in practice. (3) The third type is where the paroxysms have persisted long and the patient has malarial cachexia. The patients are those who have been exposed to the action of the malarial poison for a long period, and who have had paroxysms regularly, in some cases for six months and a year. The patients are anæmic and usually have enlargement of the spleen and liver, with more or less dropsy. There is often bronchitis and diarrhœa, and this type has been mistaken for phthisis. The paroxysms are often masked, the cold stage is frequently but feebly expressed, and sometimes omitted entirely. The patient suffers from neuralgia and gradually becomes weaker until he succumbs, unless the treatment is successful.

The fourth type is the one in which the paroxysms seem to recur from *habit.* Its history is one usually marked by more or less continued exposure to the poison and neglect to employ remedies in proper time and manner. The patients are generally more or less anæmic, but present nothing

*The words in quotation marks are from Bartholow in Pepper's System.

like the depraved physical condition of those having malarial cachexia. It is seen mostly in those persons who have undertaken to treat themselves, or have resorted to the various nostrums until the system has become impoverished to a degree, and when the physician orders quinine taken in the interval he finds it unavailing. Even after removal to a healthy neighborhood the chills will recur.

While in this connection, it will not be out of place to speak of the importance of satisfying one's self that the patient has intermittent fever. Chronic pleuritis, hepatic abscess, abscesses, hysteria, hectic fever, and other diseases simulate intermittent fever very closely. Professor Andrew H. Smith, of New York, recently reported a case of malignant endocarditis which simulated intermittent fever very closely.‡ Graves, in his Clinical Medicine, lays particular stress on the importance of diagnosticating intermittent fever, and details a case of hectic fever which had been denominated intermittent fever by several able practitioners of that day.

In the *treatment of the first type* of cases, nothing is so important as the timely administration of the compound extract of colocynth alone or in combination with calomel. Without regard to the time of the next recurrence of the paroxysm, I usually give it in doses of from ten to fifteen grains, repeated every eight hours, till the tongue has cleaned off and the symptoms of biliousness have entirely disappeared. Should the paroxysms recur after this has been effected, quinine will have to be resorted to. But it is not, according to my experience, good practice to give quinine at the beginning of this type of cases. I have never seen a case that was clearly defined of this type that would not readily yield to this treatment. When gastric irritability complicates this type, the mild chloride of mercury should always be combined with the colocynth, otherwise it is not always necessary.

In the second type of cases we are called to treat the ordinary expression of the malarial poison. This is the form in which quinine acts as a specific as much as any drug acts under the circumstances. Given properly it is almost an antidote. I have found it best to give the antiperiodic in five doses, of four grains each, beginning six hours before the paroxysm is expected and given hourly until all five doses are taken. The last dose of the quinine will, of course, be taken an hour before the time that would be occupied by a chill. I have no reason for believing that the antiperiodic virtues of quinine are increased by giving it in one large dose, as Hertz and others advise. I order the antiperiodic taken as stated above, for three consecutive days. It is given with advantage in this manner, over the practice of giving what we consider the antiperiodic quantity at any time in the interval. One reason is that during the time quinine is being taken we keep the patient in doors till the time of the chill has passed, while if it is taken in the sweating stage, the patient might go out, unduly expose himself, and bring on the paroxysm. Then, given in this manner, we are more assured that the malarial poison is neutralized; besides, the production of cinchonism for three consecutive times will make the chances for the return of the chill almost inconsiderable. The experience of several great observers would seem to confirm this position. Professor Flint declared the chances that cinchonism produce in the interval would ward off a recurring attack was about equal with failure. It would seem that Professor Loomis favors this plan of producing several cinchonisms. He says, "Having prevented the recurrence of a second paroxysm, it is important that a moderate degree of cinchonism should be maintained for a number of days by the daily administration of quinine, in moderate doses, about two hours before the time of day at which the first paroxysm occurred; ten to fifteen grains should be daily administered." ‖ I have found the antiperiodic given in the sweating stage often produced vomiting. But granting that it will not produce even nausea, the fact that the patient might go out and bring on another paroxysm is sufficient, together with the fact that no advantage would be gained, to condemn the practice. Since I have begun to give the antiperiodic later in the interval my success has been greater. My experience has led me to the conclusion that quinine given in solution is not more certainly antiperiodic. Fluids, it is well known, are more easy of absorption than powders, yet we are not on this score to ignore making our prescriptions palatable. The exhibition of quinine in capsules is a practice open to no objection if they are soluble. I have never had cause to regret using the drug in this manner. To give it in freshly made pills is also a good way. When the stomach is irritable I order two grains of oxalate of

‡See *Medical Record*, July 30, 1887.

‖Loomis' Practice of Medicine, p. 116.

cerium with each dose of quinine. When the agent is to be given to children, I have ceased prescribing it any other way than in the aromatic syrup of yerba santa when it can be taken by the mouth at all. It completely disguises the taste of the drug and makes it so palatable that children like it. When it is not advisable on any account to give it *per os* or *per enema* it can be given hypodermically with advantage. Given in doses of six grains hypodermically, I have found it equal to twenty taken *per os*. When there is furred tongue and other symptoms of biliousness, colocynth and calomel should be added to the treatment.

Sternberg ascribes the oxytoxic powers often attributed to quinine to a misconception. I have often given women advanced in pregnancy full doses of quinine, and have never had the least reason to regard it as an abortifacient. Malarial fevers often produce an abortion, and this is how the drug came to be looked upon as an exciter of uterine contractions. *Cornus florida* (dog wood), given as before outlined may be used. So also may the kindred alkaloids of cinchona and the remedies mentioned above. Fifteen or twenty grains of the bromide of potassium or sodium given during the time quinine is being taken will entirely relieve the unpleasant effects of cinchonism, such as tinnitus aurium, etc. This also lessons the tendency to nausea and vomiting. Such good results follow it that I almost follow giving it in a routine way, and never fail to give it when the patient complains of the unpleasant effects of cinchonism.

In the third type removal from the malarial surroundings is imperative. The patient's general health must be looked after. Codliver oil, arsenic and iron are the remedies which will afford the best results. Diarrhœa, bronchitis, and whatever complications may exist will demand special interference suitable to the particular case and not possible to outline here. Arsenic should be given until the symptoms of arsenical poison in the edema arsenicalis appear. Quinine should be directed against the chills or elevations of temperature for one month, if that long be necessary to dissipate them.

The fourth type, which is seemingly *habit*, calls for treatment somewhat different than the other varieties. There are several remedies which render us substantial good in these cases, and which may be relied on with confidence. The patients should be put on tonics, such as iron. I frequently prescribe tr. ferrichlor. in combination with liq. arsen. chlor. with the most satisfactory results. The best means to arrest the paroxysms are those agents which impress the nervous system. The bath of cold water is an excellent measure, used as above directed. Opium in full doses, one hour before the expected paroxysm, is one of the surest means of curing this form. It is well often to combine capsicum or piperine with the opium. Opium should be given for at least three consecutive days, or may be longer.

When the chills recur every fourteen or twenty-one days, quinine in doses of five grains, given for a period of four weeks, generally succeeds, in my hands, in curing them.

AN OPHTHALMOSCOPE FOR GENERAL USE. *

BY EDWARD JACKSON, M. D.,

PHILADELPHIA.

It would be a great gain to both doctors and patients if a much larger proportion of those who class themselves as general practitioners were able, when the need for it arose, to use the ophthalmoscope. One who has no practical experience with it cannot even properly appreciate what he reads or hears of ophthalmoscopic appearances. And there are in the aggregate many cases in which the progress of general disease could be far more intelligently followed by its routine use, without entering upon debatable ground or attempting to use symptoms of doubtful significance.

With the ophthalmoscope, as with other instruments, the cheap instrument is very apt to lack certain important features, and the costly instrument is mainly confined to the possession of those who mean to use it a good deal. It took many years to adapt the microscope to the needs of clinical work, to rid it of mechanical stages and other mechanical nuisances, and perfect its really essential parts. And the ophthalmoscope must pass through a similar pruning and adaptation before its use can be truly popular and common in the profession. For some years I have been working at this problem, and herewith present my results.

The ophthalmoscope for general use must: First, be one in which the difficulties of

* Read before the Philadelphia County Medical Society, Sept. 9, 1891.

using the instrument are as far as possible overcome. Second, it must be one that will be as satisfactory as any of the best instruments for any case that is likely to be encountered. Third, it must be cheap. For this one I have no hesitation in claiming that with it the fundus of the eye can be seen as readily as with any ophthalmoscope heretofore made; for all practical purposes as a refraction ophthalmoscope, its lens series is complete; it can be bought for eight dollars.

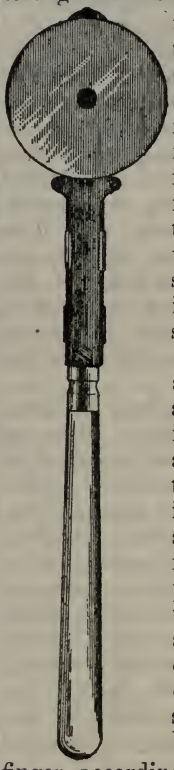
It is easy to see through, because the mirror, which is circular, 30 mm. in diameter, tilts each way to the best angle, at about 25 or 30 degrees; it has a shorter canal, and wider lenses than have most first-class refraction ophthalmoscopes; each lens is retained in exact position by a spring stop, and all the lenses or combination of lenses are available without taking the instrument from the eye.

The lens series is furnished by combinations of six lenses in two slides, and consists of convex 1, 2, 3, 4, 6, and 12 dioptres; concave 1, 2, 4, 6, 10, and 22 dioptres. To appreciate this series one must bear in mind the degrees of ametropia that are commonly encountered in practice. Among 4,000 eyes, the statistics of which I have published in the *Transactions of the American Ophthalmological Society* for 1889, only one eye had hyperopia of 13 dioptres, and only one eye had myopia of 23 dioptres.

The series does not contain half-dioptres, which are given in all the larger refraction ophthalmoscopes; but a very prominent ophthalmologist has recently said that he had the half-dioptre lenses taken out of his large instrument (Noyes' modification of Loring's) as comparatively worthless. Under especially favorable conditions there are a few ophthalmoscopists who have constant and extensive practice with the instrument who can I believe measure refraction with a little more exactness with half-dioptre lenses than they could with only whole-dioptre intervals. But the ophthalmoscopists that can do this are comparatively few, the cases in which they can do it are few, and the practical value of doing it is utterly insignificant. For those who are not in special practice half-dioptre intervals are always a delusion and snare, a hindrance, a cause of inaccuracy. They are, therefore, discarded.

Although the statistics above referred to show that in but one eye in 40 of those encountered in practice is the degree of ametropia over 6 dioptres, to one not very familiar with the properties of lenses the intervals between the stronger lenses of this series may seem too great. Such must be reminded that the effect of every intermediate lens strength may be obtained by slightly varying the distance of the lens and instrument from the patient's eye. Thus the convex 6-dioptre lens acts as such only when placed against the eye; by drawing it back less than three inches it is made to act as a 12-dioptre lens, and within that space will correct any intermediate amount of hyperopia. By withdrawing the 12-dioptre convex lens a little over one inch it takes the place of a 20-dioptre lens. On the other hand, by withdrawing the concave 22-dioptre lens a little over two inches its effect is diminished to 10-dioptres, and in that space every intermediate strength is reproduced. In the same way the withdrawal of the 10-dioptre concave lens to the same distance gives us the 6-dioptre effect.

When this is remembered it is readily seen that any measurement of refraction by strong lenses is utterly untrustworthy unless the distance of the lens from the eye is taken into account; and if it is taken into account, any additional intermediate lenses are quite unnecessary. The above series is sufficient for the direct method in all cases except the very highest myopia, for which the expert ophthalmoscopist is apt to resort to the indirect method as more satisfactory.



To one accustomed to using a disc ophthalmoscope the arrangement of lenses as here in slides will at first seem awkward and confusing, but to one who begins with this instrument, or who has already used an instrument in which the lenses are so placed, it is especially convenient. The convex lenses are all in the back slide, the concaves in the front. One can be used alone, or both slides can be moved at once by the tip of the same forefinger, according to the lens required.

In the focus of the mirror, the size of the sight hole, the blacking of it, the proportioning of the instrument, and its mechanical execution, it is to equal the best ophthalmoscopes now used. It is made by Mr. D. W. Brown, of Philadelphia.

Since this is not my first attempt at the modification of the ophthalmoscope, and another instrument has my name associated with it, perhaps it will prevent confusion if I exercise the right of naming this. And with the idea of giving it a name that shall by a single word indicate the idea of its design for general use, I shall call it the Polyclinic Ophthalmoscope.

Society Reports.

THE SECOND TRIENNIAL MEETING OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS HELD IN WASHINGTON, SEPT. 22, 23, 24 AND 25, 1891.

GENERAL SESSION.

The Congress was called to order by the Chairman of the Executive Committee, Dr. William Pepper, who introduced the President, Dr. S. Weir Mitchell, of Philadelphia.

The first scientific matter brought forward was the disease or conditions underlying the

Infection of Wounds,

including a discussion of disinfection with reference to treatment of wounds, of the relation of bacteria to suppuration, of the resistance of tissues to the multiplication of bacteria and of the effect of antiseptic agents on wounds.

The discussion was opened by Dr. William H. Welch, of Baltimore, Md., who held that the presence of certain kind of bacteria as an essential condition of wound infection is so well established that discussion of this point is not likely to arise. The comparitively simple conception that a wound to which bacteria gains access, necessarily becomes infected, has been greatly modified. The traumatic infection present there own peculiar problems. The doctrine of wound infection involves the consideration of many varying and often complicated factors relating both to the agent of infection and to the individual exposed to the infection.

The subject was considered under the following heads:

1. What are the micro-organisms concerned in the infection of wounds, and how do they act?

2. How are we to explain the great differences in the effects produced by the pyogenic micrococci; their apparent harmlessness under some conditions, their fatal influence in others?

3. What are the ways by which bacteria gain access to the wound?

4. How often are bacteria to be found in wounds treated antiseptically or aseptically? What are the character of these bacteria, and where do they come from?

5. What are the best means of surgical disinfection?

The observations as to the relative frequency of the ordinary pyogenic staphylococci and streptococci are not altogether concordant. The yellow staphylococcus appears to be more common in furuncles and abscesses than the white staphylococcus.

The author had found a white staphylococcus in small stitch abscesses and minor grades of inflammatory disturbance in wounds treated antiseptically and aseptically, which differs in certain particulars from the staphylococcus pyogenes albus. He suggested that it be called the staphylococcus epidermidis albus. The efforts to differentiate into distinct species the pathogenic streptococci have met with little success. The list of bacilli which may be concerned in suppurative and other inflammatory affections is much larger than was formerly supposed. The bacillus coli communis was referred to. The chief interest of the observations being that they furnish an illustration of the possible predisposition to infection afforded by intestinal lesions, and also give an example of the much disputed auto-infection of the suppurative inflammations examined bacteriologically, with negative results may be mentioned abscesses in which the bacteria were presumably dead, several cases of pyosalpinx and suppurating buboes and some abscesses of the liver.

There is reason to suppose that the process of suppuration serves a useful purpose and is one of the most efficient weapons employed by nature in combating invading micro-organisms. Exactly how the abscess formation checks the invasion of bacteria we do not know.

The quantity of a culture of the staphylococcus aureus required to produce suppuration is not the same for all tissues and all parts of the body. There are also variations in virulence of different cultures of the pyogenic cocci. Inasmuch as it is by their toxic products that the pyogenic bacteria do injury, it is not surprising to find that it makes a great difference in the result, whether or not these bacteria enter the tissues already equipped with a reserve force of this poisonous material, or whether they

must begin the fight unarmed. This matter of accompanying toxines is possibly of great importance in our understanding of the potentialities of the living agents of wound infection. The differences in virulence found to exist between inflammatory exudates from various sources are much greater than those observed in the cultures of the same bacteria on artificial media.

In regard to the conditions in or about a wound which favor the lodgement and development of pyogenic bacteria, it may be said that anything which interferes with the integrity of the living tissues in a wound is a predisposing cause of suppuration. Chemical irritants, such as carbolic acid and corrosive sublimate, favor the development of micro-organisms. A solution of corrosive sublimate as weak as one to two thousand is followed by a distinct line of superficial necrosis. We are not so well informed as to the influence exerted by blood in a wound. Most surgeons lay great stress on hæmostasis in surgical operations, while others advise that in certain classes of cases the wound be permitted to fill with blood clot. Is this a source of danger? Fresh blood serum does not possess any such germicidal power over pyogenic cocci as it does over the typhoid and many other bacteria. The power of the living tissues to overcome a certain number of pyogenic bacteria is well recognized, and the tendency of modern surgeons is to respect these tissues more and more. Not to destroy their vital capacities by the unnecessary application of strong chemical disinfectants, not to bruise them, not to make them too intense, not to strangle them, not to suffer the presence in wounds of spaces and bodies which remove bacteria from the influence of the living fluids and tissues.

Of the various ways in which pathogenic bacteria gain access to wounds, that by contact with infected hands, instruments, and other objects, offers the greatest danger. The possibility of infection from the air can not be ignored. Even in wounds treated aseptically or antiseptically it is not uncommon to find bacteria. The skin may have all sorts of bacteria upon it, but in addition it has its own distinct bacteria. After the skin has been thoroughly washed and scrubbed the prevailing organism will be found to be the white staphylococcus. This is often found in parts of the epidermis deeper than can be reached by any known means of skin disinfection. We can now understand how without any flaw in the antiseptic technique of the surgeon, this micro-organism may be found present in wounds, and we have here an explanation of the frequent occurrence of stitch abscesses, although the inference should not be drawn that the white staphylococcus is the only bacterium concerned in the production of these annoying complications. How much practical importance attaches to the demonstration of this coccus, the author was not prepared to say. The surgeon with good technique, who does not bother himself about this coccus in the deeper layers of the skin, is not likely to be severely punished by the behavior of his wounds. Those who put in drainage tubes and other extraneous substances will have to consider it. Some surgeons on the basis of researches on the bacteria of the skin have abandoned skin sutures. The edges of the wound being brought together by subcutaneous sutures.

In regard to the methods of surgical antisepsis, it was said that the conditions for efficient chemical disinfections have been found to be far more complicated than was formerly supposed, and the substitution, wherever applicable, of the simple and certain methods of disinfection by heat is to be commended. Chemical disinfectants still have their place for many purposes in the operating room, but their place is not in healthy wounds. Thorough scrubbing of the skin with soap and water by a sterilized brush removes many of the bacteria but not all, and cannot be regarded as satisfactory means of cutaneous disinfection. Corrosive sublimate accomplishes much less than is generally supposed. The best results obtained have been by a method in which a saturated warm solution of permanganate of potassium followed by a similar solution of oxalic acid, plays the principle disinfectant role, and this is the procedure now adopted in the gynæcological and surgical wards of the Johns Hopkins Hospital.

CONDITIONS UNDERLYING THE INFECTION OF WOUNDS, INCLUDING A DISCUSSION OF DISINFECTION WITH REFERENCE TO TREATMENT OF WOUNDS, OF THE RELATION OF BACTERIA TO SUPPURATION, OF THE RESISTANCE OF TISSUES TO THE MULTIPLICATION OF BACTERIA, AND OF THE EFFECTS OF ANTISEPTIC AGENTS ON WOUNDS.

BY ROSWELL PARK, M. D. OF BUFFALO, N. Y

The study of wound infection is insepara-

ble from that of immunity, and when we have learned that which constitutes or favors immunity, we shall approach nearer to that which is now a terra incognito. Immunity is a complex condition not dependent upon any single factor and from pathological interest as well as from clinical importance, our endeavor now must be to analyze the main question of what constitutes or confers immunity, and try to recognize and then solve its various subordinate queries. This statement too is inseparable from another which is to the effect that the surgery of to-day should aim to be aseptic and not merely antiseptic. In other words, we should abolish sepsis and not merely aim to antidote it or conquer it when present. The condition of sepsis is a complicated one consisting of a poisoning by ptomaines, toxines and albumoses having widely different properties. Some of these substances are so antagonistic that one may neutralize the other. In the intestinal canal there are produced poisonous substances which are taken up by the absorbents but then are filtered out by the liver before reaching the systematic circulation. It is by virtue of this depurative action of the liver that many cases of septic intoxication in surgical patients are avoided. In a division of the general subject of blood poisoning, a condition which may be called intestinal toxæmia or intero-sepsis, deserves a distinct place. This occurs not infrequently and may merge into a condition of sapræmia or septicæmia, but if promptly checked there is a speedy return to a desirable condition both of wound and patient. By no means do all cases of surgical sepsis have their origin in or about the wound.

We have learned a little in reference to the antagonism of different bacteria and the poisons which they produce. A microbe may enter the system and produce a proteid or albuminose, poisonous to the animal while the introduction of some other substance may neutralize this poison and save the animal. The principle is the same whether the antidotal poison be injected as such or a second species be inoculated by which it may be produced. Brunton has suggested that blisters do good in this way, by an endermic administration of proteids derived from the blood, but so altered in their passage from the vessels as to have a different effect, and probably by their chematactic properties. He also suggests that bleeding may act in a similar manner as it has been shown that the abstraction of venous blood causes an absorption of proteid matters from the tissues and these may have an action of their own on the tissues with which they come in contact. The benefits of free purgation probably find here their proper explanation.

The term chemotaxis to which reference has been made, relates to that faculty possessed by all motile bacteria, of moving towards or away from certain substances which seem to attract or repel them. The same power is inherent in the plasmodia of myxomycetes as well as in various other unicellular organisms and leucocytes if not other cells of the human body possess the same property. Chemotaxis is spoken of as positive or negative as there appears to be attraction or repulsion. Among the most actively positive chemotactic substances are cultures of bacteria. These are powerfully attracted by the leucocytes. The effect is the same whether the cultures are alive or have been killed by boiling. The active agent is some product of the life and growth of the bacteria. The leucocytes thus attracted act as scavengers for the surrounding tissue.

These facts have an important bearing upon questions which vitally concern the surgeon. In the light of these researches, it is diffiult to see how the possibility of phagocytosis can be denied and the impossibility of this process looms up in a flood of light when one discusses the phenomena of suppuration or of other kinds of infection as well as of recovery or immunity therefrom. Support of the phagocyte theory has come from the work of Hankin on defensive proteids. From the spleens and livers of various animals he has isolated the proteid which has the power of killing bacteria and he has found that this, while absent from normal blood could be obtained from the blood of febrile animals.

The separation of dead and dying matter is a process in which the formation of proteid material figures largely. An important bearing of these facts is on the use of so-called antiseptic agents. The ideal antiseptic is probably blood serum, its parasiticide properties being in all probability connected with the existence in it of a globulin which is soluble only in a weak solution of common salt. This may explain the well known antiseptic action of common salt.

It has been stated that by no means all the sources of sepsis concern the wound itself. The other principal sources of infection may be classified as follows:

1. Previous long existent toxæmia as syphilis, diabetes, acetonæmia, lithæmia, alcoholism, malaria.

2. Previous anatomical changes which

reduce vitality, as inherited diatheses, old age, amyloid change, chronic and acute nephritis.

3. Recent or acute toxæmia, as uræmia, typhoid, intestinal toxæmia, stercoral toxæmia.

4. Other acute conditions as starvation, scurvy, anæmia.

5. Conditions of environment, as bad hygienic surroundings.

6. Effect of anæsthetics.

7. Effect of antiseptics.

Antiseptics may favor infection in more than one way, mercurial and iodoform poisoning are not uncommon. With this established the case becomes one of acute toxæmia. The wounds may fail to unite and suppuration may occur again, the chemical reaction between the vital fluid and the antiseptic, may cause a loss of the properties of the antiseptic agent while the tissues on which it acts may have their constitution so changed as to favor rather than resist infection. Investigations make it appear best to keep all antiseptic agents away from absolutely clean, fresh surfaces. The value of blood serum as an antiseptic has been abundantly shown. This will be poured out in quantity sufficient to serve not only as a cohesive but as an antiseptic agent. The question here arises as to what is the best antiseptic. It would appear that for most purposes peroxide of hydrogen is the ideal antiseptic as it not merely destroys living organisms but by oxidation of undesirable and infected material acts as a scavenger of the tissues. We however, have yet to learn how to utilize to the fullest advantage the properties of blood serum.

Direct infection may be of two varieties, self or auto-infection and contact infection. The principle sources of contact infection are as follows: 1. Skin and hair. 2. Instruments. 3. Sponges or their substitutes. 4. Suture materials. 5. The hands of the surgeon and his assistants. 6. Drainage materials. 7. Dressing material. 8. Miscellaneous drops of perspiration, an unclean irrigator nozzle, the nail brush, the clothing of the operator, or bystanders, etc.

The best plan of sterilizing the skin is shaving, followed for a day or two, if there is time, by some antiseptic ointment properly prepared. The skin should then be washed with sapo viride of the German pharmacopœia with five per cent. sol. of lysol or hydronaphthol. Then there should be worn until the time of operation a compress wet with some liquid, non-irritating, antiseptic such as creolin, lysol, (five per cent.) or hydronaphthol in saturated cold aqueous solution. At the time of operation there should be a final scrubbing with hydro-naphthol soap with shaving and then the skin washed with equal parts of alcohol and ether, or alcohol and turpentine. Where there is not time for this we must content ourselves with the thorough use of the nail brush, the razor and antiseptic soap with the subsequent use of alcohol and ether.

Instruments are best prepared by dry sterilization as this injures them less than other plans.

In regard to sponges there is nothing to be added to the well known directions. It would seem better to use some cheap absorbent material which after use could be thrown away.

Silk is best sterilized by placing it in a test tube, then plugging and keeping for an hour in a steam sterilizer upon two different occasions. Silk-worm gut may be prepared by immersion for a few hours, in a one per cent. aqueous solution of corrosive sublimate and then preserving in alcohol. Cat gut is best prepared by immersion in benzine or ether to remove fat. It is then dried and soaked for one or two days in a one per cent. watery solution of corrosive sublimate after which, it is dried and transferred to oil of juniper berries, and from this to strong alcohol containing one permille of sublimate. In this, if desired, it can be boiled. It may be chromicised before putting in the oil of juniper.

The hands even after having been in contact with septic matter, may be sterilized by the following method: Wash with soap and water, using nail brush. Then wash the hands and arms with flour of mustard as though it were powdered soap. This will remove all odor. Then wash with sapo viride [G. P.] to which has been added five per cent. of lysol, creolin or hydro-naphthol. Then rinse and immerse in a strongly colored solution of permanganate of potassium. They are then rinsed and immersed in a solution of oxalic acid, sufficiently strong to decolorize the skin in two or three minutes. The oxalic acid is rinsed off and the hands may be considered aseptic.

Drainage is probably required only in septic or infected cases.

After an ideal aseptic operation, we need only a sterilized and a protective dressing. In some cases there may be advantage in impregnating the dressing with some antiseptic.

Among miscellaneous sources of infection may be mentioned the use of an unguent

applied to the skin to prevent the adhesion of dressings. Experiments have shown that ointments made with even ten per cent. of resorcin or naphthalin without the application of heat contain bacteria. The same ointments heated to the temperature of boiling water seem to be sterile and to suffer only from air contamination.

Dr. Park presented the following conclusions:

1. Study of wound infection and of the septic condition thereby produced is inseparable from a study of what constitutes immunity.

2. By a study of immunity is furnished the best clue to a due appreciation of the principles of asepsis.

3. The surgery of the future must aim to be aseptic, for so far as fresh cases are concerned we have passed the merely antiseptic era.

4. Asepsis is to be achieved not alone by attention to the wound and the paraphernalia of operation, but by the closest regard to the condition of the patient's organs and tissues.

5. Sepsis may arise from circumstances and conditions other than those pertaining to the wound itself, although hitherto, practitioners have been too prone to scan solely this field when searching for its cause.

6. Sepsis and infection are combated in more than one way by natural agencies and by inherent properties of cells and fluids totally aside from the measures which the surgeon institutes, and the wisest man is he who studies to take advantage of these vital activities rather than introduce new and conflicting elements from without.

7. A recognition of the power of chemotaxis possessed by organized and unorganized materials in such varying degree, can be utilized to great advantage so soon as it can be reasonably and clearly defined.

8. A study of chemotactic activity appears to impress one with the truth of the phagocyte doctrine which if proven, is one having a large bearing upon the principles as well as the practice of the surgery of the future.

9. The proteid material contained within, and cellular infectious organisms, both play such a role in causing chemotaxis as well as in poisoning the animal infected, that we have reason to eagerly welcome all knowledge concerning it.

10. So fast as such proteid material can be isolated, we need among other things to study its effect upon the commonly used antiseptic agents.

11. We need to study much further the anti-toxic and bactericidal properties of human blood serum and the means by which we can avail ourselves of the same.

12. Some such classification as I have attempted to give of the various causes of lowered resistance to infection, or of the causes of vulnerability or susceptibility, will certainly assist in a due appreciation thereof, and will often aid in so fortifying the patient that he may resist infection to which he would otherwise succumb.

13. The condition of enterosepsis, fæcal toxæmia, stercoral intoxication, or whatever it may be called, is certainly one which every practitioner has to fear and against which he should assiduously guard. It is not sufficiently recognized and combated.

14. A sub-form of this condition might justly be made and entitled gastrosepsis, comprising cases where defective stomach digestion, often from dilatation, brings about a lithæmic or other toxæmic condition which favors infection.

15. Antiseptic agents in the past have worked a revolution in surgical practice and results. We have now reached a time when we know they all have their disadvantages, and also understand how, if we are strictly antiseptic in our work, we can afford to discontinue their application to wound surfaces.

16. But the insurance of aseptic character of such work, necessitates the use of antiseptic agents of some kind upon everything which may directly or indirectly come in contact with their surfaces.

17. When this work is strictly aseptically performed, the use of drains or further employment of antiseptics, is either an expression of mental uncertainty or of fear. It may be in the interest of humanity, undoubtedly it often is, but it is not attaining the ideal of scientific work.

Dr. Arthur I. Cabot, of Boston, referred to the debt which practical surgeons owed to the scientific workers. It is the knowledge of how to obtain aseptic wico wounds that has revolutionized surgery. Reference was next made to the phagocytic action of the cells and to the germicidal action of the blood serum. The only question is as to which of these processes is distinctly destructive. The bactericidal action of the blood serum has been proved. These observations may serve to explain some of the phenomena in wound fevers. It may be that in erysipelas, the irritation set up by the application of blisters, iodine, etc., may serve to limit the spread of the disease by the action of the blood serum on the micrococci of the disease.

In treatment of wounds its desirable to avoid placing animal sutures in the wound. It is better to close all spaces in the wound by pressure. He had found by culture experiments that where the skin prior to the operation was free from organisms, yet at the close of the operation their presence could be demonstrated showing that bacteria had been sown on the wound by the air or otherwise. If necrotic tissue or animal sutures be present, they might constitute a nidus for the development of the bacteria.

Mr. Thomas Bryant, of London, said that if bacteria are the seed, we must remember that the soil is not of less importance. If the soil is not suitable for the growth of the seed it will not grow. No surgeon would operate on a patient except in a case of urgency until the subject had been prepared for operation. In order to prevent the entrance of the germs, irrigation is of service. For this purpose iodine water made by adding a few drops of the tincture or solution of iodine water, is the most valuable. This may be made of a light cherry hue for clean wounds, and of a dark cherry for dirty wounds. It also acts as a good styptic. As a dressing he uses wood wool. The wound is dusted with iodol, one to five parts of boracic acid. In every operation there is a certain amount of molecular death, and drainage is required for thirty-six hours. Pressure is better than deep sutures for bringing the deeper parts of the wound in contact.

Dr. Harold C. Ernst, of Boston :—While it is true that nearly all forms of suppuration are attended by bacteria, yet it has been shown that a process answering to suppuration can be produced without the action of bacteria. The products of this suppuration however, do not produce activity when introduced into other animals. It has been shown that some of the agents used to destroy bacteria, really favor their growth by diminishing the chemotactic power of the surrounding tissue cells. Notwithstanding laboratory experiments show the possible occurrence of chemical suppuration, it shall remain to be demonstrated that the infection of wounds as seen in practice, occurs without the influence of bacterial activity. The most important lessons taught by investigations in this subject are those which warn us that our pupilage is not yet over, and that we are but entering upon the first stage of our knowledge of the processes spoken of here to-day.

Mr. John Chiene, of Edinburgh, said that he had assisted Professor Lister during the whole of his time in Edinburgh. The longer he lived the more he believed in the work of Lister and the impress he had made on surgery. He considered the bacteriological investigations as of the greatest importance, for on these the surgeon must depend in his daily work. Lister long ago spoke of the antiseptic value of the blood clot. But long before John Hunter pointed out the value of the blood clot, the speaker considered that the spray was of great service. The term "integrity of the tissues" had been used by both speakers, but John Hunter had also laid stress on the "vitality of the tissues" which he defined as "the power of the tissues to resist putrefaction." He thought that not only by improving the soil but by destroying the plant, the best results would be attained.

Dr. Arpad G. Gerster, New York, spoke of the many sources of contact infection and referred especially to infection, the result of bad habits on the part of the surgeon. The surgeon may carry out all details of aseptic and antiseptic treatment and yet nullify all by a habit he may have of rubbing his nose, his hair, or his face, or as the speaker had seen, placing the knife in his mouth that he might use his hand. An important point in the prevention of infection is clean dissection with the knife without tearing or bruising the tissues. In regard to irrigation and drainage he said that this could be eliminated only where the surgeon was absolutely certain of his asepsis and thought it dangerous for the general practitioner to discard drainage. If he is not certain of his asepsis he should cling to the older methods, and from these he may ascend to the highest pitch of skill when he can work with real asepsis.

Adjournment of Tuesday afternoon.

TO BE CONTINUED.

Special Correspondence.

PARIS LETTER.

The recent discussion at the Academy of Medicine, of the causes of the feeble population of France, reminds us that the Malthusianism of to-day (nio-Malthusianisme) is a question to be carefully considered, as it strikes at the very life of nations. In the beginning of this century Mr. Malthus, a famous political economist, predicted eventual starvation for the human race unless

artificial checks to population were introduced. *Now* our scientists fear *de*population unless these checks are removed or regulated. As investigation proves that the feeble population of France is not due to the mortality of the new-born, but to a diminution of the desire on the part of women to assume the responsibilities of maternity. I am aware that I am touching upon questions around which the over-sensitives have thrown a veil, which no one has dared to lift, and, for the present, I must say, "Rest in peace," and write of other matters. "L 'affaire du Cancer" has caused considerable comment. The President of the Society of Doctors and Surgeons of the Hospital at Reims, who was called upon by the President of the Administrative Committee of the Hospitals of that city, to investigate the truth of the public rumors concerning the "cancer affair" has handed in his report. The members of the Society hesitated to accept such a mission, but considering the articles that had been published—M. Dryer's letter, the Mayor's communication to the Municipal Council—they did not think it possible to avoid it. From the depositions of seven eye witnesses it appears that:

1. Doctor E. Dryer inserted pieces of a cancerous tumor of the breast, which he had just removed, into the opposite breast by means of an incision, which he made with a bistoury, and united said incision by means of sutures.

2. These fragments had not been submitted to any of the usual manipulations supposed to be capable of attenuating their virulence.

3. The fragments or "grafts" were introduced while the patient was still under the influence of chloroform.

The Society, once in possession of this information, requested M. Dryer to appear before it and explain. He at once declared himself, by letter, unable to accede to this request. The Society was thus forced to refer to M. Dryer's letter, in which three of his assertions in no way agreed with the depositions. He affirmed that the fragments had been submitted to manipulations, which had the effect of attenuating their virulence, that they were introduced with the idea of sparing the patient the pain of an operation.

The witnesses were unanimous in declaring that the patient had just been operated upon, with the exception of one, who did not know the origin of the inserted fragments; the others affirmed that the pieces were taken immediately from the extirpated tumor and without previous attenuation introduced on the spot into healthy tissues. With this evidence, the Society declared that M. Dryer had made, in the Hotel Diew de Reims, an operation which constituted a veritable cancer graft, and at once proceded to examine the question of responsibility. In his letter of August 1st, M. Dryer took refuge behind Doctor Dicis. The Society decided that at this time M. Dryer was a *Doctor*, and performed the duties of Chief of Clinic. These titles, says the report, are sufficient to render a surgeon responsible for his acts. The affair was then placed in the hands of the Prefect of the Maine, who has transmitted the documents concerning the affair to the Minister of the Interior. The history of experimental medicine records nothing more revolting, and it is a shame that the mantle of our noble profession should rest upon the shoulders of one so far removed from that ideal, erected by Hippocrates and inculcated by the physician's oath—but

"telle est la vie."

M. J. Lucas, Championnière at the Académie De Médicine, Seance, 25th of August, gave an interesting report of his operations for the radical cure of hernia without strangulation. Since 1881, he has made 254 operations, having lost but two cases; 222 of these were inguinal, 205 were men, 59 congenital. He states that among the inguinal hernias the congenital variety gives the most satisfactory results, his operations for umbilical hernia have, however, given him the most striking results. He considers the danger run by patients submitting to this operation very small, but makes a few reservations. He does not advise the operation for very young children—for subjects over 40, except in the presence of pressing indications. In general he would operate upon all subjects wishing to dispense with a bandage, those whose labors demand it, those whose social position would be benefited by the disappearance of the hernia.

In case of military service, of marriage, etc., etc., he makes an exception for diseased and cachetic subjects—those possessing such weak abdominal walls that hernias become multiple. He states that congenital, inguinal hernia should be operated upon *without* exception, especially if it be accompanied by some testicular ectopia.

Lysol, the new antiseptic, is used to a small extent here. Koch recommends it in a recent article, stating that it is superior to Creolin.

We have a vacation now, and, as I am

anxious to visit the School of Hypnotists, at Nancy, I will write my next letter from that city.

Lucia Redding Thompson, M. D.,
Paris, France.

Selected Formulæ.

CARBOLIC ACID AS A LOCAL ANÆSTHETIC.

Dr. C. T. Meacher, in *Items of Interest*, an American Dental journal, suggests a 5 per cent. solution of carbolic acid in water as a local anæsthetic that is safe and reliable. Four or five drops should be injected under the gum on each side of the tooth to be extracted. He says in most cases this is effective, and where inflammation exists around the root the action is most satisfactory. Dr. Meacher thinks that with moderate care there need be no fear of constitutional symptoms arising, considering the small quantity used. M. Viau of Paris, who read a paper on the subject before the Société d'Odontologie in 1886, expressed his opinion that it was of quite as much power as cocaine, and did not produce any dangerous symptoms.—*Lancet.*

THE SALICYLATE AND THYMOLO-ACETATE OF MERCURY IN SYPHILIS.

Dr. Dzadek (*Med. News*) has employed intra-muscular injections of salicylate of mercury in a long series of cases of secondary and tertiary syphilis, and always with most satisfactory results. The solution used was as follows:

℞ Hydrarg. salicylatis.....gr. xvj--xxiv.
Mucilag. gummi arabici.....gr. viij.
Aquæ destillatæ .....f℥vss.
M. ft. suspension.

Of this, one Pravaz syringeful (♏xv) was injected at a time; this was repeated at intervals of three days. He selected the gluteal region as a site for injections. The time during which the cases were treated varied from three weeks to two months. The therapeutic value of the salicylate of mercury was especially remarkable in syphilitic affections of the skin and of the mucous membranes; syphilitic eruptions and slight relapsing forms yielded to the treatment in from two to four weeks. The local reaction was slight—even less than after the use of calomel and of the yellow oxide of mercury. In no case did an abscess form, either at the point of injection or in its vicinity. Infiltrations were rare, and the more pronounced symptoms of mercurialism did not develop.

He has also with advantage used the thymolo-acetate of mercury in several cases of syphilis. The formula of the aqueous suspension to be injected is as follows:

℞ Hydrarg. thymolo-acet.....parts 1.5.
Mucilag. gummi arab.....parts 0.5.
Aquæ destillatæ.....parts 20.
M. ft. suspension.

The injections of a seven per cent. suspension of the drug were made at intervals of three or four days. From six to ten injections suffice in most cases of recent and non-inveterate syphilis. He has especially observed the therapeutic value of the treatment in the early stages of the disease. Syphilitic roseola and the papular affections of the mucous membranes yielded after from four to six injections, or in from twelve to twenty days; the relapsing syphilides, after from two to four injections; the papular cutaneous forms and the ulcerative affections of the mucous membranes after from six to eight injections, or in from fourteen to twenty-five days; the pustular and tubercular affections of the skin required a larger number of injections. This method of treatment occasioned little pain; in no case did an abscess or considerable infiltration develop. During the last two years he has not encountered, as a result of the toxic action of mercury, disturbance of the digestive organs, of respiration (embolism) and circulation, or any general disorder of importance.

CANTHARIDES IN CARCINOMA.

Wolfert (*Norsk Magazin for Lægevidenskaben*, No. 7, 1891), in a case of previously operated and recurrent carcinoma of the left mamma, of the size of a walnut, cautiously administered, after extirpation of the node, the following:

℞ Tinc. canthaird. }
Vin. camph., } aa gm. 5. (fl℥jss).
Mucil. gumm. arabic, gm. 200. (fl℥iv).

The cancer did not recur, the patient married again, bore two children, and still lives.

In 1879 the writer treated a case of carcinoma of the pharnyx, with cachexia. Under the use of cantharides the symptoms not only were ameliorated, but the growth did not increase in size, the patient's strength returned, and the patient continued well. In 1880 he operated on a woman for a large carcinoma of mammary gland. The same treatment was instituted. The patient still lives free from any recurrence.

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO., (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

CHANGE OF OWNERSHIP.

THE BUTLER PUBLISHING COMPANY (Incorporated) has purchased all rights and title of THE MEDICAL AND SURGICAL REPORTER and kindred publications, and will publish the same. All bills owing to THE MEDICAL AND SURGICAL REPORTER should be paid, and all claims presented to the above named company.

LEADING ARTICLE.

ANÆSTHETICS IN OBSTETRICAL PRACTICE.

The value of anæsthetics in cases of other than normal labor is no longer a matter of dispute or a questionable practice. The benefits derived from their employment in such instances are manifold and patent to every obstetrical attendant. As to the propriety, however, of assuaging the sufferings of a woman in an ordinary case of normal labor, there is by no means a unanimity of opinion.

In the discussion on anæsthetics at the meeting of the *Medico-Chirurgical Society of Glasgow*, session of 1890–91, in the published report, edited by the secretary, J. Walker Downie, M. B., F. F. P., etc., we find two interesting papers upon this topic, from which we make some extracts.

The first paper:—"Anæsthetics in Relation to Midwifery," was discussed by DR. William L. Reid.

The speaker confined his remarks to the two main anæsthetic substances—chloroform and ether. Regarding the relative value of these agents in labor and operative midwifery, he considered them as both equally valuable in securing thorough anæsthesia, subject, however, to the restrictions to be made in the ensuing remarks. Referring to the mode of chloroform administration, he preferred a single ply of flannel on a small wire frame, upon which the anæsthetic was to be used with a drop bottle. With these agents, a mild anæsthesia can be readily kept up, and rendered more profound in the

course of a few minutes if occasion should require it.

For ether administration, he deemed the only safe plan the employment of a Clover's inhaler or some similar instrument.

Dr. Reid usually examines the heart before giving an anæsthetic, but the knowledge that heart disease exists, only makes him the more anxious to use chloroform or ether, because he thinks that in such cases the strain of labor is vastly more dangerous without an anæsthetic than with it. The same fact, he holds as true in patients with diseased kidneys.

In twenty-five years' experience with anæsthetics in midwifery practice, he had never seen a fatal issue; in fact, he had never even seen a woman in danger from the effects of these agents. In the major portion of his cases he had resorted to the employment of chloroform.

In his opinion, a lying-in woman is peculiarly fitted for escaping the dangers usually connected with the ordinary production of anæsthesia. The following causes seem to Dr. Reid to account for the great rarity of fatal results in obstetrical anæsthesia:

The left venticle of her heart is considerably hypertrophied, and so, less likely to weaken readily in its action.

2. She is kept in the recumbent position, and so, to that extent, defended from syncope.

3. The action of the heart is aided by the alternate relaxation and contraction of the uterus.

4. The anæsthesia tends to produce anæmia of the brain, whereas the labor pains give rise to engorgement of that organ.

In reference to the assertion that chloroform may kill the parturient woman by inducing post-partum hæmorrhage, the speaker from his experience was inclined to the belief that there is some truth in this view, but he also thought that the danger could be averted by the hypodermatic injection of ergotin, and by manual compression of the uterus.

Referring to the use of chloroform in labor, as being dangerous to the fœtus, inasmuch as it might be born so deeply under the influence of the drug as to be incapable of resuscitation, Dr. Reid thinks that he has good grounds for believing that, contrary to what one would most readily suppose, the child suffers but little risk from this cause. Why, with chloroform vapor circulating in the blood of the mother, the fœtus should not be in danger from the use of the drug, he is not able to explain satisfactorily. He mentions the fact that he has seen children born and cry lustily after a few seconds in cases where the mother had been deeply under chloroform for at least an hour, and, on the other hand, he has never seen a child born dead under circumstances in which he could reasonably attach blame to the use of the anæsthetic.

The conclusions reached by Dr. Reid regarding the use of chloroform and ether in midwifery are as follows:

1. In severe labor and ordinary operations he is content to use chloroform, in view of its convenience and safety under these circumstances.

2. In long and severe operations, especially when there is much loss of blood, he prefers ether, given by means of Clover's inhaler. This involves more trouble, but its probable greater safety ought to turn the balance in its favor.

3. He believes that it is advisable to have several medical men present when an anæsthetic is given, but thinks that it would be wrong to enforce this by law. [This remark of Dr. Reid is rendered necessary owing to the proposed enactment of a law in Scotland compelling the presence of two additional medical men, when an anæsthetic is to be administered. This question was put to a vote at one of the meetings of the *Medico-Chirurgical Society*, of Glasgow, which meeting was largely attended by representative men of the profession in Glasgow and the West of Scotland, and it was unanimously agreed "that no such legal enactment was required, and were any such law enacted it would in many cases be prejudicial and even dangerous to the patient."—Ed.]

The only other paper read at this meeting

upon the subject under consideration, was by Dr. Samuel Sloan, its title being, "Anæsthetics in Obstetric Practice."

In this paper, the author states that the more experience he has had with chloroform in obstetrical practice, the safer and the more valuable has he been led to consider it. He now administers chloroform, to the *obstetric degree*, in nearly every case of confinement. The length of time the patient is kept under its influence depends largely on the nature of the case. He has kept a patient seven hours under it. The method he uses is to pour a few drops of chloroform on a clean handkerchief which has been crushed and placed in a dry tumbler. This is held near the patient's mouth. Occasionally he allows the patient to hold it at first, partly to give her confidence; usually it is held by the nurse.

If the patient is in the second stage of labor and the pains are almost continuous, the chloroform is administered almost incessantly, but it is not given to the surgical degree; this being reserved for only serious and prolonged operations. Dr. Sloan states, in fact, that in what may be called minor obstetric operations, such as the application of the forceps at the outlet, or low in the cavity of the pelvis, he is in the habit of removing the chloroform entirely before beginning such operations, because the muscles are apt, under this degree of chloroform influence, to be rigid, and the patient whilst sufficiently under the drug to be free from conscious pain, is not sufficiently under it to be passive, and is yet too much under its influence to be able to control her movements. Chloroform in such cases, he thinks, is more of a hindrance than a help, bringing on reflex spasms of the vagina and hysterical restlessness as soon as the necessary manipulations are attempted. Dr. Sloan does not think that the patient suffers much by this withdrawal of the anæsthetic, since he finds that though no more chloroform is administered, the first time the patient fully recovers consciousness is when she hears the child cry. He never examines a patient's fitness for chloroform. Given to the extent as above, he has never witnessed a single case of after mischief attributable to the anæsthetic, not even a single case of sickness. He considers the recoveries more likely to be good than the reverse where chloroform has been *judiciously given.*

The two papers thus fully quoted express the views of our foreign colleagues upon the subject of anæsthesia in labor.

Here in this country, the leading obstetricians do not deem it essential to make it an invariable rule to administer an anæsthetic in every case of labor. They agree, that whenever painful or harassing complications arise which are liable to prostrate the patient and protract labor, an anæsthetic is indicated. Among such indications which call for the use of these drugs may be mentioned an unusually firm or resisting perineum, muscular spasms, œdema, a relatively large fœtal head or a relatively small pelvis, a vaginal cicatrix, a vesical calculus, a rigid os uteri, or an unusually sensitive nervous system, ill calculated to bear pain. In such instances an anæsthetic will not only shorten labor, but will prevent undue shock which would be sure to lead to profound prostration. It seems to us, therefore, that anæsthetics should at least be employed in all states of labor in which painful resistance to expulsion is encountered, or in which pain is unusually severe.

In unnatural labor—that is, a parturition which, if left undisturbed, would not terminate favorably either to the mother or child—the propriety of resorting to these agents cannot be disputed.

In fact, there seems to be no good reason why anæsthetics should not habitually be employed in cases of labor.

CORRESPONDENCE.

EXOSTOSIS OF THE ROOT OF LEFT LOWER DENTES SAPIENTÆ.

To the Editor of The Medical and Surgical Reporter:

A gentleman called at my dental office suffering from violent shooting pains in the

left side of the face and neck owing to a badly decayed tooth, which had previously been filled with amalgam filling, and which was removed by the advice of his physician. This gave him little or no relief. Finally he decided to have the tooth extracted. I applied all the necessary power that is required in the extraction of these teeth, which extract easily, owing to the space left for their development. After making my diagnosis, I excised through the alveolus and extracted the tooth, having three well-defined roots, but all had become exostosed. The hæmorrhage after the extraction was quite profuse, which in this case was a benefit. I syringed the cavity with carbolic acid (15 drops to an ounce of water) and plugged the cavity with absorbent cotton, saturated with the same solution, which I instructed him to remove after each meal and apply a new plug the same as I did. The next day he complained of a great deal of pain that soon subsided, and in a very short time the part came together very nicely. I have seen many cases of exostosis and I am of the impression that this condition is most marked in the lower teeth.

C. H. M. Neall, M. D., D. D. S.

A LAW CASE.

To the Editor of The Medical and Surgical Reporter:—At a meeting of the Greene County Medical Society on the 8th inst. the following resolutions were adopted:

Resolved, That we endorse the action of Dr. J. T. Ullom, chairman of the registration committee of this society, in arresting Dr. J. J. McClelland for violating the law relating to the practice of medicine and surgery in this county.

Resolved, That we hereby authorize the committee to take such steps which in its judgment may be necessary to enforce the law.

The grounds upon which the arrest was made, and which are admitted by both parties to the suit are as follows: One, Dr. McClelland of Columbus, Ohio, after advertising extensively in the county papers and otherwise has been making monthly visits to Waynesburg, this county, for the purpose of practicing medicine and surgery, and had prior to his arrest practiced to some extent at the above place in accordance with this advertisement.

An examination of the medical register showed that he was duly registered, but upon further examination of the records it was found that he had not in addition thereto procured a license as required by the Act of Assembly of 1877 relative to "itinerant" practitioners. The defense will claim that the whole of the act of 1877 was repealed by the act of 1881, and that the section of the act of 1877 requiring "itinerants" to take out a fifty dollar license is not, therefore now in force.

The act of 1881 makes no specific provision for "itinerants," but the tenth section reacts: "that all acts or parts of acts heretofore passed, and inconsistent with this act, be and the same are hereby repealed." The prosecution will claim that the section of the act of 1877 requiring "itinerants" to pay an extra license of fifty dollars is *not* "inconsistent" with the act of 1881, and is therefore in full force.

Drs. Ullom, Brock and Millikin compose the registration committee and they have been assured by the county commissioners that the latter will co-operate with the committee in the prosecution.

While the case will, of course, go before a jury, the question to be decided is really not one of fact, but simply a question of law, which so far as I know has not been passed upon by the courts.

If the Greene County Medical Society finds it necessary to take the matter to the higher courts, the Pennsylvania State Medical Society will, I have no doubt, come to our assistance if called upon.

J. L. Millikin, M. D.,
Cor. Sec'y. Greene County Medical Society.

Book Reviews.

INTERNATIONAL CLINICS. Vol. II. July 1891. J. B. Lippincott Co., Phila.

In general appearance of make up and divisional arrangement, the second volume of International Clinics follows that of the initial number. The general practitioner will, however, without doubt be rejoiced to find that the lectures presented in this volume, deal rather with the more common forms of disease as met with daily in an average practice, and that the unusual and rare text-book diseases, so many of which were discussed in the previous issue, have not entered its pages. While the latter are instructive and of much interest to many, we take it that the journal will find its widest range of usefulness in teaching the latest and best methods of combating diseases which are less unique.

The opening pages are devoted to a brief

biographical sketch of the late Joseph Leidy, M. D., a very good portrait of whom appears as a frontispiece.

In the department of medicine the first lecture is upon "Ulcerative Endocarditis" from a clinic by Dr. Wm. Pepper. The lecturer presents very full histories of two cases of this disease, tracing them with their various symptoms through their successive stages until death ensues. The records of the *post mortem* examinations are exceedingly full and instructive. The article is illustrated with well executed colored plates which show both the primary heart lesions and the secondary involvements of kidneys and spleen. Culture tubes with their growths in various stages of development are also depicted.

A lecture by Dr. Jas. C. Wilson upon "The Treatment of Typhoid Fever by Systematic Cold Bathing," detailing the results arrived at by this method of treatment (without the administration of medicines) in the German Hospital in Philadelphia, is highly interesting. The apparatus used and the method of preparing and administering the baths is described at length. During a service of 16 months, Dr. Wilson and his colleagues have thus treated 160 cases of typhoid fever, with the remarkably low mortality of 7 cases, less than 5 per cent. The patients so treated were not picked cases selected for an experiment by this method, but were just taken as they presented themselves at the Hospital for admission. The lecturer claims for this treatment—and his results certainly bear out his claim—that it is superior to any other yet used in typhoid fever.

Dr. Arthur Ernest Sansom of the London Hospital contributes an interesting lecture upon the "Pathology of Angina Pectoris," in which he carefully traces out the causes of that dread affection.

Dr. James Tyson in his lecture upon "Chronic Diffuse Nephritis" gives a full resumé of the latest knowledge regarding this disease, with very full directions as to its treatment. The significance of tube-casts of various kinds is thoroughly explained.

Dr. J. M. Anders' lecture upon "Lead Colic" is illustrated by a photograph of his patient in which the "wrist-drop" resulting from paralysis of the extensor muscles is excellently shown.

A clinic upon the "Permanent Cure of Hernia in the Groin" by Dr. Tiffany, of Baltimore, leads us into the department of surgery. The usual methods of suture of the ring and obliteration of the canal and sac are advised.

Dr. John Ashurst, Jr., contributes a clinic upon the methods of performing many of the rather more difficult but still rather common operations of the present day. He discusses the operations of "Removal of the Breast for Scirrhus; Stretching of the Sciatic Nerve; Excision of the Head of Femur; Hæmorrhoids; Finger Amputations; &c., &c." Many practical suggestions as to diagnosis, causes, and treatment of the different lesions for which the above operations are to be performed, are given and the steps of the various operative procedures are carefully set forth.

As the removal of a scirrhus the lecturer advises thorough cauterization of the whole exposed surface with a solution of zinc chloride. This following thorough removal of the cancerous mass enables one to give a more favorable prognosis, though the author believes the disease sooner or later will return. Nerve stretching is often successful in relieving obstinate neuralgia when all other measures fail. Especially it is better than resection of a nerve, which latter causes paralysis. Dr. Ashurst advises excision of the head of the femur when it and the acetabulum are carious and after the means in an earlier stage, for bringing about anchylosis, have failed. The result is a shortened but useful leg.

In a long lecture by Dr. John B. Deaver delivered at the German Hospital in Philadelphia, among other operations detailed are those of tracheotomy for cut-throat with a wound of large extent and an account of Wyeth's amputation at the hip-joint. But cases recovered and their treatment is fully described.

In the department of gynæcology and obstetrics, Dr. Palmer details the general management of confinement cases at the Cincinnati Hospital at some length and also presents a concise tabulated series of results since 1881.

Dr. W. Gill Wylie of New York follows with a lecture upon that troublesome disease "Endometritis." Its etiology is carefully considered and its treatment fully outlined.

J. Bland Sutton, F. R. C. S., of Middlesex Hospital contributes a carefully elaborated study in a clinic upon "The effects of double Ovariotomy and Oöphorectomy upon the Secondary Sexual Characters of Women." Dr. Sutton after very extended investigation concludes that—no unusual secondary sexual

characteristics develop; that atrophy of the breasts and obesity, regular menstruation, loss of sexual appetite and the existence of great physical change, is by no means a constant but rather an unusual sequence to these operations.

"Habit in Reference to Sleep and Sleeplessness" by Macfarlane of Glasgow, and a case of "Compression of the Spinal Cord due to Fracture of the Vertebræ" by Starr of New York are prominent lectures in the department of neurology.

Ophthalmology, dermatology, and otology are represented as before by lectures of Jackson, Duhring and Burnett.

In the present volume thirty-eight clinical lectures covering the whole ground of the practice of modern medicine, divided as it is into its various specialties, from the leaders in modern medical thought and experiment, make this number of the clinics a valuable text-book to all.

THERAPEUTICS.

IODOLE AND ANTIFEBRIN IN CEREBRO-SPINAL MENINGITIS.

The perusal of Dr. M. I. Krotkoff's paper (see below) has recently induced Dr. Vladimïr I. Sübbotin, of Balashov, (*Meditzinskoie Obozrenie*, No. 18, 1890, p. 495), to try Iodole and Antifebrin in a severe case of sporadic Cerebro-spinal Meningitis. Like his predecessor, the author obtained truly brilliant results. The patient, a previously always healthy, robust merchant of 18, fell ill on July 30th. When first seen by the writer, on August 8th, the lad was suffering from excruciating headache (especially about the back of the neck), some impairment of consciousness, obstinate sleeplessness, frequent nausea and diarrhœa, anorexia, fever (39.5° C.), photophobia, meteorism, abdominal tenderness. There were also present flushed face, congested eyes, myosis, slow reaction of the pupils, herpetic rash around the mouth, thickly-coated tongue, dry and hot skin, scanty rubeola over the chest and abdomen, weak pulse (95 per minute), and general prostration. During the night there appeared severe bilious vomiting of several hour's duration. On August 6th there supervened aching pain and numbness about all limbs, tenderness of the cervical vertebræ, retraction of the head, and rigidity of the posterior cervical muscles. On August 7th, the patient's left extremities were found completely paralyzed and affected with cutaneous hyperæsthesia, the wrists and fingers contracted. Up to this day the case had been regarded as one of enteric or typhus fever, and treated as such. Cerebro-spinal Meningitis was now diagnosed, and the following combination resorted to:

℞ Iodoli purissimi.....0.30 grammes.
Antifebrini.....0.18 "

M. f. pulvis. D. S.—A powder every three hours.

Besides, the following adjuvant means were ordered: 1. Four Milanese blisters to the back of the neck (2) and mastoid processes; 2. Ice compresses to the vertebral column, below the blisters; 3. Irritant (saline) enemata; 4. A hypodermic injection of $\frac{1}{12}$ grain of Morphine (in view of insomnia); 5. Beef and milk, in tablespoonful doses, repeated at short intervals. A steady improvement set in from the beginning. On August 17th, the Iodole powders were discontinued. On August 20th, the patient got up perfectly well.

In the *Meditzinskoie Obozrenie*, No. 17, 1889, p. 389, Dr. Krotkoff, of Saratov, has published two cases of typical Cerebro-spinal Meningitis, referring to girls, aged $4\frac{2}{3}$ and 9 years respectively. In the former case, the treatment was commenced on the third, in the latter on the first day of the disease, the little girl receiving 0.05 gramme of Iodole and 0.08 of Antifebrin, the older 0.12 of Iodole and 0.2 of Antifebrin, four times a day. The former was completely well on the twentieth day (of the symptoms), the other on the tenth. Considering the formidable character of the disease in question, one cannot help hesitating to attribute the extremely happy issue of the three cases to the treatment adopted. A more extensive series of clinical experiments in the same direction might elucidate whether the two authors had to deal simply with a happy, but blind, coincidence of the events, or really happened to come across a surprisingly efficacious means of lowering the enormous mortality from Cerebro-spinal Meningitis. — *Merck's Bulletin.*

ON THE ABORTIVE TREATMENT OF HERPES BY THE APPLICATION OF EITHER PURE ALCOHOL OR OF AN ALCOHOLIC SOLUTION, AFTER THE METHOD OF PROFESSOR LELOIR.

The treatment of herpes by applications of pure alcohol or of alcoholic solutions sug-

gested itself to M. Leloir under the following circumstances. He himself became subject to intermittent attacks of herpes labialis, and it occurred to him to try the effect of an application of Eau de Botot at the moment when the eruption began to make its first appearance. At the end of some minutes, he observed that not only had the pain entirely disappeared, but that the progress of the eruption was also arrested. In three-quarters of an hour the applications of Eau de Botot had completely stayed the herpetic eruption. Since then this remedy, as employed by M. Leloir in both clinical and private practice, has given most remarkable results.

In his inaugural dissertation M. Dupas has further developed the theories advanced by M. Leloir in one of his clinical lectures given at the Hospital St. Sauveur in the year 1885. He proceeds to explain the symptomatology and pathological anatomy of herpes. He next gives a short critical history of the various kinds of treatment practiced for herpes previously to that adopted by M. Leloir. Under the influence of treatment with alcohol, says M. Leloir in his clinical lecture, it will be found that at the erythematous stage of the disease the complete disappearance of the eruption is the rule—and that too, very rapidly—within a few hours, or even less, if the treatment has been sufficiently energetic.

When the herpes has reached the stage of vesication the disappearance of the eruption should take place in a few days at most.

When the disease has reached the period of vesico-pustulation, or even that of pustulation, it will be found that the duration of the eruption is very considerably shortened, The vesico-pustules and pustules subside and dry up with great rapidity. The same remark applies to the congestive inflammation of the surrounding epidermis. With this treatment you may see a violent attack of either ordinary herpes or herpes zoster develop and be completely cured, all in the course of a few days.

Nor is it on the eruptive element only that this treatment exercises a beneficial influence. It may be affirmed in a general way that the pain at the seat of the eruption is always lessened in a remarkable manner, and the same is true in most cases of the neuralgic pains in adjacent parts.

M. Dupas then passes in review the various forms in which M. Leloir makes use of alcohol. At first, about the year 1882, M. Leloir generally employed Eau de Botot or alcohol 90 degrees in strength. In 1884 he used alcohol of 90 degrees strength with a slight admixture of carbolic acid, which seemed to him to lessen the burning sensation, and even the element of pain. Since 1885 he has prescribed in succession alcohol of 90 degrees with a slight addition of either resorcin, thymol, or menthol.

The following are some of the formulæ preferred by Professor Leloir:

1.	Alcohol of 90 deg.,	100 grammes.
	Resorcin, pure, .	2 grammes (*i. e.*, 10 grains to the ounce.
2.	Alcohol of 90 deg.,	100 grammes.
	Thymol, . .	1 gramme (*i. e.*, 5 grains to ℥j).
3.	Alcohol of 90 deg.,	100 grammes.
	Menthol, . .	3 grammes (15 grains to ℥j).
4.	Alcohol of 90 deg.,	100 grammes (or ℥j).
	Thymol, . .	1 gramme (5 grains).
	Resorcin, . .	2 grammes (10 grains).
5.	Alcohol of 90 deg.,	100 grammes (℥j).
	Menthol, . .	3 grammes (15 grains).
	Extract of Cannabis Indica, . . .	5 grammes (25 grains).
6.	Alcohol of 90 deg.,	100 grammes (℥j).
	Phenic acid, . .	25grammes(about 1 grain).
7.	Alcohol of 90 deg.,	100 grammes (℥j).
	Phenic acid, . .	2 grammes (about 1 grain).
	Extract of Cannabis Indica, . . .	4 grammes (20 grains).
8.	Alcohol of 90 deg.,	200 grammes (℥j).
	Resorcin, . .	6 grammes (15 grains).
	Hydrochlorate of Cocaine, . .	1 to 4 grammes (2½ to 10 grains).
9.	Alcohol of 90 deg.,	50 grammes (℥j).
	Tannin, . .	6 grammes (ʒj).
10.	Alcohol of 90 deg.,	50 grammes (℥j).
	Tannin, . .	5 grammes (50 grains).
	Chlorhydrate of Cocaine, . .	1 gramme (10 grains).

11. Alcohol of 90 deg.,	500 grammes (Oj).
Extract of Cannabis Indica, . . .	25 grammes (25 grains).
Hydrochlorate of Cocaine, . . .	6 grammes (6 grains).
Essence of Peppermint,	50 grammes (6 minims).

These different solutions are applied by meams of pads made of wadding frequently renewed during the day.

M. Dupas concludes by bringing forward some very convincing cases in support of his views.—*Jour. Dermatology.*

CHLORIDE OF METHYL AS A LOCAL ANÆSTHETIC.

Dr. S. E. Berezovsky (*Letopis Khirürgitcheskaho Obshtchestva V'Moskve,* December, 1890) describes experiments on dogs which he has made with the object of testing the anæsthetic action of chloride of methyl, as well as its effect on various animal tissues. The substance was used in the form of a spray. The experiments showed that: 1. a spray of two seconds' duration, when directed against intact integuments, produces complete anæsthesia lasting from fifteen to twenty seconds, the tissues remaining sufficiently soft to allow cutting; 2. a spray of five seconds' duration, while inducing a somewhat longer anæsthesia, freezes the skin to an inconvenient degree; 3. a seven seconds' spray gives rise to consecutive local congestion and inflammation; 4. a twenty seconds' spray causes sloughing of the tissues down to the muscular layer; 5. a convenient and harmless anæsthesia induced by a two seconds' spray, can easily be prolonged up to five minutes by repeating the spray at short intervals; 6. sufficient anæsthesia of exposed bones can be produced in the same way; 7. the spray does not cause either gangrene or thrombosis of blood vessels. The author next employed chloride of methyl (a spray of two seconds' duration, repeated according to the necessities of the case) as a local anæsthetic, in a long series of operations, such as circumcision for phymosis (4 cases,) removal of elephantiases of the prepuce (1,) evulsion of toenails (2,) excision of cancer of the lip (2,) and atheroma (3,) large-auricular dermoid (1,) incision for empyema (2,) scraping out tuberculous ulcers and fistulæ, etc. The results were invariably most satisfactory, the operation being in all cases absolutely painless from the beginning to the end, while the healing of the wound left nothing to be desired, even in badly-nourished patients. The only disagreeable effect was a burning sensation at first; this, however, quickly gave place to complete numbness of the area sprayed upon. On the whole, the writer concludes that the chloride of methyl spray can be employed in all cases where an ether spray is used as a local anæsthetic; and that the former should be preferred to the latter, since 1. it induces anæsthesia "comparatively more quickly" than ether spray; 2. chloride of methyl is uninflammable, and hence can be safely employed in cases of cauterization, etc.; 3. it does not undergo any change from exposure to light or air; 4. it does not irritate mucous membranes even in children; and 5. it is cheaper than ether, since only very small quantities are required.—*Brit. Med. Jour.*

A NEW TREATMENT FOR CANCER.

Professor Adamkiewicz (*Przeglad Lekarski*), who has been for a long time engaged in the study of the poisonous nature of carcinoma, published in the form of a short notice, the successful treatment of 3 cases. No information is given concerning his method of treatment,—a sad imitation of Koch,—only that "he succeeded in producing atrophy of disseminated cancerous tumors." The remedy will be made public when his experiments and clinical observations are finished. The remedy does not elevate the temperature, and does not act injuriously upon healthy organs; nor does it affect the general state of the patient.

In 2 cases, with cancer of the lower lip under treatment by the new remedy, the lymphatic glands diminished in size and local reaction appeared. Microscopic examination of the cancerous tumor and the lymphatic glands showed "that the tissue was rarefied on account of the disappearance of cells."

In the third patient, also with cancer of the lower lip, all the tumefied glands of the neck (13 in number) almost entirely disappeared. The tumor itself was changed in its appearance and dimensions. The hard tumefaction in the mucous membrane around the mouth disappeared. Speech, whistling, and smoking became easy; the body-weight increased 4.20 kilogrammes (9¼ pounds,) in 5 weeks.

ATROPINE IN ENURESIS.

The following is a brief account of a trial

with atropia in 12 chronic bed-wetters in the New York Infant Asylum, Mt. Vernon, N. Y: Nine boys and three girls, the ages ranging from 4 to 10 years, were selected for treatment. It is a custom in the institution to put the children to bed at 6 o'clock and to take them up at 10 to urinate. Being desirous of testing the value of atropia, the habits of life were not changed. The plan of treatment was that used by Dr. Wm. Perry Watson. A solution, consisting of 1 gr. sulphate atropia to 1 oz. distilled water; of this one drop was given for every year of age of the patient, at 4 and 7 P. M.; one-half of this quantity was given, however, in each case for the first few days; no unpleasant symptoms followed, and the full amount was given. Physiological symptoms were produced in three, but were unimportant. After six weeks slight improvement was noticed in four; at the end of the third month these four wet but once or twice a week. Seven were well at the end of the fifth month, rarely wetting. Treatment continued two months longer, when the dose was reduced one-half; this was given two months and stopped. It is nine months since treatment was stopped, and there has been no return of the trouble. The other five, which includes the girls, showed but slight improvement at the end of the fifth month of treatment, wetting nearly every night. During the next three months improvement was gradual, and at the end of the eighth month they wet not oftener than twice a week. During the tenth month there was only an occasional wetting. The dose was reduced one-half, and after a year of continuous treatment there was no wetting. The atropia was stopped, and there has been no return of the enuresis in six months. Eighteen months ago we had 12 chronic bed-wetters of the worst order; to-day they are well—the only medicine used was atropia, given as above.—*Archives Pœdiatrics.*

MEDICINE.

MYXŒDEMA.

The author Buzdygan reports two very minutely observed cases of this disorder, to which the English physician, Ord, first gave the name "Myxœdema," Charcot "cachectic pachydermique," and which is identical with Kocher's "cachexia strumipriva." The first case was that of a female, aged thirty-four; the other; a tailor, fifty years old. Both cases exhibited entirely those characteristic symptoms described by Ord, namely;

1. Characteristic œdema of the skin of the face, us well as of both extremities, thickness of the mucous membrane in the oral cavity, considerable enlargement of the tongue.

2. Changes in the thyroid gland; in one case fibrous degeneration, in the other atrophy.

3. The affection of the nervous system was reduced in both cases only to diminution of the memory and depression of intelligence.

4. Lymphatic glands enlarged.

5. Voice changed, depending on hypertrophy of the mucous membrane of the larynx. This latter may also cause dyspnœa.

6. The changes in the blood are not distinct, no leucocytosis being present, as some authors have reported.

7. Paræsthesiæ in separate spots on the skin, itching, burning, as well as conjunctivitis catarrhalis, caused, according to Landau and Ewald, by irritation of the sympathetic nerve.

8. Both cases prove that after the process of digestion, mucin appears. In one case mucin also was found in the urine.

9. Temperature always subnormal (36.1° C.).

10. A certain connection between the changes in the genital apparatus in females and myxœdema can be accepted. In one of the author's cases menstruation had already ceased in the 28th year, four years before the appearance of the disease, and examination showed atrophy of the uterus.

11. As to the relation between the two sexes, ten females to one man is the generally accepted ratio.

12. Myxœdema mostly occurs in adults (over thirty years.)

13. The treatment in both of the author's cases, as in general, was without effect. Death always follows with the symptoms of collapse or uræmia.—*Gaillard's Med. Jour.*

FORCED RESPIRATION OF OXYGEN.

Dr. G. E. Fell, of Buffalo, records in the *Journal of the American Medical Association*, June 6th, 1891, two interesting cases in which forced respiration of oxygen was used to combat the effects of overdoses of morphine. In the first case forced respiration by means of a face mask was first tried, but without much success. Tracheotomy was then performed, and continuous forced respiration maintained through the tube. With the sole exception of the still con-

tracted state of the pupils and the absence of cyanosis, there were at first no signs of life observable. The pulse and heart beat were quite imperceptible, but little by little they returned, and after twelve or fourteen hours of uninterrupted forced respiration the patient had so far recovered as to be able to breathe for herself, and she ultimately made a good recovery. In this case Dr. Fell observes, "artificial respiration would at no time have been of any avail to the patient." The second case was similar in some of its features. The face mask had again to be abandoned in favor of respiration through a tracheotomy tube, the gas being found to pass into the stomach and bowels as well as into the lungs. Improvement was noticed for a time, but an unlucky act of vomiting was followed by the entry of solid matter into the lungs and sudden cessation of the heart's action. The amount of labor entailed in the maintenance of this continued forced respiration is described as very great, and only possible by the help of "an army of students."—*Brit. Med. Jour.*

THE PULMONARY COMPLICATIONS OF STRANGULATED HERNIA.

From an article by Dr. J. Lesshaft, of the Berlin Pathological Institute (Virchow's *Archiv*, 123, iii.,) it would appear that the frequency with which pneumonia follows upon the reduction of strangulated hernia—operated on by taxis or by herniotomy—and the relation which such lung trouble bears to the intestinal lesion have both been variously estimated. Dr. Lesshaft is mainly concerned in correcting the impression conveyed by Dr. v. Pietrzikowski, who has recently maintained that pneumonia (as judged by clinical signs) is comparatively frequent in these cases, and who further supports the views held by Gussenbauer as to its causation. These views refer the pulmonary condition to embolism following upon thrombosis in the veins and capillaries of the walls of the strangulated bowel, in those cases at least in which no other explanation—e. g. by direct extension from peritonitis or pyæmia—can be afforded. Dr. Lesshaft, on the contrary, after an analysis of all the fatal cases of hernia examined at the Berlin Pathological Institute during thirty years, thinks the hypothesis of embolism is not justified on pathological grounds. He shows that the circumstances under which pneumonia occurs as a sequel to strangulated hernia, and the character of the pulmonary lesions, are such as may well be explained by the entrance into the air passages of vomited matters. The condition, therefore, is one of *Aspirations-pneumonie*, or *Schluck pneumonie*; and that it should be more liable to occur in cases of severe strangulation, or those in which gangrene of the gut takes place, is not surprising, since these are just the cases in which vomiting is most likely to be severe. Pietrzikowski has adduced experimental proofs in support of his thesis, which, however, are not substantiated by Dr. Lesshaft, who found that in the rabbit, pneumonia never followed artificial strangulation of the intestine; and in the dog it only occurred when it was possible for the aspiration of vomited matter to take place. Indeed Dr. Lesshaft is convinced that pulmonary infarctions do not occur in connection with the intestinal changes.—*Gaillard's Med. Jour.*

RECENT RESEARCHES ON THE RELATIONSHIP OF MENTAL TO CEREBRAL PROCESSES.

One of the most interesting of Dr. Münsterberg's researches is that which relates our sense of time duration with the respiratory act. After a most laborious investigation experimental results as to the perception of duration were found to be quite contradictory. There had been no want of ingenuity or precision in the observations. Münsterberg perceived that the discrepancy in the results must depend on the investigators themselves. He discovered that the cause is due to the fact that inspiration increases and expiration diminishes the power of attention, and that the respiratory rhythm is affected byattention. He thus demonstrates a wholly unsuspected relation between our estimate of the passage of time and muscular sense. Nor is this all. Reasoning on the lines of natural selection and the evolutionary hypothesis, he says: "An external stimulus can only have significance in preserving the organism if it have a centrifugal effect." Sense stimulus issues, for the most part, in muscular contraction; it issues in contraction, but not necessarily in movement, for we may have, of course, equilibrium due to the opposed contraction of antagonistic muscles. Thus, even when we sit down in the easiest position in our most comfortable arm-chair, and, letting the muscles go flaccid, set ourselves to think, we shall nevertheless be able to recognize the strain of antagonistic muscles, and discover a certain rigidity of the neck. His attention being thus directed to the importance of the muscular sense, Dr. Münsterberg instituted an elaborate series

of experiments which would tend to show that all our capacity of measuring quantity is dependent on feelings of strain which arise from muscular tension. Feelings of quantity differ from feelings of quality, in that the greater contains the less. Dr. Münsterberg thus resolves all measures of duration in time and extension in space into dependency on the varying quantity of muscular sensation. The small muscles of the eye and ear would thus come to play an importont part in acquainting us with varying intensities of visual and auditory phenomena. Dr. Münsterberg, therefore, boldly proceeds on this basis of muscular strain to measure and reduce to a common standard the intensities of the different senses. Unfortunately, in this series of experiments, Dr. Münsterberg allowed himself to become the subject of experiment. It remains to be seen, by a careful repetition of these experiments in other hands, how far subjective expectation was a factor in the results.

Like Herbert Spencer and many others, Münsterberg would appear to desire to resolve our notions of time and space into simpler elements. But, as Professor Ladd observes: "To describe the rates and order and duration of successive ideas is a very different thing from explaining the idea of succession," we may show what contributes to the developed notion of time and space in the evolution of the individual, but the Kantian position would certainly appear to be impregnable. No collocation of sensations can possibly amount to the forms of time and space, for they are associated only in time and space, and to attempt to derive that in which they inhere from them is what is popularly called "putting of the cart before the horse."

Valuable as it is to correlate the physical chain with conscious experience, it should ever be remembered, to use Münsterberg's own metaphor, that the physical chain is known only within the "fixed eye" of consciousness. When we use the phrases "cause," "external world," "matter," etc., we use terms which have a meaning in consciousness alone. In referring the consciousness of the individual man to that which lies without him, we establish a relation. But what meaning has relation except as for that which experiences the relation, namely, conscious thought? A relation divested of all known quality is non-existent. When all our psycho-physical labors are concluded the criticism of consciousness remains. As Dr. Münsterberg himself informs us, it is idle to seek in physiology a meaning for the fact of consciousness itself. The criticism of the nature of consciousness must be found, if anywhere, within consciousness itself. Such a criticism, so far as it has been made, has long recognized the impossibility of an entity or thing-in-itself, which neither thinks nor feels. But, of course, this is *caviare* to those who eagerly swallow a cheap and easy materialism. Those who identify a physical with an ontological explanation are the worst of metaphysicians, because they are wholly unsuspicious of the fact that they are so. They adopt a hypothesis, the presuppositions of which they have never attempted to analyze. They remind one of the famous personage who:

> Was certain that the world is square,
> Because she'd travelled fifty miles and found
> No sign that it is circular anywhere.

—*Brit. Med. Jour.*

A CASE OF CONGENITAL HYGROMA.

Dr. Benjamin Ipavic (*Wiener med. Wochenschrift*, No. 24, June 13th, 1891) relates a case of congenital hygroma of the left axilla cured by antiseptic drainage. The patient, a boy aged 2 years, was born with a tumor the size of an apple, situated well on the outer side of the left nipple. During the first year it grew very slowly; towards the end of the year a navel-like depression appeared near its middle, and the tumor diminished somewhat. In the second year it grew rapidly and extended into the axilla. On the side of the thorax it reached as high as the clavicle, and its inferior limit corresponded to the fifth rib and presented all the typical characters of a congenital hygroma. An incision was made on the outer side of the cyst, 4 centimetres long, and a tolerably large quantity of yellow fluid, partly blood-stained, was evacuated. A counter-opening was made, a drainage tube inserted, and carbolized dressing applied. The whole of the hygroma did not collapse with the first incision. Fifteen days later a fresh incision and counter-opening was made and drainage continued. During convalescence the child contracted measles. The first opening was made on March 13th; by the end of June the cyst had shrunk to the size of a walnut, and the openings cicatrized. This, with some adjacent loose skin, was excised. At the end of July the wound was completely healed and the child in good health.—*Brit. Med. Jour.*

SURGERY.

THE TREATMENT OF VARICOSE VEINS.

Dr. William Taylor, in the *Provincial Medical Jour.*, advocates blistering. He discovered its good effects, accidentally, when treating a case of gout by means of blisters, and had since tried it in many cases with considerable success, and found it specially useful in old people. He considered blistering to be "eminently restorative" in varicose veins. Dr. Taylor did not believe in elastic stockings, and considered operative treatment unscientific. He supposed that the coats of the veins participated in some way which he could not explain, in the restored vitality set up by the action of the blisters. He found that the veins remained sound for several years, but were then apt to become distended again, and required the treatment to be renewed. Its great advantage was that it could be used in cases where palliative treatment was contra-indicated, and that it always did good to the solid œdema so often associated with the varicose condition. The details of the treatment were as follows: 1. Remove the cause. 2. Obviate the tendency. 3. Elevate the limb for twenty-four hours. 4. Blister from the foot upwards, six inches daily, watching the kidneys and bladder. First paint the part with Rubini's tincture of camphor, then with blistering fluid, and lastly with collodion. The blisters must rise and serum be withdrawn to do good. 5. When whole limb is blistered, apply plaster to the whole length of the vein for two weeks. 6. Remove the plaster and see what is the result of the treatment. If the veins bulge, blister again; if they are all right apply more plaster, and allow gentle exercise for a week. If at the end of that time the veins are still in good condition, no further treatment is needed.

Landerer, in the *Med. Press*, May 20, 1891, details a new method of treating varicosities. This consists in the application of a kind of truss, that was applied like a garter, and by its permanent pressure on the saphena vein effected a cure. Pressure was obtained by an india rubber pad situated on the inner surface of the truss and filled with water. The pressure was constantly kept up until the wall of the dilated vein was ulcerated through. He had adopted this method of treatment from an observation of a deceased colleague, Herr Ravoth, who treated varicoceles by the application of a truss.

Tobin gives particulars, in the *Dublin Jour, of Med. Science* for June, 1891, of a case of septic phlebitis treated by him, in which the disease was secondary to the removal of portions of varicose veins, and originated not in the operation wounds but in a small ulcer near the ankle. On the ninth day after operation symptoms of acute septic phlebitis were fully developed. The patient had had two marked rigors; temp. 105° All the superficial veins on inside of leg and three inches of long saphenous vein were engaged. Mr. Tobin reflected the skin from the affected parts and removed every diseased vein, following each till an apparently sound point had been reached. The subsequent history was satisfactory. The wound healed rapidly. No further rigor occurred. Severe constitutional disturbance, indicating that secondary centres of infection had formed during the delayed interference, continued, and it was not till a month after the operation that the patient's temperature was normal, and his condition in every way satisfactory.—*Epitome.*

RELATION OF MALARIA TO SURGICAL OPERATIONS.

Dr. M. Perez (*Annals of Surgery,*) says one should avoid as much as possible operations in places or districts where malaria prevails. In cases of operation upon individuals residing in malarial districts, or even those who have formerly dwelt in such regions, although they may never have presented malarial symptoms, they should be subjected to a preliminary treatment by quinine, in order to avoid complications.

Individuals may be met with in whom there is a latent existence of the germ of malaria. These latter may develop when the strength of the patient has been lowered by hæmorrhage, suppuration or other causes.

If one had to decide between a bloody and a bloodless method of operation, the latter should be chosen, for beside avoiding hæmorrhage, a mixed infection is thus prevented.

In cases where operation on account of some suppurative process is necessary, and were malaria has formerly existed, a careful analysis of the urine and an examination of the liver, spleen and kidneys should be made, for the patient may be suffering from diabetes or amyloid degeneration.

If hæmorrhage or intermittent pain follow the operation, they may be combated by the various preparations of quinine.

TREATMENT OF PENETRATING WOUNDS OF THE ABDOMEN.

Dr. Lanphear concludes as follows:

1. All cases of penetrating gunshot wounds of the abdomen demand laparotomy; most others also require it.

2. The operation should be done immediately after the injury, if possible, so as to control bleeding before the patient is exhausted.

3. Any time within twelve hours may be regarded as the "time of selection," but the lapse of many hours, or even days, need not prevent operation, since death from septicæmia is likely to occur.

4. A condition of collapse is not an insurmountable contra-indication.

5. The existence of peritonitis demands rather than forbids, an operation.

6. In gunshot wounds Senn's hydrogen gas test should not be employed, as the indications are *always to operate;* perforation of intestines is not necessary to render the wound fatal. In other penetrating wounds the test may be employed.

7. Laparotomy is, in such cases, comparatively an insignificant operation. Any surgeon of ordinary skill ought to be able to successfully operate.

8. In case of emergency, the operation here described can be made without an elaborate set of instruments. A success can be obtained by the use of only: (*a*), a knife; (*b*), scissors; (*c*), needle and thread; (*d*), hæmostatics; and (*e*), *good judgment.* —*Medical Review.*

THE PRESENT STATUS OF THE TREATMENT OF URINARY CALCULUS.

Every few years we find the practice in any particular form of disease undergoes radical changes, so that the methods in vogue in the near past are almost entirely superseded by newer and more modern ones; or possibly, the profession reverts to an operation largely practiced in the past, one which has remained quiescent for a number of years, only to be again brought forward.

In regard to the affection under consideration, the modern (present day) sentiment appears to be as follows:

1. Wherever possible, resort to litholapaxy.

2. If litholapaxy is contra-indicated by a sacculated bladder, a high degree of cystitis, stricture of the urethra, or an irritable, contracted bladder, one of the cutting operations must be performed.

3. If the stone is not very large, and can be extracted by that method, the median perineal method is preferred.

4. If the stone is very large, or if there is reason to suspect the co-existence of tumors of the bladder, or any reason calling for a complete exploration of the interior of the bladder, resort should be had to supra-pubic cystotomy.

5. The existence of cystitis, or other necessity for drainage of the bladder, calls for the lateral operation.

From the above summary it at once becomes evident that the range of lateral lithotomy has been largely curtailed, while that of litholapaxy has been wonderfully increased. In fact, the crushing operation is now almost universally recognized as the operation of choice whenever possible. The grounds upon which this decision rests are that the crushing operation is less risky; it is applicable to all ages; the time of convalescence is very short compared with the other operations, and the mortality is much lower.

The chief objection against litholapaxy is the possibility of leaving some fragment of the stone in the bladder, to act as a nucleus for a new stone. This oversight has frequently occurred, but the fragment has always been detected early, and is easily removed by reintroducing the lithotrite.

The dangers and difficulties of the median operation are usually slight, but its range of successful application is limited. The time necessary for the healing of the wound is an objection.

Supra-pubic cystotomy is somewhat difficult of performance, more paraphernalia are required, and the dangers of complications are perhaps greater than those of any other operation for the relief of this trouble.

At present the tendency is to almost entirely banish lateral lithotomy from the list of surgical procedures applicable to this affection, preference being given to either the median or supra-pubic operation. Time only can determine whether this condition of affairs will continue or not. Some surgeons still cling to the lateral incision, and are loath to discard it.

In this paper we have endeavored to present to our readers, in as concise form as possible, the views held by the leading surgeons of the day, and have aimed to avoid expressing any prejudiced or biased views. To sum the whole matter up in a few words, we can say—this is an age of litholapaxy.—*Cincinnati Lancet and Clinic,* May 30th, 1891,

---

INGROWING TOE-NAIL.

Dr. Pürckhauer recommends the following method in the treatment of ingrowing toe-

nail: A forty per cent. solution of potassa is applied warm to the portion of the nail to be removed. After a few seconds the uppermost layer of the nail will be so soft that it can be scraped off with a piece of sharp-edged glass: the next layer is then moistened with the same solution and scraped off; this must be repeated until the remaining portion is as thin as a sheet of paper, when it is seized with a pincette and lifted from the underlying soft parts and severed from the other half. The operation does not require more than half an hour's time, is painless and bloodless, while the patient is delivered from his suffering without being disabled even for an hour.—*The Pittsburg Medical Review.*

GYNÆCOLOGY.

MASSAGE AS APPLIED TO THE TREATMENT OF INCONTINENCE OF URINE IN FEMALES.

At the February meeting of the Royal Academy of Medicine in Ireland (*Dublin Jour. Med. Science*, April, 1891) Dr. Bagat read a paper on this subject. He gave a full account of the treatment of this affection by the Brandt system, by Sänger's method, which consisted in dilatation of the vesical sphincter, and also by massage, by distension of the bladder with warm water, as practiced by Nissen and Marion Sims, junior. He had cured three cases by the use of Brandt's system, omitting some of the steps which he considered useless. The most essential part of this method of treatment was the direct treatment of the neck of the bladder by the finger in the rectum or vagina. In children one used the finger in the rectum. The first case was that of a woman aged 30, married eight and a half years, who had borne five children. She had suffered from incontinence more or less since her last confinement eighteen months previously, and had become worse during the last nine months, her water passing from her whenever she walked about, or on making any sudden effort, such as coughing. She frequently passed her water under her when asleep. Examination showed perineal laceration of the first degree, a rather patulous urethra, slight prolapse of the anterior vaginal wall, and vagina and perineum abnormally distensible; uterus and appendages normal; no abnormal tenderness or irritability of the bladder could be detected on passing a sound; the urine was normal. She was at first treated every day for four days by Brandt's system, omitting "the lifting" of the bladder. She was told to wear woollen drawers, and to try to control her sphincter whenever she felt the water passing from her. After this she was treated every second or third day for twenty-nine days. At the end of this time a permanent cure was effected.

The second case, an unmarried woman of 24 years of age, had suffered from childhood from enuresis. Two years previously she had been treated every second day for six weeks by electricity without benefit. Examination revealed nothing abnormal but a slight cervical catarrh, cured by the application of pyroligneous acid. She was treated by Brandt's system—omitting the "exercises for the adductors of the thighs" and "the bladder lifting"—every second day for five weeks, at the end of which time she was discharged quite well.

The third case was similar to the first. Incontinence on exertion had lasted three years. Treatment was carried on for four weeks; during the first week daily, only the "lifting" being omitted. Afterwards the treatment was performed every second or third day, and the tapotement of the lumbar and sacral regions, as well as the exercises for the adductors of the thighs, were also omitted.

Dr. Bagot discarded the bladder lifting, because it would be impossible to elevate and seize that organ by the manœuvre described by Brandt when it was empty; and, were the bladder full, the procedure could not be carried out on account of the sensitiveness of the organ. He failed to see how tapotement of the lumbar and sacral regions could be of any use in this affection, or in uterine displacement, and he had discarded it. The exercises for the adductors might be of use when the pelvic floor was greatly relaxed. The chief part of this method was the direct treatment of the neck of the bladder.

Dr. Bagot had treated two patients by the method of Sänger, who believed the basis of the affection to be paresis of the vesical sphincter with, perhaps, a certain tenuity of the muscular bundles. This method was not indicated when there was any very great dilatation of the bladder neck and whole urethra. In these cases, artificial narrowing of the urethra, by some such method as Schultze's or Pawlik's, was more likely to succeed. When the dilatation was not so great, Sänger advised that his method should be tried. Massage by distension of the

bladder with warm water was of use in cases of contraction of the bladder following long-continued incontinence of urine from any cause, such as fistula, or where patients had formerly suffered from cystitis of long standing. Dr. Bagot urged the necessity of a careful diagnosis in all cases, paying special attention to the urine and to the other pelvic organs. He found Dr. Nitze's cystoscope to work efficiently, and he employed this method of examination in all cases of bladder trouble. In reply to some objections by Dr. More Madden, Dr. Bagot said that, in applying massage where stroking movements were used, they were performed by the external hand through the abdominal wall, the fingers in the vagina being held quite still, and being used simply to raise and support the parts while being massaged. The internal hand did not move more than during an ordinary bimanual examination. He explained that he had not said he massaged the bladder, but its neck. This he considered the essential part of the Brandt treatment, and it could be applied per vaginum or per rectum, no matter how empty the bladder might be.

OBSTETRICS.

VOMITING OF PREGNANCY AND HYSTERIA.

Kaltenbach holds that the clinical history and the "cures" of cases of uncontrollable vomiting of pregnancy indicate that the disease is essentially due to hysteria. Pregnancy involves physiological and psychological conditions favorable to the development of hysterical symptoms in a modified form. Hyperæmesis is often cured by a process akin to suggestion, like ordinary hysteria. "Doing something," dilatation of the os, massage, etc., often succeeds if the practitioner gains the patient's confidence, and hosts of drugs have answered, apparently under the same conditions. On the other hand, all these vaunted medicines and operations have failed when employed by physicians who possibly did not possess as much tact as knowledge. Hyperæmesis may suddenly cease if the patient be alarmed, as in a case of the author, where the patient was reduced to a skeleton; a day being fixed for the induction of labor, her friends frightened her by saying that she could not survive such an operation. The vomiting ceased. The same sudden arrest of hyperæmesis was observed by Cazeaux in a young wife whose husband was seized with symptoms of strangulated hernia. In a third case, the vomiting ceased on the outbreak of an acute exanthematous fever. Kaltenbach describes a bad case where the patient, aged twenty-one, made an unhappy marriage, and was unkindly treated by her husband. Very severe vomiting set in during her first pregnancy, and she was sent into a Hospital. It was suggested to her that she had lumps of unwholesome material in her stomach, and that their removal would cure her. Some milk was given to her, ceremoniously, and shortly after the stomach was washed out. Its contents bore no indications of either over-acidity or any abnormal ferment. The patient was then informed that all was right, and that the vomiting would not return. It ceased accordingly, and she was safely delivered at term. In short, Kaltenback urges that hyperæmesis gravidarum should be treated as a purely hysterical complaint. Prompt treatment is indeed necessary, for as in hysterical vomiting of non-pregnant women the patient may, if at first neglected, die of syncope or nervous exhaustion even when the vomiting has been stopped. But isolation from domestic cares and imprudent friends, with appropriate moral treatment, should be enforced before so extreme a step as artificial abortion is undertaken.—*Boston Med. Surg. Jour.*

MORPHINE IN PREGNANT, PARTURIENT AND NURSING WOMEN.

Fürst (*Arch. d' Obstet. et de Gyn.*, March, 1891.) Owing to the contradictory opinions on the subject, Fürst has made a study of the effect upon the fœtus, of morphine administered to the mother. One woman during her first pregnancy had taken about 1,200 hypodermic injections of a three per cent. solution of morphia; during her fourth pregnancy 800 of a similar solution were taken. The children were well developed physically and intellectually—and they had not acquired the morphine habit. Before birth, however, the fœtus were quiet after the exhibition of the drug to the mother and the movements became painfully active when its effects passed off. From this and similar observations Fürst concludes that morphia does not compromise the life or health of the fœtus to so great an extent as has been assumed. Its moderate use in pregnant women is without danger and it may be given with advantage in the treatment of threatened abortion or premature labor. During labor its use is more dangerous, especially in pro-

longed labor. In nursing women the drug passes rapidly into the milk.

INCISION OF THE OS UTERI DURING PARTURITION.

Guéniot (*Jour. de Méd.*, March 22, 1891,) says that after one has tried various other means for overcoming rigidity of the os without success, one may be forced to have recourse to incisions, and he advises the following method in case incisions are decided upon: 1. Rigorous antisepsis. 2. The use of long and strong scissors, or in certain cases of a blunt-pointed bistoury. 3. The directing of the instrument with two or more of the fingers. 4. The pressure of the fingers within the uterus upon the uterine tissue in such a way that bridges or prominences will be thrown out which can be readily cut. 5. The multiplication of these incisions superficially in preference to diminution of their number with increased depth. 6. In cases in which it is advisable to limit the number of incisions to two or three, it is better to make them in the transverse diameter of the neck and so avoid wounding neighboring organs.

PÆDIATRICS.

THE RADICAL CURE OF HERNIA IN CHILDREN.

The various operations for the radical cure of hernia in children are discussed by Dr. Henry O'Neill in the *British Medical Journal.* In his opinion, the most suitable cases for operation are the following: 1. Those of children of the poor, who either are unable to buy trusses or can not look properly after their daily application. Unless a truss is properly fitted and applied it is worse than useless. 2. Those of children in whom the hernia is so large that an ordinary truss is not sufficient to keep it reduced while the child is running about at play. 3. Most cases where a truss has been worn for at least twelve months without improvement, or where the hernia is increasing in size. 4. Those of children who are likely to become laborers in later life. 5. Every case after kelotomy has been performed for the relief of strangulated hernia.

In deciding upon the method to be employed, each case must be treated according to its own peculiarities, and exposure of the sac is usually necessary before these can be ascertained. In congenital hernia Macewen's method is best. If the sac has been torn and the wound is not easily closed, the sac may be ligated close to the neck and cut off half an inch below the ligature, and the upper end of the sac sutured to the abdominal muscles above the internal abdominal ring. This is known as Bank's method. Barker's method may also be selected, by which the sac is ligated in two places and divided between the ligatures, the upper part being sutured to the abdominal muscles and the lower part retained in the scrotum.

The following conditions must be observed to insure success: The patient is to be prepared for the operation by being given a warm bath each day for several days, having the bowels kept free, being given a milk diet and being kept in bed. The parts are to be prepared by thorough washing with soap, then with alcohol, and finally with a solution of carbolic acid or creolin. All hæmorrhage is to be arrested, and the wound drained with a bone drainage-tube, chromicized catgut being used for sutures and ligatures. The bandage and the dressings, which should be of absorbent wool, are to be firmly covered with an India-rubber web bandage. The wound should be dressed seldom, and only when the discharges stain the outer dressings, or when the temperature rises suddenly above 101° F. An opiate may be given for two or three nights. An anæsthetic should be used for the first two dressings, to prevent the child from crying and straining the abdominal wall.

Mr. R. W. Parker also contributes a paper on the same subject, and describes his method of operating. An incision two inches long is made to expose the sac, which is then cleared of the looser and more external layers. All the adventitious structures are not cleared away, for the sac proper in children is very thin and liable to tear. The spermatic cord being put well out of the way, the sac is drawn down as far as possible and three or four stitches are put in, drawing the neck of the sac firmly together. The object is to retain the silk ligatures permanently *in situ*, or as long as possible. If drawn too tight they are apt to cut their way out and so lead to failure. The neck of the sac is now allowed to retract well back within the external abdominal ring, after which the pillars are drawn together and the wound is closed.—*N. Y. Med. Jour.*

HYGIENE.

GOUT AND FRUIT EATING.

In the last number of his *Archives of Surgery*, Mr. Jonathan Hutchinson says that he has for many years been in the habit of forbidding fruit to all patients who suffer from tendency to gout. In every instance in which a total abstainer of long standing has come under his observation for any affection related to gout he has found on inquiry that the sufferer was a liberal fruit eater. Fruits are of course by no means all equally deleterious; cooked fruits, especially if eaten hot with added sugar, are the most injurious, the addition of cane to grape sugar adds much to the risk of disagreement. Fruit eaten raw and without the addition of sugar would appear to be comparatively safe. Natural instinct and dietetic tastes have already led the way in this direction, few wine drinkers take fruit or sweets to any extent, and Mr. Hutchinson suggests as a dietetic law that alcohol and fruit sugar ought never to be taken together, and he believes that the children of those who in former generations have established a gouty constitution may, although themselves water drinkers, excite active gout by the use of fruit and sugar.—*Brit. Med. Jour.*

HYGIENE AND HOSPITALS IN ST. PETERSBURG.

In 1889 the 11 hospitals of the city ministered to nearly 50,000 sick persons—that is, to 5 per cent. of the entire population of the city. There should be reckoned besides in St. Petersburg 42 hospitals sustained by the different institutions, 40 infirmaries and dispensaries and 16 lying-in establishments. In general the municipal council devotes special attention to the department of public health. It has constructed an immense filter through which passes all the water that is distributed to the city; it renders healthy the populous portions; it supplements the efforts of physicians in giving gratuitous service to the poor; it visits the poor in advance that they may not come upon the city for support; it creates abattoirs and laboratories for the analysis of articles of food or in its preparation; it inspects the markets, the back shops, the kitchens of the restaurants, etc. That which argues much for its activity, there are numbers of statistical bureaus. In 1881 the mortality of St. Petersburg had risen to 38.2 in 1,000; in 1884 it was only 34.4 to 1,000; it has since continued to decrease, and in 1889 it was only 27.2. In ten years it had, therefore, diminished 33.5 per cent. Such figures require no comment. Would that every district of Russia would take for its model its capital.—*L' Union Medical.*

MEDICAL CHEMISTRY.

A NEW SUBSTITUTE FOR MUSK.

Another claimant for favors as a cheap substitute for musk made its appearance in trade some weeks ago. It is manufactured in Germany, and appears in the form of a white, crystalline powder in needle-shaped crystals a few millimeters in length. It is called tonquinol. It is said to be suited both to soap and perfume manufacture, to remain impervious to the influence of light for a prolonged period, and to be easily soluble. An alcoholic solution of 1 to 50 may be diluted with water to any extent, and herein it differs from musk Baur. Tonquinol is said to be soluble in most of the usual solvents, including fats, oils, ether and chloroform. Its odor is not affected by boiling caustic potassa. The price is about 25 per cent. lower than that of musk Baur. —*Chem. and Drug.*

NEWS AND MISCELLANY.

THE VASOMOTOR NERVES OF THE RETINA

Doyou (*Arch. de Physiol.*, 3, iii, l, p. 13, 1891) finds that electrical stimulation of the sympathetic nerve or asphyxia causes dilatation of the retinal blood vessels. The same result occurs when the animal is asphyxiated after section of the sympathetic nerve, so that obviously, besides the sympathetic nerve, there is still some other channel by which the vasodilator impulses reach the retina. This is the fifth nerve. If in a dog the sympathetic nerve be divided, after waiting twelve days until the nerve fibres of the sympathetic are degenerated, then exposure and stimulation of the Gasserian ganglion within the cranium caused dilatation of the retinal vessels, and at the same time redness of the lips and gums.—*Brit. Med. Jour.*

A COURSE OF LECTURES ON DISEASES OF THE URINARY APPARATUS BY DR. J. W. S. GONLEY.

A course of lectures on Diseases of the Urinary apparatus is to be delivered by Dr.

J. W. S. Gonley at the Mott Memorial Hall, 64 Madison Ave., New York, beginning Tuesday, October 6, at 8.30 P. M. There will be one lecture every Tuesday night at the Mott Hall, and one clinic at Bellevue Hospital every Saturday at 3 P. M. The lectures and clinics are free to the profession and to students of medicine.

MENSTRUATION IN THE MALE.

Paul Albrecht (*L'Anomale*, 1890, Ill.,) draws attention to the fact that white blood corpuscles appear in the urine of men at regular intervals, are present three or four days, and then disappear. This he interprets as a kind of menstruation. The idea is not a very strange one, for it is a known fact that men with excessive hypospadias menstruate. He offers this as another proof of the independence of menstruation and ovulation. It is to be hoped that further investigation will afford a clearer exposition of the subject.

VACCINATION.

Before the vaccination by Jenner was adopted, smallpox was one of the most formidable scourges of the human race, causing a mortality of 10 per cent. Since its general adoption it is less than 1 per cent. During the prevalence of smallpox in Prussia, from 1857 to 1861, nearly eight thousand among the civil population died. The mortality in the army, where vaccination was rigidly enforced, was practically *nil.*

During the period of thirty years just before the introduction of vaccine in the province of Trieste, the deaths from smallpox alone were 14,000 per 1,000,000 of inhabitants, and only 182 during the period of two years which followed the practice of vaccination.—*Weekly Medical Review.*

A DIAGNOSIS.

A writer in the *Western Medical Reporter* facetiously writes: Nature with a lavish hand has endowed the human body with no less than s'teen million of spots to which an ache or pain can be attached. When each one of these spots, both inside and out, is filled with a hard platinum tipped pain; when your head aches so that you are conscious of all the ruffles and scallops on your brain just as you see them in the pictures in your physiology; when your heart thumps and your stomach wobbles and you have the feeling that something is wallowing through your inside works; when your sternum feels stove-in and there is an uneasiness under your shoulder blades as though your wings were beginning to sprout; when you are one moment alive to the finger tips with thinking of the things you must get up and do and the next completely exhausted by even the thought of doing them; when your back-bone has the sensation of being twisted by a monkey-wrench; when you are so dizzy that you can't see, and your ears ring and eyes water and your nose is in such a state that it is presumption to lay aside your handkerchief for one short minute; when you cough and sneeze and groan in turn—in fine, when you feel like the very deuce—you can set it down that you have the grip.

EXPENSIVE DRUGS.

The following price-list, copied from Vol. II, page 56, of the *Diary of a War Clerk* (Lippincott & Company), will tell some of the many disadvantages under which the Army Medical Department of the Confederate States of America labored during the Civil War:

Quinine, . . .	$100.00	an ounce.
Calomel, . . .	20.00	"
Blue Pill, . . .	20.00	"
Opium, . . .	100.00	"
S. N. Bismuth, . .	100.00	a pound.
Bicarbonate of Soda,	5.00	"
Bichlorate of Soda, .	14.00	"
Ol. Bergami, . .	100.00	"
Cupri Sulph, . .	10.00	"

CONTRACT-PRACTICE IN BERLIN.

The Berlin correspondent of the *Therapeutic Gazette*, July, 1891, gives some racy news from the immaculate German capital. One part of this letter possesses a special interest for the physicians of New Orleans. The correspondent describes the evils of contract-practice as it exists there, and which he dominates "society practice"—precisely what it is called in New Orleans. Our physicians may find some consolation in reading the correspondent's remarks, and if they do find it they are welcome to it. He says:

"The Berlin physicians are just now greatly agitated by the question of 'Krankenkassenaerzte' (physicians of sick-benefit societies). Hitherto a member of such a society was compelled to consult the doctor of the society, who received a yearly salary for his services. As all Berlin workingmen and working women are legally compelled

to belong to a sick-benefit society, the work of doctors elected by such societies is naturally an enormous one. Their houses are actually besieged by patients, while hundreds of other physicians have no patients at all. The consultations which the "society doctors," as I will call them, grant to each patient are ridiculously short and absolutely incapable of benefiting the patients. I have heard of doctors "doing" over one hundred patients a day, and also have heard the number of minutes allotted to various consultations:

Minor surgical cases, . .	15 minutes.
Gonorrhœal affections, .	10 "
Headache and other pains, .	5 "
Influenza, ...	6 "
Rheumatism, . . .	6 "
Examination of the lungs, .	5 " etc.

It is evident that this state of affairs is an improper one and equally undesirable for both patients and doctors. To enhance the morbid character of the affair, the compensation of the physicians is a ridicuously low figure, viz: *eight Phennige* (two cents) per consultation, on an average. This figure is no fancy of your correspondent's brain, but has been officially fixed by statistical investigations and has been published broadcast in all papers. Imagine the blissful state of the practitioner rewarded by two cents for an auscultation of the chest. At last the Berlin doctors have waked up and taken energetic steps toward extinction of this shameful condition."

THE CHINESE CEMENT SCHIO LIAO.

The Chinese manufacture under the name of Schio-liao an excellent cement capable of joining broken porcelain, glass goods, stoneware, marble, etc. The proportions and ingredients are as follows: Lime reduced to a fine powder 54 parts, alum 6 parts, fresh blood 40 parts. The materials are vigorously worked up together into a mass of a homogeneous consistency. When diluted it may be used for saturating cardboard and objects made of paper, the result being that they become as hard as wood. The Chinese also use this cement in a dilute form as a protective varnish for the walls of their houses, and also for varnishing the interior surface of those vessels in which they carry oil and other fatty matters.—*Pottery and Glassware Rep.*

ALCOHOL IN PATENT MEDICINES.

A drink of whiskey is resorted to by the toper to "make him feel better." Alcohol seems to produce a temporary elation which many makers of patent medicines take advantage of. If a dose of the medicine seems to affect the patient at once, the presumption is that he will go on taking the remedy. Besides this, if the alcohol habit is once formed it will be hard work to discontinue taking the medicine just as it is hard to stop drinking whiskey when the habit is once formed. Look out for a majority of the "bitters"—they are simply disguised alcohol.

In the report on nostrums, proprietary medicines and new drugs, which was read before the American Association for the Cure of Inebriates, is found in the appendix the following list of the results of the analyses of a large number of well-known patent medicines. Some of the more popular ones contain alcohol as follows:

	Per cent. of Alcohol
Dr. Buckland's Scotch Oats Essence, (Also 1–4 gr. morphine to the ounce.) A more insidious and dangerous fraud can scarcely be imagined, especially when administered as this is recommended, for the cure of inebriety or the opium habit.	35
The "Best" Tonic,	7.65
Carter's Physical Extract,	22
Hop Tonic,	7
Howe's Arabian Tonic. "Not a rum drink."	13.2
Jackson's Golden Seal Tonic,	19.6
Leibig Co's. Coca Beef Tonic,	23.2
Schenck's Seaweed Tonic, "Distilled from seaweed after the same manner as Jamaica spirit is from sugar cane. It is therefore entirely harmless, and free from the injurious properties of corn and rye whiskey."	19.5
Atwood's Quinine Tonic Bitters,	29.2
L. F. Atwood's Jaundice Bitters,	22.3
Moses Atwood's Jaundice Bitters,	17.1
Brown's Iron Bitters, "Perfectly harmless. Not a substitute for whiskey."	19.7
Burdock Blood Bitters,	25.2
Carter's Scotch Bitters,	17.6

GYNÆCOLOGY IN SPAIN.

Gynæcology is at present occupying the medical world of Madrid, and in accordance with the grandeur that is inseparable from Spanish monarchy, the attempt to found a suitable institution for the teaching of midwifery and diseases of women in Spain is being made on a most elaborate scale.

The last number of *El Siglo Medico* gives the scheme of the intended institution. From the report I learn that the course of study in the new institution is to be extensive and thorough. Three years' study will be required for the license. The studies appointed are:—

1. The anatomy of the female, with special reference to midwifery and diseases of woman.
2. Embryology and histology.
3. Physiology, especially in its relation to the female.
4. Hygiene.
5. Midwifery.
6. Diseases of women.
7. Female surgery.

The practical instruction is to include:—

1. Obstetric clinics.
2. Gynæcological clinics, and
3. Instruction in the use of instruments and so forth.

During the first year the students are required to study anatomy, embryology, histology, and attend laboratory instruction for the first session; in the second session of the year, physiology and hygiene are added.

The second year is devoted to practical midwifery, gynæcology and pathology, and surgery of the female.

The third year is devoted to clinical teaching.

Everything that forethought and an intimate knowledge of the requirements of the profession demand is being done to place Spanish gynæcological medicine in the front rank. All will wish the undertaking success. We cannot forget that in the past, Spain promoted science; Roger Bacon drew his inspiration from the Peninsula, the Spaniard Bonetus introduced in modern times the oral instruction of deaf mutes, Servetus foreshadowed Harvey in the discovery of the blood, and it was a Spanish monarch who honored Vesalius, the father of anatomy. The country of Cervantes, Lopez de Vega, and Calderon, is capable of much good work. The conquest of the Western Hemisphere, the expulsion of the Moors, the legacy begotten of Charles V in the German Empire, the family feuds of the Bourbons, all diverted the Spanish from science, but a happier epoch commenced with Alphonso's birth, and everything points to the "victories of peace" that will elevate Spain to its rightful place among civilized nations.—*Medical Press.*

THE IDENTITY OF PUS COCCI AND ERYSIPELAS COCCI.

At the meeting of the Medical Society of Hamburg, of June 9th, E. Fraenkel demonstrated the cocci of pus procured from inoculation with the cocci of erysipelas. He had already procured a true erysipelas in the ear of a rabbit by inoculation with pure cultivation of the streptococcus, and now he had succeeded with the converse experiment of producing the streptococcus from inoculation with the cocci of erysipelas. Clinical observation confirmed what he had stated. Abscesses containing streptococci were often met with in patients suffering from erysipelas. In a case of secondary facial erysipelas, a point of exit was found in a whitlow under the nail which contains streptococci. In another case a primary erysipelas of the face was followed by a phlegmon of the breast and the mediastinum, as well as by pleurisy. Streptococci were found in all these cases. For the sake of experiment he inoculated pure cultivations of the erysipelas coccus upon the peritoneum of mice, and on the ear of rabbits. In the first case peritonitis was set up and in the other abscess of the ear. In both cases examination revealed the streptococcus as usually met with in abscesses.

MEDICAL AND SURGICAL REPORTER

No. 1806. PHILADELPHIA, OCTOBER 10, 1891. VOL. LXV.—No. 15.

CLINICAL LECTURE.

ASTHMA.

BY JAMES M. ANDERS, M. D.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE, CLINICAL MEDICINE, AND HYGIENE AT THE MEDICO-CHIRURGICAL COLLEGE, OF PHILADELPHIA.

We have before us to-day A. B., 17 years of age, the son of a farmer. Since four years of age he has had attacks of dyspnœa, at first supposed to be croupous. He now has rest from the attacks for a week at a time. They usually occur at intervals of about a week or ten days. One way he gets rest, namely, by leaning forward over the back of a chair. Family history is almost negative. A sister had convulsions commencing with teething and continuing through life. His attacks came on in the morning, between two and three o'clock. In all patients, similar attacks usually come on after midnight, and may be preceded by itching of the skin; by a sense of constriction in the throat. Sometimes, in this patient's case, the attack lasts only until morning; sometimes all the next day, and the patient feels as if his windpipe was stopped up. He wheezes, especially when the breath is being blown out. When the attack is passing off, he spits up mucus. The patient thinks a "cold" brings on such attacks.

The symptoms given point to asthma. Asthma may be symptomatic; it may be a disease *per se;* it may be secondary to emphysema; secondary to brain troubles and to heart disease.

On examination, vocal fremitus is normal. On inspection, there is epigastric impulse. This is probably due to hypertrophy of the right ventricle. On percussion, resonance is normal in all parts, while auscultation reveals nothing abnormal. If examined during an attack, the lower part of the chest would be seen to be depressed at each inspiration; his hands would be found grasping the knees in order to aid respiration; vocal fremitus would be normal unless some of the tubes were entirely occluded in local patches, and when this does occur it is generally at the back.

The physical signs to guide one, however, are those obtained by percussion and auscultation. During an attack there would be exaggerated percussion resonance, because of the contraction of the smaller bronchioles preventing free exit of air. On auscultation, we get all kinds of râles, whistling, snoring, cooing, etc. Being all made in a dry stage, they would be classed as sibilant or sonorous râles. Sibilant râles show that the caliber of the smaller tubes is much diminished. When the attack is about to break up, the sounds become more moist and we get subcrepitant râles. In the larger tubes we may get mucous râles. The subcrepitant râles are heard both on inspiration and expiration. When the attack breaks up the air seems sometimes to pass suddenly with perfect freedom to all parts of the lungs. Sometimes an attack passing off, stays away for weeks, or even months. It may come back without any apparent cause. Sometimes the patients know the cause, which may be that they have eaten something indigestible or have taken cold.

The predisposing causes of asthma are summed up in one word: heredity. Asthma is closely allied to emphysema, which is also hereditary. The disease is apt to skip one generation. We are apt to find in the family a history of convulsions also. Frequently, where there are cases of asthma in a family, you also have cases of rheumatism; well marked gouty, or rheumatic diathesis. It may not, however, be in the same generation in which the attacks of asthma occur. In this young man's family there is no history of gout nor of rheumatism, but of convulsions, you will recall.

The exciting causes are powders or dusts

of various sorts in the atmosphere (some people who live in the country and are affected may move to a city where the atmosphere is smoky, and be entirely relieved). One exciting cause is the influence of a well-marked "cold," as in this case. Any irritation of the nerves of the nose, of the stomach, of distant organs, may cause asthma by reflex action on the nerves of the bronchial mucous membrane.

The prognosis should always be guarded. When the attacks occur in the young, are not severe, with long intervals between and where there are no complications, the prognosis may be favorable. When the attacks come on at middle age, where they are severe and especially where they have led to secondary affections, such as emphysema, the prognosis is unfavorable as to recovery; favorable as to life.

Asthma is not a disease of old age. Before ten years, more cases occur than in any other decade. The reason it is seen in the old so frequently is because those who develop the disease while young, carry it through life with them.

The treatment must be directed to breaking up the attack and to prevention of a recurrence during the interval.

During the attack if it be severe, the remedy must be heroic. Not, however, in the old. In the young adult, in very severe cases, give morphine, not more than ¼ grain doses hypodermically. It is not generally necessary to repeat the dose. If morphine will not succeed or is contraindicated, chloroform may be given by inhalation. It should be given until the attack shows signs of breaking up, when a return of the attack should be awaited before again using it. It may be necessary to carry the chloroform to the point of insensibility. This does no harm but should not be carried beyond that point. Another remedy is tincture of lobelia, which may be given in 5 or 10 minim doses every half hour until the attack is broken up. Some cases will not stand lobelia. The lobelia should be stopped as soon as the attack is over. Smoking of stramonium leaves saturated with a solution of nitrate of potasssium, then dried, is a valuable remedy. Nitrate of potassium may be tried alone. It is prepared by taking a piece of bibulous paper, soaking it in a saturated solution of the potassium nitrate and allowing it to dry. This is then burned so that the smoke may be inhaled. The effect of this remedy is not understood; it may be due to the smoke; it may be due to chemical substances formed in he combustion. Chloral may be used, and may be given in a single dose of 30 grains. If no relief follows, 30 grains more may be given, but you should not go beyond this. Bromide of potassium does good, but is too slow to use during the attack. It may be used, with other remedies, during the interval, and gives beneficial results. It is said that when everything else fails, alcoholic stimulation is sometimes found to be of use. It is best given in the form of hot toddy.

To prevent the recurrence of the attacks, first remove the known causes. Then attend to the food, clothing, exercise. Woolens should be worn next the skin and moderate but persistent exercise in the open air, should be taken. Patients who suffer from asthma should take light suppers, as overloaded conditions of the stomach certainly have a tendency to bring on severe attacks.

To control the passive congestion which occurs during an attack and some time after, iodide of potassium or syrup of hydriodic acid should be given. The use of either of these remedies must be persisted in; the effect is always gradual. Along with the iodide of potassium in these cases, we give arsenic as follows:

℞ Potassii iodidi..... gr. v.
Liq. potassii arsenitis..... m. v.

after meals, in water. When the patient cannot take the iodide, give syrup of hydriodic acid. Arsenic feeds the blood and stimulates the respiratory centers.

As a word of caution, let me tell you never to advise the patient to use chloroform himself. We shall tell this patient to use tincture of lobelia, five minims every half hour, until the attack is broken up; besides, we shall give regularly the prescription containing the iodide of potassium and Fowler's solution.

There are remaining a few minutes, which it might be well to develop to the differential diagnosis of asthma. The most frequent conditions with which it is confounded, are acute or chronic bronchitis. Bronchitis frequently causes a certain degree of shortness of breath, especially when associated with heart affections. However, the dyspnœa of bronchitis does not come on nor go off so suddenly as that of asthma, nor do we have the absence of respiratory murmur during the attack, and abundance of expectoration at the end of it.

Asthma is frequently associated with emphysema. These two affections are each cause or effect of the other at different times. The history sometimes tells us which is the primary affection. When attacks of asthma show

the absence of symptoms and physical signs between the seizures, it is indicative of the absence of emphysema. This was the case in the patient before us. In emphysema, the dyspnœa is permanent, the chest is permanently enlarged.

Another disease sometimes mistaken for asthma is a spasmodic contraction of the diaphragm, occurring usually in hysterical women. In this disease there is the same form of inspiration but there is not the same violent effort at expiration. In hysterical cases there is inspiration after which the breath is held, and then the expiratory movement is easy.

In membranous croup the breathing at first seems like a bad attack of asthma. In croup, however, the dyspnœa attends inspiration, not expiration; indeed in all diseases which affect this part of the organism, that is the larnyx and trachea, the dyspnœa occurs on inspiration.

Another disease mistaken for asthma, is intercostal neuralgia. In this disease, there is tenderness at the point where the nerve emerges; the breathing would not be similar to asthma on expiration. There would not be the pain in asthma, which is present in intercostal neuralgia. In intercostal neuralgia the seat of tenderness is either near the spine, in the back, or near the sternum, in front.

COMMUNICATIONS.

SUCCESSFUL OPERATION IN FRACTURED AND DISLOCATED VERTEBRÆ.

BY H. A. BOYLE, M. D.,

STATE HOSPITAL, FOUNTAIN SPRINGS, PA.

On May 8, S. M., aged 20 years, was admitted to the State Hospital at Ashland, suffering with an injury to the spine which he encountered by being struck by a passing train at St. Clair. He was under considerable shock and had complete loss of motion and sensation from the hips down. From the deformity and symptoms a diagnosis of backward dislocation with or without fracture of the 10th, 11th and 12th dorsal vertebræ was made. Attempts at reduction by extension and pressure were without avail, and an operation was suggested to the patient, which he refused. There was slight priapism, but no paralysis of the sphincter. For the first week after the injury catheterization was necessary, but after that he was able to void his urine. Once the urine was bloody, but frequent use of the catheter kept the bladder in good condition. He had continual, severe ataxic pains from the knees down, more marked in the left leg, with hyperæsthesia in both legs. Stubborn constipation was always present, which was controlled by enemata. Temperature was never more than one degree from the normal, usually a little below. Much care was necessary to prevent bed sores. He was put on a mixture of Tr. Nucis Vomicæ and Fl. Ext. Ergot, of each ℥ss. 20 drops 4 times daily. Nocturnal emissions were very common. His appetite was always poor, but the stomach never irritable. He gradually sank, until on July 12, he consented to an operation, when Dr. Biddle, assisted by the hospital staff and Dr. Brady, of Scranton, cut down on the spinal column, and found a sharp dislocation between the 9th and 10th dorsal vertebræ backward and between the last dorsal and first lumbar forward. The bodies of the three vertebræ being so far backward as nearly to occlude the canal and producing great pressure on the cord or the two sites of dislocation. The cord was also stretched from the normal position. An incision 8 inches long to the left of the spinous processes was made. All of the bony canal down to the bodies of the three dislocated vertebræ was removed and the posterior part of the bodies was chipped off and shaped up to relieve the cord, thus leaving that part of the cord in this situation entirely without any bony covering posteriorly. Spiculæ of bone were removed and the wound made thoroughly aseptic by the use of bichloride solution 1 to 1,000. In shaping out the bodies the cord was lifted out of place with a retractor. Continued suture of ordinary black silk was used, and a drainage tube inserted. He was under ether about 30 minutes and stood the operation well. Primary union took place with no bad symptoms. On the second day after the operation he showed slight signs of motion in the toes, this movement being barely perceptible. Sensation also was faintly noticed. Since that time the ataxic pains have ceased, he now has good sensation and motion, and can stand up and walk with the aid of parallel bars. He sleeps and eats well, is cheerful and has gained much flesh. The history of this case seems to point out that in many cases of fractured and dislocated vertebræ with much pressure, immediate operation might do much good, and that

many patients with "broken back" who otherwise would go on gradually but surely to death, might be saved by such procedure.

OPERATIVE TREATMENT FOR RUPTURED PERINEUM. *

BY DR. E. E. RICHARDS,

OF NORRISTOWN, PA.

This injury to the perineum is of such frequency that the operation for its repair is the commonest and best known plastic procedure.

The inconvenience of ruptured perineum scarcely needs any explanation. We have following it, loss of functions of the sphincter ani muscle, rectocele, cystocele, prolapsus and procadentia uteri, and a train of nervous symptoms whose name is legion.

Believing that "an ounce of prevention is worth a pound of cure" in this matter especially, let us consider the causes which lead to this accident, and the best means of averting it.

The most frequent predisposing causes are a small inferior strait, a long and rigid perineum, all malpresentations as podalic, occipito-posterior varieties, broad shoulders, any degeneration as cicatricial tissue, either sudden or protracted expulsion of the child, and the use of forceps before natural dilatation has been effected.

For the prevention of tears, we can resort to gradual dilatation controlling uterine contractions, emptying the rectum to prevent tenesmus; by having the patient assume the lateral position and thus modifying the contractions by support of, and forward pressure of the head, by enucleation of the head, and the use of an anæsthetic, as ether, to bring about relaxation of the parts and preventing tenesmus.

With a rigid and unyielding perineum, lateral incisions are preferable to a laceration.

The sign of danger is the white triangular glistening mark along the perineum, and the incision should be made on the lateral margin at a point corresponding with the tuberosity of the ischium, the incision being made with a probe pointed bistoury, turning the edge out, and cutting for a distance of 1 c. m., during a contraction. If the perineum is still white an incision should be made on the opposite side. With all of these precautions carefully observed, we may have a ruptured perineum. When a rupture is discovered after labor it should be sewed up at once. This condition is frequently apparent to the patient when the physician has been known to stubbornly deny its existence, the patient complaining of a smarting and burning sensation over the torn surface upon voiding urine. In this enlightened day and generation there is nothing to justify neglect in the immediate repair of laceration of the perineum, even less the stupidity of the physician who fails to recognize such a condition.

The best procedure is the primary operation, especially when the sphincter ani is not much involved. The contra-indications being exhaustion due to hæmorrhage, and a long and difficult labor.

The torn parts still fresh and bleeding are brought in apposition by means of sutures. Union is sometimes consumated by keeping the parts together without suture, by bandaging the limbs together and observing cleanliness—but this method is not to be relied upon—sutures can sometimes be introduced without the use of ether.

When labor is more than 24 hours over, the primary operation is useless, and a secondary operation must be resorted to, in which case it is always necessary to etherize. The vulvæ should be allowed to return to their normal condition, all congestions and contusions being allowed to disappear before an operation is attempted.

There are certain preliminaries which it is the duty of every operator to observe, in order, not only to promote the healing of the wound, but also to insure the formation of a strong cicatrix. To this end the general health should receive proper attention. Careful attention must be given to the relief of symptoms of hæmorrhoids, or vaginal and uterine discharges. Internal piles are a frequent complication of ruptured perineum in consequence of the injury to the sphincter ani. Some of the most distressing subjective symptoms of piles will be absent; but the hæmorrhoidal swelling will cause great inconvenience to the operator, and they always imply a more or less unhealthy state of the surrounding mucous membrane. Discharges from the genital tract may prove very prejudicial to the healing process. Where they occur they must be corrected before any operation is attempted, as their presence upon the denuded surfaces will retard the healing process. Hot water injections, pledgets of cotton soaked in glycerine, with the addition of boracic acid or of glycerite of tannin, applied to the cervix will generally

* Read before the Montgomery County Medical Society, July 22, 1891.

do much good. Where the lacerations have been of long standing, frequently the general health is seriously impaired, and operative measures would be almost useless, unless tonic treatment has restored, in some measure at least, the general health. Among operators, opinions differ considerably as to the details of the operation, some preferring one kind of suture and some another, and also as to the best kind of after treatment, but all are guided by one principle, the necessity of sewing up the parts so as to secure the best possible union.

Two forms of rupture present themselves for our consideration, partial and complete.

In partial rupture the laceration involves the tissues down to or partly through the sphincter ani muscle. Complete larceration extends through to the anus and involves more or less of the recto-vaginal septum and wall of the rectum. In rare instances the laceration is central, extending from the inferior vaginal wall to some point in the perineum, the fourchette and sphincter ani remaining intact.

The indications are to restore as near as possible the normal relations of the separated tissues.

In operation for partial rupture, for a week previous, the patient should be prepared by emptying the alimentary canal by proper purgatives, and this can be secured by the administration of Hunyadi Water, before breakfast, or the Fld. Ext. Cascara sagrada ♏. x–xxx three times daily—or any other suitable purgative.

The patient should be placed largely upon a liquid diet during the last three days preceding, and an enema should always be administered shortly before the operation. The purgative must not be given with such frequency as to produce diarrhœa and thus cause serious inconvenience during the operation.

The instruments required are a Tenaculum, and good tissue forceps, a pair of scissors curved on the flat, strong needle holder and strong needles, half curved near the point and without cutting edges, silver wire and Chinese silk, and catgut sutures, for deep and superficial stitches, and antiseptic sponges.

The patient should be placed in the lithotomy position immediately after she is under the influence of an anæsthetic, the legs to be supported by two assistants, or what is infinitely better, a Clover's crutch, if it can be had. The vagina, vulva and anal region should be irrigated with a solution of corrosive sublimate 1–3000.

The glistening smooth surface of the cicatrix will determine the full extent of the laceration.

The denudation should extend upward along the labium of either side, and well up into the depression or angle where the floor of the vagina and labia come together. Upon the floor of the vagina the freshening should extend backward to the crest of the rectocele, the elevation formed by the bulging forward of the vagina.

Denudation of the vaginal walls can be most rapidly accomplished by inserting the finger into the rectum, thus making the surface to be freshened tense and elevated.

The first suture is introduced near the sphincter ani, the sutures to be inserted about ¼ inch apart, the needle entering the same distance from the edge of the wound and carried through from the patient's left to right side. The finger should be kept in the rectum, to prevent the needle from penetrating into the rectum, and to guide it safely through the recto-vaginal septum. A supporting suture, the last of all, can be inserted at the upper limit of the freshened surfaces, passing through the labia and coming out in the cavity of the vagina.

The ends of the wire of each suture, should be loosely twisted to prevent being pulled out by accident. When all the sutures have been introduced the wound should be cleansed and disinfected with a bichloride solution, and the wire twisted, commencing with the lowest. The twisted ends can be secured by perforated shot, or the ends can be gathered together and covered by a piece of soft rubber tubing.

The patient's thighs should be bandaged together, and she to be placed on her back, and the catheter introduced every 5–7 hours. The bowels should be confined for 4 or 5 days, and at the expiration of that time a warm water enema should be given to secure a liquid discharge, the sutures to be removed in 8–10 days. Abduction of the thighs should not be permitted until the 14th day.

In the secondary operation for complete laceration of the perineum, the preparatory treatment for partial rupture should be rigidly enforced. The chief objects of this operation are to restore the functions of the sphincter muscle, and restore the perineal body.

The freshening should extend along the triangular cicatricial surface of each half of the divided perineum, and along the entire edge of the rent into the recto-vaginal septum. For the first suture the needle is

introduced just at the margin of the anus, and ¼ inch from the denuded surface. It is directed through the recto-vaginal septum to the angle of the rent and back along the opposite side at a point corresponding to the insertion. In this instance also, great caution must be observed that the needle does not enter the rectum. A second suture is passed parallel with this, the remaining sutures being inserted as in the operation for incomplete rupture.

(In a case upon which I recently operated I introduced a double drawing-string stitch of strong catgut along the denuded anterior margin of the obliterated sphincter ani, in which good union resulted, and the securing of an efficient sphincter ani.)

The bowels should be confined for 7–9 days, after the operation, and then opened with an enema which should *invariably* be administered by the physician.

In removing the stitches the anus stitches should remain in until the bowels have been evacuated so as to preserve the freshly united structures.

As complete union in this condition is very difficult of accomplishment the operator need not feel disappointed if a second or third operation should be found necessary.

I have been interested in the marked nervous symptoms which have developed in some cases that have recently come under my observation following operative measures.

Sleeplessness, fear of impending evil, loss of memory, a feeling of horror that they may be becoming insane, and such symptoms as might make one fear serious mental derangement.

I am not prepared to advance any theory as to the cause or combination of causes which may give rise to these symptoms, and should be pleased to hear from those members of the profession who have had similar experiences as to their views in this matter.

SUPPURATIVE INFLAMMATION IN UNDETECTED FRACTURE.*

J. T. WILSON, M. D.,

SHERMAN, TEXAS.

Simple fractures, both complete and incomplete, in the long bones, more especially those of the arm and forearm, which were not recognized at the time of injury, are not extremely rare occurrences, as I doubt not the results of such cases that do not make an early recovery come under the observation of most practitioners.

I am inclined to think that a majority of these cases occur in children, in which the fracture is not complete and the ends never become much displaced.

There may be complete simple fractures of the humerus, of one of the bones of the arm, or of one of those of the leg, with but little displacement. These fractures may go on undetected, and recover with only a little soreness or tenderness at the site for a time, without a knowledge of the true nature and extent of the injury, or until symptoms arise calling attention to disease of the surrounding structures or of the bone itself, when the fracture may then be discovered.

They may not be recognized at the time of injury, because of so little displacement and the absence of easily detected crepitus; because of insufficient thoroughness in the examination on account of the pain and soreness thereby produced, or lack of expertness in the examiner; or there may be so much swelling when the case is seen and the displacement and other symptoms so much wanting, that, after careful examination, some cases will yet remain undetected. In incomplete fracture, as that so often occurring in children, the deformity may be so insignificant, and in the absence of crepitus, that it may escape detection in rare cases by the most expert surgeons.

If the patient is in moderate health and the degree of ordinary care exercised in the management of the injury, a large majority of these cases make good recoveries, and in many the fracture is never discovered; but there are other cases, whether from fault of the system, from carelessness in regard to the management of the injury, or sometimes from gross neglect, a subsequent accident or some other unknown cause, that have unpleasant and sometimes serious results.

We are sometimes invited to examine a patient for some trouble of the leg, arm, or forearm, and find a more or less local swelling, acute or dull aching pain, tenderness and throbbing; the swelling may be hard or soft, and fluctuating; there may or may not be marked constitutional disturbance. If pus has formed—and usually it has—there will in a majority of cases be fever, etc. Upon inquiry we will be able to elicit the history of an injury sometime previous; this injury may or may not have received surgical attention, but after a day or two of pain

* Read before the North Texas Medical Association, June, 1891.

and soreness—which may then subside—and there seems to be no further trouble except weakness and an indisposition to use the limb. Very soon, however, the point of injury will become more tender, there will be a little swelling, and this will increase each day until fever appears, the pain and soreness increase, the constitutional disturbance may be considerable, and rigors with perspiration announce the advent of suppuration.

Roswell Park, in a recent and most instructive and interesting lecture on surgical pathology, delivered at the College of Physicians, of Philadelphia, declared that "we are prepared to make the brief and explicit statement that, clinically, at least, we have no suppuration except such as is produced by bacteria; in other words, that pus is a product of parasitic origin." And Senn, in his new work, *Principles of Surgery,* states that "the brilliant results which have been obtained by the antiseptic treatment of wounds make it exceedingly probable that all wound-infective diseases are caused by living micro-organisms," and again in the same chapter "it requires no longer any arguments to show at this time that all inflammatory wound complications—among them suppuration—are without exception caused by the introduction into the tissues of specific pathogenic microbes." He also states that "an abscess which develops in tissues debilitated by a contusion or some antecedent lesion usually reaches greater dimensions than if it occur in otherwise healthy tissues," and then we find Holmes making the following statement: "the inflammation is evidently infective, for it has a tendency to spread not only along the periosteum, but through the connective tissue of the Haversian canals to the medulla, which is often seen in these cases to be in a condition of diffused suppuration." Therefore, it cannot be doubted now that the weight of authority ascribes all suppurative inflammation to living microbes, and while they exist in the part the disease is liable to and generally does spread.

In these cases of suppurative inflammation following a fracture that has not been detected, it is usually difficult to find out just where the nidus of infection was established and the point where the inflammation began, whether in cellular tissue, a diseased blood-vessel, periosteum, or the fractured end of the bone proper. It may be that at the point of fracture, by some slight movement of the ends, a loose spicula of bone or contusion of tissue irritates the parts and thus lights up the trouble. In fracture, even though it be partial and the displacement be ever so slight, there is a localized disturbance of tissue function; there may be slight hæmorrhage, and though it may be slight and quickly arrested, there follows blood stasis, dilatation of the capillaries, nutrition is arrested, infiltration and inflammation ensues, and the parts are favorable for the action of pathogenic micro-organisms. It probably begins most frequently in the cellular tissue and extends to the surrounding parts, or it may begin as a periostitis and extend to the bone, destroying its structure and the surrounding tissues as well, and, indeed, may result in that dread disease osteo-myelitis. The inflammation most frequently begins at a single point, but it does sometimes originate at two or more points simultaneously; in the latter case it spreads much more rapidly.

Sometimes extensive bone necrosis has taken place before the case has been observed, perhaps the entire bone may be involved and any other contiguous bones.

Suppurative inflammation following an undetected fracture is much more likely to occur in unhealthy subjects. Syphilis, tuberculosis, chronic malarial poisoning and a debilitated system favors the development of suppuration. Malarial toxæmia is especially prone to develop it when a bone has been wounded.

There may be a suppurating surface in some other part of the body and microbes entering the circulation of the blood or lymphatics find a lodgement at the seat of fracture where the tissues have been contused and become infiltrated, not able to resist the infective action and thus precipitate suppuration.

The diagnosis is not difficult for there are usually well marked symptoms of pus formation.

The general constitutional disturbance, fever, rigors, perspiration, coated tongue, probably constipated bowels, restlessness, frequent pulse, pain in the part, swelling, sometimes discoloration, tenderness and fluctuation all tell in unmistakable terms the doleful tale.

The condition of affairs with such a train of symptoms must not be mistaken; prompt recognition is all important and treatment should not be delayed. A limb and even a life may depend upon prompt and decisive action and this is all the more imperative if there should happen to be osteomyelitis, for here radical measures only will promise any favorable results.

The indications are generally clear. If we see the case before the formation of pus and symptoms point to a periostitis or deep

tissue infiltration, then in my judgment deep incision through the periosteum under an antiseptic and anæsthetic, and an antiseptic solution brought in contact with the exposed surface, full vent given to any pent up serum or blood, a drainage tube passed in and the parts covered with antiseptic gauze; if suppuration has already begun the incision should be made through the suppurating surface in such a way that its bottom can be reached, all pus washed out thoroughly, irrigated with a hot antiseptic solution and well packed with antiseptic gauze through which issues a drainage tube. All pus microbes should if possible be destroyed, the cavity washed out frequently and the surrounding parts kept in an aseptic condition. If dead bone be present it should be removed, scraped away with gouges and chisels, resection when indicated, if this is not effectual the entire bone may be taken away leaving the epiphysal ends if healthy and as much periosteum as possible. If the parts can be rid of all sources of infections, kept sweet and clean absolutely, it is surprising how rapidly the work of reparation proceeds and what good results are sometimes obtained in very unpromising cases; but I repeat the chief object is to be sure of getting rid of the pus microbes; everything else are but adjuncts and unless this be accomplished we will have many failures and some sad disasters. Then everything in the way of dressings, the hands, instruments, the parts, applications, water, &c., must all receive antiseptic treatment; in this bacteriological era this antisepsis must be thorough, nothing else will be acceptible, and the times demand it.

A little carbolized water, the hands washed with simple unboiled water, the ligatures saturated in a carbolized solution for a few moments, dirty sponges, unclean bandages and drainage tubes and all called antiseptic treatment in this day will not be tolerated. The surgeon who proceeds to dress a wound in such a way may be held personally responsible for any bad results and subject himself to the liability of a suit for malpractice.

Rest is necessary to both part and system in bad conditions, rest to the part for a time at least under all circumstances will be required. So much for the local treatment. Of no little importance is the addition of constitutional treatment and we must be guided in this by the conditions we find. If it be a strumous subject he will require special treatment for that diathesis, if a syphilitic or antisyphilitic treatment will be required to meet the demands. If suffering from malarial infection appropriate special measures for the disease must be had recourse to. In all cases no matter what the complication or if there be no complication, it will be found necessary to maintain the secretions in proper condition and by special diet and tonics to build up the general system and have the various organs perform their functions.

THE USE OF ATROPIA SULPHAS IN DISEASES OF THE EYE.

BY ARTHUR D. MANSFIELD, M. D.,

ASSISTANT SURGEON IN THE PRESBYTERIAN EYE, EAR AND THROAT CHARITY HOSPITAL, BALTIMORE, MD.

If there be any class of drugs that is essential to the ophthalmologist it is that class of drugs known as mydriatics, and standing preëminent in the class is atropine, theactive principle of belladonna, given to us in the form of the sulphate, a salt readily soluble in definite proportions and to any extent.

Should the specialist in eye diseases be asked to surrender all but one drug, and retaining but one, continue the practice of treating affections of the eye, I think most certainly the drug retained, would be a solution of atropia, or should the value and worth of the mydriatic appeal to us in another way—having a very limited knowledge in diagnosing eye affections, and being unable to tell just what was the matter with an eye which should fall under our observation and care, and some doubt exist as to what should be done. I think a safe and sure rule to be observed would be to instil in such an eye, a solution of atropia.

The importance and value of the mydriatic in the treatment of eye diseases is incalculable. It would not perhaps be without interest to enumerate some of the uses of atropia.

In the use of atropia we see its manifold applications, in the first place its value in diagnosis is well known, if upon ophthalmoscopic examination the fundus appears cloudy, either from degeneration of the vitrous humor, or senile, or traumatic changes in the lens, or the cornea become opaque, the instillation of the atropia solution enlarges the pupillary orifice, and enables the ophthalmogist to obtain a better view of the fundus.

If again the pupil be contracted from

various causes, the use of a mydriatic is brought into requisition. Again, in cases where there exist posterior synechiæ with either partial or entire occlusion of the pupil denoting an old iritis, the use of the mydriatic is very valuable, or if the adhesions have been severed at the time of the iritis, the use of the mydriatic at a subsequent date *i.e.*, when the iritis has disappeared as far as outward signs are concerned will reveal the plastic exudations adherent to the anterior surface of the crystalline lens.

The mydriatic is useful again in diagnosing the extent of the development of senile cataracts. Should the use of atropia be taken from us as a diagnostic means, important as it is, yet we would suffer a greater loss in the want of a mydriatic as a curative agent to many of the graver affections which assail the eyes.

It is as a mechanical agent, perhaps more than any other property; for a mydriatic must be considered as a mechanical agent, that atropia finds its greatest use and marks its most brilliant results in eye work.

When we see a case of iritis the main indication as far as preservation of sight is concerned, is the removal of the iris from its apposition with the lens, thus preventing the adhesion of the two opposing surfaces and allowing the vessels to disgorge themselves and remove lymph and other plastic materials thrown out. In wounds of the cornea with escape of the aqueous humor, the iris and lens coming in contact with open wounds of the cornea subsequent adhesions perilous to future vision would follow, were not a mydriatic instilled, thus separating the parts while the parts could be divided. We see a valuable use of atropia in all cases of operations upon the iris where we wish to keep the iris from attaching itself to the lens.

Not to weary my readers, I will pass on, only mentioning a few of the remaining uses. Occasionally we see the importance of a mydriatic such as atropia in cases of hypermetropia with internal squint and more or less amblyopia in the crossed eye, in many cases the strabismus disappearing and emmetropia resulting in not a few cases. The use of a mydriatic in testing errors of refraction revealing latent astigmatism and hyperopia and other uses show the value of atropia to the eye specialist. But is atropia and its use restricted to specialists? By no means, else would I not write this article. The general practitioner depends upon the specialist as much as the specialist depends upon his fellow practitioner. There is no reason why the general practitioner should not do as much good, and sometimes more good, with atropia as the specialist can, I say the general practitioner can sometimes do more good with the judicious use of atropia than the specialist can. E. G., seeing a case of iritis, the early instillation of atropia sulphas in a solution, gr. iv, ʒj., will prevent adhesions that only a subsequent iridectomy can sever in many cases, and then only partial recovery of sight.

To bring my article quickly to an end I will speak briefly of its contra-indication. Atropia and mydriatics do good in most eye affections and perhaps the rule may be a good one to state that you can do no harm in using atropia, yet there is one condition in which the use of a mydriatic causes positive injury to the eye and rapid and hopeless impairment of vision, it is to this irreparable loss of sight and danger to the eye that I wish to caution any of my readers who may considers it necessary to pay heed.

In cases of glaucoma where the eye-ball is tenser and harder than usual, accompanied by pain (not always though,) and no apparent redness of the parts of the eye, a gradual contraction of the field of vision, pitting of the disc spectra of light about artificial lights, etc. In this condition mydriatics are contra-indicated and myotics, such as eserine, are clearly and positively indicated. With this one injunction upon the use of atropia, I recommend to the use of the general practitioner that valuable drug.

Society Reports.

SECOND TRIENNIAL MEETING OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS, HELD AT WASHINGTON, SEPTEMBER 22, 23, 24, AND 25, 1891.

GENERAL SESSION, WEDNESDAY.

(*Continued from page* 538.)

The first paper read was on

THE LATE MANIFESTATIONS OF SYPHILIS,

by P. S. Conner, M. D., of Cincinnati, Ohio.

Dr. Conner said that more than any other disease, not excepting tuberculosis or cancer, syphilis is the common meeting ground of us all—physicians, surgeons, obstetricians, spe-

cialists, pathologists, sanitarians. Modified by transmission through a dozen generations, it is still a dreadful and dreaded ill. Were there only the early lesions, syphilis would take place among the minor ills, and this is the history in the large proportion of cases. Probably in three or four out of five of the acquired cases, the disease is short-lived and does but little damage. There is, however, no means of saying in any individual that in a few months or years the disease will be eliminated. Those syphilitic by inheritance suffer from late lesions in far greater ratio than the acquired cases.

There is no sharply defined line between the early and the late constitutional symptoms. Speaking generally, the late lesions are neo-formative, the early hardly ever so; so that the gumma is the sign and seal of the tertiaries. Further, they are not communicable. As a rule, they are quietly developed. No region or organ is exempt from invasion with resulting new growths. Of most frequent occurrence are the affections of the bones and of the nervous system. The lesion of the bone may be single or multiple. The symmetrical involvement of bones is exceptional. Liquefaction is rarely observed, and suppuration only an accident. As ordinarily seen at the present day, extensively destructive and deforming bone inflammations are almost confined to the head and the nasal regions. The reason of this is probably the exposed position of the bones, the thinness of some of them, the abundance of small vessels, and the intimate fusion of mucous membrane and periosteum. In the adult and acquired there is seldom difficulty in recognizing the specific character of the lesion.

Though a large proportion of chronic bone and joint disease in the child, the adolescent and the young adult is tubercular, yet the cases in which it is syphilitic are by no means few. This may be recognized by the location of the disease, by recognition of traces on the cornea, the teeth, and the skin, by application of the therapeutic test and, when practical, by inoculation.

The most frequent and the most dangerous lesions are those of the nervous system. Dr. Horsley, in speaking of cerebral gumma, declared that "medicinal treatment in no wise cures, and only very temporarily alleviates the trouble. . . . Excision offers the only chance for the patient." Is this the fact? Has not more than temporary alleviation followed the use of the iodides? However great the advances of brain surgery in the last few years, would not the outlook of the syphilitic be worse than it is, if only in the removal of the gumma could be found a chance of recovery? The affections of motion, sensation and intellection are frequent in the order given. The first at some time and in some degree is present in every case. Hysteria may mean syphilis. It is infrequent in men, while brain syphilis is rare in women. In brain syphilis, paralysis is more common than convulsions. Sensation frequently remains unaffected. Disturbances of intellection are almost necessarily associated with any brain lesions.

In certain cases, although rare, marked motor, sensory and intellectual disturbance occur suddenly and together. Ordinarily after sleep the patient is found in a state of stupor, from which it is possible to rouse him partially. The muscles are relaxed. The pulse rate is decidedly lessened, the breathing is slow, and the temperature is subnormal. Under mercurial treatment, promptly and persistently maintained for many months, relief even permanent may be expected and secured.

Spinal lesions are of infrequent occurrence. Exostoses of the spinal canal may occur and neoplasms develop. There may be pain and paralysis affecting different parts according to the location of the lesion. A question of much interest is the causative relation of syphilis to locomotor ataxia. That the majority of ataxics have had syphilis cannot be questioned. Tabes is certainly not of true gummatous origin. Nor can the sclerosis be regarded as the result of the diffused formation so often found in the cerebro-spinal axis. As in other parts of the body syphilitic treatment generally fails to cure or even to retard the evolution of symptoms.

There are many things about late syphilis that deserve careful study. What is the explanation of the long years of intermission with the after development of grave functional and organic disturbance? Where has the disease been lurking all these years?

What are the relations of syphilis to other diseases and to injuries? Pre-existing tubercular disease renders probable a more severe and often a more rapid syphilitic course. To the "strumous" individual the specific infection is more dangerous than it is to others. That specific lesions may become tuberculized has been proven, but only rarely does the tubercle bacillus find a nidus in and about a syphilitic new formation. Syphilis is not likely to be inoculated on a person suffering with cancer, and if it is there is no good reason why the two diseases should not each go on in its natural way. On the other hand, cancer may and not so

very rarely does attack an area in which there has long been specific thickening and induration, as in the chronic leucomata of the tongue. Once in a while a gumma undergoes cancerous degeneration, more often when situated in the tongue than elsewhere. The local affection, no longer amenable to specific treatment, goes on steadily from bad to worse. In certain localities, especially in the breast, a gumma may readily be mistaken for a cancer. If syphilitic growths do not become sarcomatous, they often resemble sarcomata, and many reported successful operations for the malignant affection has been really one in which a gumma has been removed.

As a rule, the wounds of syphilitics, when the disease is in a latent stage, heal as promptly as in other cases, although union may be delayed or even prevented until after the patient has been brought under the influence of the anti-specific remedies. This is less true of wounds of the soft parts than that of the hard parts, as fractures, where, at times, false joints will form in spite of the most judicious treatment. When the specific lesions are in the process of evolution, the chances of interference with proper repair are not few, and no operation should be done at this time which can be postponed. I deem, at any time before doing an operation, the success of which depends on primary union, it is well to keep the patient for several weeks under the influence of the iodides and mercurials. Very rarely does any wound become actually syphilitic. In one who has had the disease, although there have been no manifestations for years, any traumatism may be the starting point of extensive specific lesions.

In very many cases of aneurism, under forty years of age the lesion may be consequent on syphilis.

The mortality rate of acquired syphilis is rare. In its inherited form the disease is a very grave one. Four-fifths of the pregnancies terminate prematurely.

Dr. Abner Post, Boston, co-referee said: In speaking of syphilis he spoke from the standpoint of the clinician and student and not from that of the pathologist. He called especial attention to what is known as late hereditary syphilis. This relates to those who have inherited the disease and only after a lapse of years show symptoms corresponding to the tertiary symptoms of acquired syphilis. The later forms of acquired syphilis are not necessarily a part of the case. The so-called late lesions occur much earlier in the history of the disease than we are in the habit of thinking. After the third year the chances of a recurrence grow steadily less. As a preventive of late symptoms early treatment by mercurials must be ranked high but no method will allow us to promise a cure that is absolute immunity from subsequent attacks.

The different systems were taken up in order. Induration and enlargement of the lymphatic glands is one of the common symptoms of early syphilis. In late hereditary syphilis the part played by the lymphatics is great.

Cutaneous lesions are second in frequency to the lesions of the nervous system in late acquired disease.

Diseases of bones were next referred to. A difference between tuberculosis and syphilis lies in the preference for syphilis for the long bones and their shafts, while tuberculosis attacks by preference such bones as those of the wrist and ankle. Disease of the joints are at times undoubtedly the result of syphilis.

Reference was next made to intestinal and gastric symptoms in syphilis. It is fairly well established that very serious lesions of the gastro-intestinal tract may take place. As one of the possible causes of disease of the ileo-cœcal valve, syphilis must be given a certain amount of consideration.

In diseases of the nervous system there is a large field which lies practically unexplored in congenital syphilis.

An interesting question is, "How much influence should a negative history have in a doubtful case?" There are many cases in which the existence of syphilis is not known by the patient.

Every prognosis must be a matter of special consideration. It is the persistence of the damage and not the specific lesions that cause the persistence of the symptom. There is something to be deducted in the matter of treatment. Anti-syphilitic treatment has great power over the active process late lesions, but it is powerless to restore the tissue already destroyed. The attempt to destroy a syphilitic tertiary sore is in general futile. The late lesions of inherited syphilis are as readily controlled as those of acquired disease. The amount of iodides that may be administered is very large. In regard to the treatment as an aid in retrospective disease too much value must not be placed upon this element in doubtful cases, for mercurials and iodides do have some influence over tuberculosis.

The study of syphilitic phenomenon is a necessity of medical progress. The possi-

bility of syphilis renders uncertain the diagnosis of tuberculosis and cancer, and other malignant forms of disease. We need the most careful clinical studies; we need Hospitals specially devoted to syphilis; we need to make its study obligatory.

The subject was further discussed by Dr. Robert T. Edes, of Washington and Dr. James Nevins Hyde, of Chicago.

Adjourned.

THURSDAY.—DISCUSSION ON FIBROID PROCESSES [CHRONIC INTERSTITIAL INFLAMMATION SCLEROSES] THEIR PATHOLOGY AND ETIOLOGY WITH ESPECIAL REFERENCE TO THE INFLUENCE OF DIATHESIS AND HEREDITY.

The discussion was opened by Dr. A. L. Loomis, of New York.

Fibroid processes cannot be spoken of as degenerations for they imply an active process productive in character. There is always a higher than normal grade of activity in those elements which develop connective tissue. The only way in which fibroid tissue can develop is from growing cellular elements. He excluded from the list of the fibrosis all conditions of simple preponderance of fibroid tissue from the atrophy of other elements. Two forms of fibrosis were described at length, the hyperplastic and the inflammatory. The first is due to diminished nutritive supply to parenchymatous atrophy, to nuclear proliferation and to connective tissue hyperplasia. The inflammatory form is due to parenchymatous degeneration, to constitutional influences and to local attraction by the products of tissue change, positive chemotaxis.

All those agencies which diminish the vital forces by which the cell appropriates to itself its proper elements, tends to the production of fibrosis. These agencies may be mechanical, chemical or mental. Among the causes of fibroids may be mentioned direct stimulation of fibrous growth, all conditions including a limited degree of nutritive supply, all conditions and elements which induce perverted nutrition, either degeneration or necrosis including mechanical forces, perverted or defective nutritive supply, and all toxic and trophic influences.

The relation between diathesis and fibroid processes were next considered. A diathesis may manifest itself by any bodily function displaying an activity out of proportion to the stimulant applied. In the fibroid diathesis the growth of fibroid tissue is out of proportion to the amount of stimulation. Fibroid processes are not always injurious as is seen in cases of cured tuberculosis. In seventy cases of cured tuberculosis under the observation of the writer, fifty-four presented well marked evidences of fibrosis. Diathesis often determines the nature or prominent action which will follow any given irritant or stimulation, provided more than one is possible. It also modifies the ratio between the established process and its causes.

The speaker next referred at length to the special manifestation of the fibroid process in the arteries, heart, kidney and liver.

Dr. William Osler, of Baltimore, considered the fibroid process under the head of degenerative, inflammatory and developmental. The degenerative were subdivided into the atrophic, the secondary degenerations, the toxic forms as from lead, ergot, syphilis, the sclerosis associated with similar changes in the smaller arteries and capillaries. The degenerative form includes the greatest number.

The inflammatory form was subdivided, the secondary forms in consequence of reactive inflammation following hæmorrhage, tumors, foreign bodies, abscess and trauma, the scleroses which follow primary encephalitis or myelitis.

The following questions were suggested for consideration:

1. What is the relation of vascular change to the degenerative scleroses? How far histologically are they mesodermal or ectodermal, or are they mixed, containing both neurogliar and collacenous connective tissue.

2. The lobar scleroses of children. What is the nature of the primary affection? Is it inflammatory? An encephatilitis or meningencephalitis or is the essential lesion in the vessels.

3. Developmental. Can we recognize a purely ectodermal form?

Dr. Charles L. Dana, of New York, referred to the chronic fibroid processes of the spinal cord. He classed these into—first, primary degenerative; second, secondary degenerative; and third, reparative and inflammatory. The first includes locomotor ataxia, lateral scleroses, combined scleroses, progressive muscular atrophy and amyotrophic sclerosis. These scleroses are not inflammatory but due to the destruction primarily of cells and fibres. The causes of this degeneration were ether toxic substan-

ces or disturbance of nutritive equilibrium by infectious vascular strain or imperfect nutritive supply. They are not related to any special diathesis.

The secondary fibroid processes, so-called, have been shown by French pathologists to be probably in great extent neurogliar proliferations or gliosis, not a fibrosis.

The inflammatory scleroses, including chronic myelitis, diffused myelitis and transverse myelitis are mixed processes composed of a simple necrotic process, inflammatory processes and secondary degenerations.

Dr. William Councilman, Baltimore, referred to the fibroid process as found in the liver, giving the results of investigations made in the Johns Hopkins Hospital. He dwelt upon the fact that the first element in the fibroid process was a necrosis. The fibrosis is not the result of stimulation. The tendency to growth is always present and as soon as the opposition is removed it manifests itself.

The Congress then adjourned *sine die.*

Selected Formulæ.

FOR TENDER FEET.

Tramps, either amateur or professional, who suffer from sore feet after an unusually long walk, will experience great relief from soaking the feet once or twice a week in a half-pailful of hot water to which a piece of nitrate of potassium the size of a small walnut has been added.

PARSONS' LOCAL ANÆSTHETIC.

℞

Chloroform	12 parts.
Tinct. aconite	12 "
Tinct. capsicum	4 "
Tinct. pyrethrum	2 "
Oil cloves	2 "
Camphor	2 "

Dissolve the camphor in the chloroform, then add oil of cloves and then the tinctures. The venerable Dr. Parsons, in sending this formulæ for publication, says: "I cannot expect to remain much longer in this world, and I want the profession to know the value of this local anæsthetic."—*Southern Dental Journal.*

EXALGINE IN NEURALGIA.

Dr. T. R. Fraser has found this remedy very efficacious in production of anæsthesia, especially in neuralgia. The dose varies from a six centigrammes (one grain) to a gramme (fifteen grains) in twenty-four hours. The following formula is recommended by him:

℞

Exalgine	2.50 grammes.
Peppermint water	5 "
Orange syrup	30 "
Distilled water	120 "

S.—A teaspoonful twice a day.

—*La Presse Médicale Belge.*

In case the peppermint taste be disagreeable to the patient, the following formula recommended by Dujardin-Beaumetz, may be employed:

℞

Exalgine	2.50 grammes.
Tinct. orange peel	5 "
Distilled water	120 "
Syrup orange	30 "

S.—A tablespoonful morning and evening (0.25 grammes), 4 grains of exalgine.

—*Deutsche Med. Zeitung.*

GONORRHŒA.

Thomas R. Neilson states that the plan of internal treatment which he has pursued for so many years past, consists, first, during the earlier stages of the disease, in the administration of an alkaline sedative mixture, with the purpose of alleviating the scalding caused by urination, the tendency to frequent micturition and to chordee. The standard formula in his dispensary practice has been.

℞

Potass. acetat	3 drachms-½ ounce.
Potass. bromid	1½ drachms.
Acid boric	2 drachms-2 scruples.
Tinct. belladon	30 minims.
Liq. potass. citrat	8 ounces.

M. Sig.: A teaspoonful in water every three or four hours.

Secondly, as soon as the symptoms are in a measure relieved, the administration of either oleoresin of cubebs and balsam copaiba in capsule, or cubebs alone in powder, in teaspoonful doses, or finally, where chordee is troublesome, a combination of two parts by weight of powdered cubebs and one part of bromide of potassium, given in the same doses, and from three to four times daily.—*Univ. Med. Mag.*

FOR HAY FEVER.

L'Union Médicale recommends the following snuff for hay fever:

℞

Acid boric. pulv	gramme 2.0.
Natr. salicyl	gramme 2.5.
Cocain mur. pulv	gramme 0.12.

M. Sig. For snuff.

For the eye symptoms a solution of sulphate of copper or sulphate of zinc, for a wash, 10 drops of iodide of ethyl or 3 drops of nitrite of amyl may be inhaled at the onset of an attack, and the patient sent to a different climate or place.

TO REMOVE THE ODOR OF IODOFORM.

While there are several preparations that will remove the odor of iodoform from the hands, the most of them merely substitute an almost equally unpleasant odor. The *Deutsche Medizinal Zeitung* claims that washing the hands in linseed meal and water, once or twice, will cause an immediate disappearance of the odor of the drug.

IN ACUTE BRONCHITIS.

A simple expectorant mixture in acute bronchitis is:

℞ Ammon. muriat.....3ss.
Mist. glycyrrhiz. comp.....3iv. M.
Sig. Take a dessertspoonful every four hours.

The dose is smaller in the extremes of life, and in severe coughs it is given every three hours.

Tablets of the muriate of ammonium and the compound licorice mixture are very efficient. When the secretions are with difficulty brought up, the use of senega is advised.

When the secretions are abundant and not easily coughed up, turpentine in emulsion is an excellent remedy, not so pleasant, perhaps, as terebene or terpine hydrate, but rarely failing to do good in properly selected cases. The formula, with occasional modifications to suit particular cases, is:

℞ Ol. terebinthin.....3ij to 3iij.
Mucil acaciæ.....q. s.
Aq. cinnamomi.....3j.
Aquæ, q. s ad.....3vj. M.
Sig. A tablespoonful in a little water every four hours.

Ofttimes the cough is of such an irritating character that these ordinary expectorant mixtures avail little; then recourse must be made to a narcotic in some form. Codeine, a very useful alkaloid of opium, has the advantage of not constipating as much as morphine. A good combination is:

℞ Codeinæ sulphat.....grs. viij.
Syr. prun. Virginian.....3ij. M.
Sig. A teaspoonful in a little water three or four times a day and at bedtime if necessary.

—*Therapeutic Gazette*, July, 1891.

"ACTINA."

Prof. Flavel B. Tiffany, says the extensively advertised "Actina" has this composition:

℞ Menthol crystals.....3j.
Alcohol.....3ss.
Ether sulph.....3j.
Oil mustard.....3ij.
Sponge sufficient to make.....3j.

Or

℞ Menthol crystals.....3j.
Ether hydrobromic.....3j.
Oil mustard.....3ij.
Sponge sufficient to make.....3j.

—*Kansas City Med. Index.*

AMENORRHŒA.

The following is recommended as a reliable emmenagogue in many cases of functional amenorrhœa:

℞ Bichloride of mercury.
Arsenite of sodium, aa.....gr. iij.
Sulphate of strychnine.....gr. jss.
Carbonate of potassium.
Sulphate of iron, aa.....gr. xlv.
Mix and divide into sixty pills. Sig.: One pill after each meal.

—*Revue Med. Chir. Mal. Femmes.*

HÆMORRHOIDS.

Preissmann (*Fort. der Krank.*) recommends the application of pledgets of cotton soaked in the following:

℞ Potassii iodidi.....3ss to 3j.
Iodi.....gr. iij to gr. xv.
Glycerin.....3j. M.

OIL OF TURPENTINE.

Oil of turpentine is administered in France preferably in the form of *Recamier's emulsion*, which, according to the *Pharmaceutische Zeitung*, is as follows: Oil of turpentine, g. 12; egg yolks, No. 2; syrup of mint, g. 64; syrup of orange flower, g. 32; syrup of ether, g. 22; tincture of cinnamon, g. 2.

THE HYPODERMIC USE OF QUININE.

The statement was lately made at the *Société de Pharmacie* that Dr. Laveran had renounced his habit of prescribing lactate and hydrochlorate of quinine for hypodermic injections. Taking advantage of the property possessed by antipyrine of aiding in the solution of the salts of quinine, he now employs a formulæ composed of 1 gramme of hydrochlorate of quinine, 50 cg. of antipyrine and 2 grammes of water. He says that these solutions give no pain whatever, while those of the hydrochlorate alone, or the lactate alone, have usually caused a certain amount of trouble.

A PURGATIVE FOR CHILDREN.

℞ Castor oil.....3iv.
Infusion of coffee.....3ij.
Powdered sugar.....3v.
Yolk of egg.....No. j. M.

Make an emulsion.—*L' Union Médicale.*

A STIMULATING EXPECTORANT.

℞ Ammon. carbonat.....gr. v.
Tr. Nuc Vomicæ.....ɱ x.
Tr. Scillæ.....3ss.
Inf. Serpentariæ.....3j.
M. Sig. Three times a day.

—*Fothergill.*

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO., (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

THE CHOICE OF AN ANÆSTHETIC IN OBSTETRICAL PRACTICE—THE PROPER TIME FOR ITS ADMINISTRATION AND THE METHOD OF ADMINISTERING.

Relative to the choice of an anæsthetic in labor we have two principal drugs to deal with—ether and chloroform. The former is the more stimulating, but it is bulky, inflammable, and not infrequently irritating to the lungs; chloroform, on the other hand, is sedative, more agreeable to the taste, more concentrated and powerful, and requires a less amount to cause analgesia or anæsthesia. For these reasons, chloroform is justly considered to be the agent *par excellence* in producing obstetrical anæsthesia. This is true, however, only of its use as an analgesic (Lyman). When complete anæsthesia is required for the graver operations of midwifery, ether should be employed.

In reference to the time at which the anæsthetic should be given, chloroform, ordinarily, should not be administered during the first stage of labor, partly because of its tendency, when given at too early a period, to weaken the contractions of the uterus, and partly because protracted anæsthesia has a tendency to impair the cardiac force (Lusk). There are, however, numerous exceptions, as for instance, when patients suffer more severely during the first stage than during the second. In point of fact, the time for the use of these agents should depend largely upon the individual peculiarities of each case, remembering that the object desired is the alleviation of pain by *anæsthesia*, and not the production of *narcosis* through a determination to abolish pain altogether. According to Dr. Lyman, and other authorities, the unfavorable results which are often ascribed to anæsthesia during an early period of labor are due to an altogether *excessive* use of the anæsthetic.

In the major operations of obstetrical work, when profound anæsthesia (narcosis) is required, ether, as previously stated, should be employed, and its administration is to be

conducted on the general principles observed in its employment for other surgical purposes.

In normal labor, chloroform is manifestly preferable, and the mode of its administration for this purpose differs materially from that employed for surgical anæsthesia. While the one is a continuous state of partial anæsthesia in which the influence of the agent is slight and readily passes off, the other is a regular progressive process carried steadily to a definite point, the patient being so profoundly narcotized that a return to consciousness requires considerable time. The open method of exhibition is the better.

At the beginning of each pain the patient should be directed to take a number of deep inspirations, the anæsthetic being kept at a little distance from the mouth. By this means, according to Dr. W. T. Lusk, the patient is prevented from inhaling an undue amount of the anæsthetic during the expiratory efforts which are put forth in the acme of the pain.

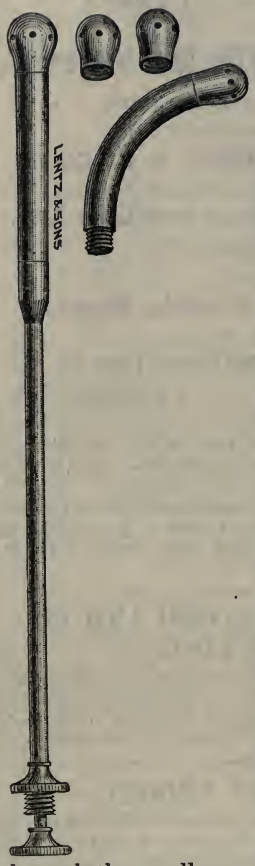
The chloroform should be used in small quantities at a time—the additions being made drop by drop. Continued attention should be paid to the general state of the patient during the use of the agent, remembering that success in the management of obstetrical anæsthesia requires the most scrupulous care and incessant watchfulness, as well as considerable skill upon the part of the anæsthetizer.

THE PHARMACY OF IODOL.

Dr. Tronchet lately communicated to the *Bulletin Médical* his views as to the pharmacy of iodol, which he thinks should be employed with olive oil. In quantities of 10 to 150 it makes a clear and elegant preparation. He gives the following formulæ: Emulsion—Iodol, 1 gram; neutral glycerin, 10 grams; water, 20 grams; gum acac., 2.50 grams. Solution—Iodol, 10 grams; olive oil or oil of sweet almonds, 150 grams. Crayons and Bougies—Iodol, 50 cg.; lanolin, wax and gum, of each 25 cg. Ointment—Iodol, 1 gram; vaselin, 10 grams. Dr. Tronchet says he has tried all the formulæ and prefers the above.

CORRESPONDENCE.

A NEW INSTRUMENT FOR THE APPLICATION OF OINTMENT TO THE MALE URETHRA.



To the Editor of the Medical and Surgical Reporter:—I submit to you and your readers an instrument for the application of ointment to the male and female urethra. The cut shows the simplicity of the instrument. The barrels are interchangeable and fitted to different sized bulbs graduated from 18 to 22 American scale. If the ointment is very thin, it can be drawn up into the barrel, and if too stiff, remove the barbarrel and by repeated thrusts into the ointment it can be completely filled. When properly charged and introduced into the urethra, gradually withdraw the instrument and at the same time push the piston home, forcing the ointment through the small openings in the bulb, thus distributing the ointment evenly over the dilated urethra. The ointment makes its exit through the largest circumference of the bulb, and therefore insures its thorough application. The instrument can, by removal of piston, be converted into an irrigator, for the thorough cleansing of the urethra.

Lentz & Sons made the instrument I am using, and I must thank them for the wood cut they have so neatly executed. The instrument is gotten up antiseptically and can be readily cleansed.

Dr. D. W. Boone,
Bellaire, Ohio.

Truth is mighty, but she is ignominiously worsted when she encounters a fishing excursion.

Book Reviews.

TABLES FOR DOCTOR AND DRUGGIST, compiled by Eli H. Long, M. D., Professor of Materia Medica, Buffalo College of Pharmacy; Adjunct Professor of Materia Medica, Medical Department, University of Buffalo. Detroit, Geo. S. Davis, 8vo., 133 pp. Price, $2.00.

The object of this excellent compilation is to bring into convenient form for ready reference information that is wanted daily by the physician and pharmacist. The work is divided into five parts: (1) a table of solubilities; (2) table of reactions and incompatibles; (3) table of doses and uses of medcines; (4) table of specific gravities, and (5) table of poisons and antidotes.

The table of solubilities treats especially of the solubility of the various substances in water and alcohol at 15° and 100° C., but also treats of all other solvents likely to be used by the physician or pharmacist.

The table of reactions and incompatibles is the distinctive feature of the book; no reactions are included that are not recognized by good authority or that are chemically improbable.

The table of doses fiurnishes what seems to be a complete list of medical substances now employed, with their doses and principal uses.

The table of poisons includes symptoms, toxic doses, treatment, and explanatory notes.

The compilation is an exceedingly valuable one, the book is well printed, and deserves a place in the library of every physician and druggist.

NOTES ON NEW REMEDIES, INCLUDING THOSE ON THE ADDITIONS TO THE BRITISH PHARMACOPŒIA OF 1890, compiled by E. B. Shuttleworth, Dean, and Professor of Chemistry, Ontario College of Pharmacy; Lecturer on Pharmacy at Trinity Medical College, Toronto; Editor of the *Canadian Pharmaceutical Journal*, etc. Toronto: Monetary Times Printing Co., 72 Church Street, 1891. 16mo., 87 pp.

These notes have been compiled from original and secondary sources into a form very useful to the physician and pharmacist.

In treating of the various remedies, the chemical characters are first considered, then the general characters, then the properties and uses, and finally the method of administration.

The notes have evidently been carefully prepared, and the little book is printed with very clear type on good paper.

PERISCOPE.

THERAPEUTICS.

THE ABORTIVE TREATMENT OF GONORRHŒA.

The treatment of gonorrhœa in its early stages by strongly irritant injections, particularly those of nitrate of silver, at one time exceedingly popular, is now seldom applied by those most experienced in venereal diseases. This is because such treatment in practice was often ineffectual, and because when it failed the violence of the original attack of urethritis seemed to be greatly exaggerated. As a result of this increased severity and duration of inflammation, tight strictures were much more commonly observed than was the case when gonorrhœa was treated by less irritating injections. It was also claimed that epididymitis was a very common sequel of anterior urethritis treated by nitrate of silver. The latter statement has, however, been shown to be false.

There are, then, sufficient grounds for abandoning a treatment which is so uncertain as to its successful issue, and is liable to be followed by a condition more grave than that for the cure of which the remedy is applied. There have always, however, been a number of practitioners who steadfastly adhered to the abortive treatment of gonorrhœa by silver nitrate, and who could show records in proof of their statements that in suitable cases the method was followed by sufficiently satisfactory results.

It has lately been proved experimentally that silver nitrate as a germicide acts upon the gonococcus even more powerfully than bichloride of mercury, and the employment of this drug in weak solution has been advocated as an excellent continued treatment in gonorrhœa.

Both the gonococcus and nitrate of silver produce the same effect upon the urethral mucous membrane; that is, they cause a desquamation of the epethelium and an active inflammation of the deeper structures. The nitrate of silver, however, acts very rapidly—within a few hours—while the gonococcus requires several days to produce its full irritant effect. If, then, before the gonococcus has time to penetrate more deeply than the epithelium, an injection of silver is employed, it seems fairly reasonable to hope that it may not merely destroy the microbe, but may also cause it to be thrown out from the urethra by occasioning almost imme-

diately an active inflammatory discharge, which, from its owing its cause solely to a chemical irritant, may be expected to subside entirely in a few days. If, however, the gonococcus has had time to penetrate deeply within the mucous or submucous layer, further irritation cannot accomplish its throwing off, but will simply diminish tissue resistance, and all the pabulum of the invading microbe, thereby increasing its multiplying powers.

It seems clear, then, that the abortive treatment cannot be entertained except in the very earliest period of a gonorrhœa; that is, when the tickling at the meatus and the drop of clear or slightly clouded mucus denote that the epithelium is invaded. Picard, the ablest modern exponent of the abortive treatment, holds that a red meatus, with swollen, everted lips, a turgid glans and intense pain, constitute absolute contra-indications to this method of treatment, even if the case is seen early in its course.

The strength of the injection should vary from fifteen to twenty grains to the ounce of water. This produces a sufficient degree of irritation, yet is not strong enough to be followed by subsequent cicatricial contraction. The patient should first be instructed to urinate. Then the nozzle of a blunt-pointed syringe should be inserted into the meatus, the urethra should be compressed about two and a half inches farther back, so that the injection may not penetrate more deeply than is required, and the silver solution should be forced in so that all the urethra anterior to the point of pressure is fully distended. The solution should be retained a few seconds; it can then be allowed to escape by relaxing the pressure of the nozzle against the meatus. The anterior portion of the urethra should be distended and emptied till the syringe contains no more fluid. Urination should be postponed after this as long as possible.

According to Picard, the pain of this treatment is rarely severe. In a few hours there is a yellowish-white running, often blood-stained. This diminishes, becomes white, and in twenty-four hours is changed to a purely serous discharge, which entirely disappears in a few days. If the free discharge persists for from twenty-four to thirty-six hours, the treatment may be repeated, provided the parts are neither red nor painful.

The unfortunate part of this method is that patients rarely present themselves before the invasion of the urethra is too far advanced to admit of the abortive treatment. In suitable cases, however, it is a safer method and gives fairly constant results.=*Univ. Med. Mag.*

THE TREATMENT OF NON-OPERABLE CANCERS BY MEANS OF INTERSTITIAL INJECTIONS OF PYOKTANINE.

V. Mosetig is reported to have presented before the Society of Physicians of Vienna (*La Tribune Medicale*, April 2d, 1891), several cases of cancer materially improved by injections of pyoktanine:

1. A woman with sarcoma of the lower jaw. After fifty injections (in all 120 grains of pyoktanine) considerable diminution in size of the tumor.

2. Sarcoma of the sternum. Only the fibrous stroma of the tumor remained.

3. A man, 58 years of age, suffering for eight months with sarcoma of the tongue and floor of the mouth. Result: removal of all bad odor and pain; the tongue has become again mobile.

4. Female, aged 47, with an epithelioma of the face. Twenty-seven grammes of pyoktanine used, with the result that the infiltration is less hard, several nodules have separated off; the general condition has much improved.

Amelioration was also obtained in a woman with cancer of the bladder and in a man with an adeno-cancer of the pelvis. In the former there was cessation of the hæmaturia; in the latter, the tumor diminished three-quarters in size. Mosetig recommends that the solution be made of the strength of one part pyoktanine to 500 of liquid; the injection, containing two to three grammes of the active substance, should be made at the periphery of the tumor on a level with the healthy tissue.

Under the influence of the injections, the pains are said to disappear, the tumor is observed to gradually diminish in size and to become in part sloughing, in part to soften and to undergo fatty degeneration and absorption. Billroth, on the other hand, had tried the staining fluids in about thirty cases without ever having observed absorption or diminution in offensive odor. Sometimes a softening of the tumor was seen, but it could be considered as due to an aggravation of the disease rather than to anything else.

In the same journal (May 21st), Mr. Quinn reported before the Chirurgical Society of Paris that he had used injections of pyoktanine in tubercular as well as cancerous cases. In the former, no result whatever was obtained, in the latter, slight amelioration.

In a case of epithelioma of the mouth, the injections were followed by very marked facial œdema. In a case of lympho-sarcoma of the thigh, ten injections were made. The centre of the tumor was softened, but not the slightest influence was exerted on the periphery.—*Jour. Cut. Gen. Dis.*

EUROPHEN.

This new antiseptic medicament designed to replace iodoform is obtained by the action of iodine upon isobutylorthocresol. Its pharmacolgy and bacteriolgy have been studied by Siebel, and its therapeutic action by Eichhoff.

Europhen is an emorphous, yellow powder, exhaling a slight odor resembling that of saffron. It is insoluble in water and in glycerine, and is more soluble than iodoform in alcohol, ether, chloroform and the oils. Europhen adheres better than iodoform to the skin and to open wounds, and an equal quantity of it by weight, will cover a surface five times greater.

This iodide of isobutylorthocresol is not toxic. Dogs were found to take 2 or 3 grammes of it with impunity and the human organism will bear 1 gramme of it without unpleasant phenomena save a slight feeling of weight in the stomach.

The urine of patients who had absorbed Europhen did not contain iodine.

Eichhoff employed it successfully in dressing both hard or soft chancres. He used it as a powder, and also in the form of 1 per cent. or 2 per cent. ointment. He furthermore employed it successfully in hypodermic injections for syphilitic patients suffering from the secondary and tertiary symptoms of syphilis. These injections consisted of 1 gramme of Europhen to 100 grammes of olive oil, and of this, one-half to one cubic centimetre was injected daily in one dose.

Eichhoff also employed Europhen in varicose ulcer and ulcerative lupus as well as in eczema, psoriasis and favus, in all of which it proved to be efficacious.

Ointments containing 1 per cent. to 2 per cent. of Europhen are as strong as need be used. Five per cent. ointments caused a certain amount of irritation.—*La Semaine Medicale*, July 29, 1891, *Repertoire de Pharmacie*, Aug. 10, 1891.

THE ACTION OF SULPHUROUS ACID ON THE ECONOMY.

The importance of a knowledge of the effects of sulphurous acid on the human organism has been of late very much increased by the frequency with which this agent is now employed for the preservation of wine and vegetables. It is known that after animals have been poisoned by breathing air impregnated with sulphurous acid, the highly irritating properties of the gas are manifested by the injected state of the blood-vessels of the mucous membrane of the respiratory tract where the sulphurous acid has come in contact with it, the blood of the viscera being found dark and coagulated. Also that animals that are not killed recover very rapidly, but after a few days show signs of bronchitis and pneumonia, and die. The subject has recently been examined by Dr. L. Pfeiffer, who in some experiments employed sulphurous acid in the form of neutral sulphite of sodium, and not in the free state, so as to avoid the caustic action. He found that both warm and cold-blooded animals recovered very rapidly from an almost moribund condition, which showed that there must be either very rapid elimination or a chemical change into some harmless substance. Experiments instituted with the object of elucidating this point showed that 96.5 per cent. of the sulphite was eliminated by the kidneys as sulphate, the remaining 3.5 per cent. only as sulphite. When a large quantity of sulphite had been administered it was nearly all eliminated in five hours. Dr. Pfeiffer believes that when vegetable feeders are made to breathe air containing free sulphurous acid for some considerable time a reduction of the alkalinity of the blood is induced. In animals breathing air containing from one to three parts of sulphurous acid per thousand intense inflammation of the tracheal and bronchial mucous membrane was produced, also inflammatory foci in the tissue of the lungs, the blood in the capillaries becoming black and coagulated. Injections of a 5 per cent. solution of sulphurous acid into the stomach set up very extensive and severe gastritis, not only all the coats of the stomach itself being affected, but also the superficial portions of neighboring organs, as the liver and the diaphragm, death occurring in from three to five minutes. It is suggested that this rapid and far-reaching action may be due to the disengagement of the gas by the heat of the stomach, so that it diffuses itself much more rapidly than a liquid could do. Dr. Pfeiffer finds that in some wines there is as much as eight parts of sulphurous acid, probably as bisulphide of lime, in 100,000, and that in preserved vegetables, such as are used in the

army and on board ship, there is often a very appreciable quantity either free or combined with alkalies, this being especially the case with preserved asparagus.—*Lancet.*

A SUGGESTION FOR HYPODERMIC PURGATION.

At a meeting of the Louisville Medical Society, one of the members, Mr. Flexner, called attention to a comparatively new drug, the sulphate of eseredine, from the laboratory of Bœhringer in Germany. It appears that so far its use has been restricted to animals, on whom it acts, when injected subcutaneously, as a purgative. Should this action be reproduced in the human subject, we shall probably find a valuable addition to our Pharmacopœia. The principle of active purgation in any stage of peritonitis as an effectual means of draining the peritoneum is now very generally recognized. There are often difficulties, however, in the way of administering croton oil or other powerful cathartics by the mouth, especially where vomiting is already a pronounced symptom. As another speaker pointed out at the same meeting it is very desirable that we should have something as a purgative to act in a manner corresponding with apomorphia as an emetic. Certainly a drug that would act rapidly in the manner indicated, without undue depression of the nervous system would be invaluable in many conditions of the abdomen and pelvic organs. The suggestion is of very great interest and of possible future value, and surgeons who make the abdomen the field of their operations may find it worthy of careful attention. The mastering of all bodily functions, physiological and anatomical, by the local selective action of remedies is probably only a matter of time.—*Med. Press.*

LOCAL USE OF MENTHOL AND ENCATYPTOL IN AFFECTIONS OF THE MIDDLE EAR.

Dr. Adolph Bronner, gives some interesting facts concerning the use of these remedies in certain diseases of the ear. "The most favorable cases seem to be those of chronic swelling of the mucosa, whilst in the initial stages of some cases of sclerosis I was inclined to think that I had prevented the encroaches of the disease. When the mucosa is greatly swollen, I direct the use of a snuff of boric acid with two per cent. of menthol to be frequently used in small quantities, while at the same time I inflate the middle ear with the catheter and menthol vapor. A few drops of a twenty per cent. solution of menthol in olive oil is poured into an antiseptic capsule, and this is then firmly attached to the catheter." The capsule used is similar to the Hartman capsule, and the current is passed through by use of Lucæ's modification of the Politzer bag. The vapor is slowly inflated, and much stress is put on the *prolonged use* of this agent upon the diseased mucosa. "I do not remember having produced any pain or inflammation from this procedure, and on the contrary, I think, that by the use of the menthol I have been able to relieve the slight occasional pain."—*Archives of Otology.*

TREATMENT OF PHTHISIS.

In a clinical lecture Dr. William Pepper deals with certain points in the treatment of pulmonary phthisis. Inhalations are better than the use of drugs in paroxysms of cough. As an inhaler he prefers a simple jar with ample cork. Through the cork insert two tubes, have the material to be used placed in the jar, and allow the patient to draw air through the shorter tube. This apparatus can be made in a portable form by using short bent tubes, corked at each end, in which is placed sufficient of the preparation for one dose. A number of these tubes can be carried in the pocket; when the patient feels that a spell of coughing is coming on, he can open a tube and inhale its contents. A fair prescription for this purpose is the following:

℞
Creasoti.....3j.
Tr. iodi.....3iij.
Chloroformi.....3ij.
Sp. vini rect.....q. s. ad. 3j. Misce
Sig. Inhale ten drops.

Carbolic acid can be substituted for the creosote in somewhat smaller doses. Thymol, a highly volatile antiseptic, agreeable in odor, can be tried; tincture of conium may replace the chloroform. Occasionally, for a variety of reasons, a cough mixture may be necessary. Given in syrup form the expectorants are apt to be somewhat nauseating. Dr. Pepper prefers some such pill as the following, which relieves cardiac excitement in case of fever, is rather expectorant, and allays irritation:

℞
Ext. opii.....gr. iii-v.
Pulv. digitalis.....gr. xv-xxx.
Pulv. scillæ.....gr. xv-xxx.
Quininæ sulph.....gr. xxx.
Div. in pil. xxx. Misce
Sig. One, two to four times a day.

If the squill nauseate, it may be left out.

In place of the opium, if it be found to be too constipating, codeine may be given. Constitutional measures which will at the same time favor the appetite, be antiseptic, and help to render the lung a less favorable nidus for the bacillus, can all be added in one prescription, such as the following, which is not unpleasant to take:

℞

Creasoti	gtt. xxxij.
Tincturæ gentianæ co	ʒj.
Tincturæ nucis vomicæ co.	ʒij.
Sp. vini gallici	ʒij.
Glycerini	ʒj.
Vini xerici	Oj. Misce

Sig. A dessert to two tablespoonfuls.

—*St. Louis Med. and Surg. Jour.*

ACONITINE IN TRIGEMINAL NEURALGIA.

Dr. Seguin, in his lectures on the treatment of neuroses, strongly recommends the use of this alkaloid in cases of tic-douloureux. His opinion is that cases are either cured by this drug, or that, at least, it is possible to give long intervals of freedom from pain; but it must be pushed, and its administration is not without danger. The form which he recommends for its administration is in a pill containing $\frac{1}{200}$ of a grain of Dusquenal's crystallized aconitine. These pills are given to the patient in gradually increasing quantity until numbness is felt all through the body with chilliness, and, in some cases, even nausea and vomiting. At first he gives one pill twice a day to females, and three times a day to males, and it is not unfrequently necessary to give as many as twelve pills daily. After the dose is found which is both efficacious and tolerable the treatment is kept up for several weeks after the pain has ceased, and the patient is directed to take a large dose—two or three pills—on the least return of the characteristic sharp pain. Even if no syphilitic history is given, and although there should be no reason to suspect it, this treatment is continued with the administration of the red iodide of mercury in doses increased from one-twentieth to one-fifth or one-sixth of a grain, and iodide of potassium from twenty to forty-five grains, largely diluted with water, after each meal. This medication is continued for two or three months steadily, and a course of a month of it is subsequently given every few months. Along with those drugs the patient must have an abundance of nutritious food, and it is advisable to administer cod-liver oil as well.—*Lancet.*

THE ADVANTAGE OF COMBINING IODINE WITH GLUCOSE.

The remedial value of iodine is well known. But it is also a fact that full doses cannot be administered internally except in the form of iodine of potassium. As a rule, in the various forms of disease to which free iodine is applicable any combination having an alkaline base is not desirable. In order to secure the specific action of a remedy adapted to relieve chronic disorders, and it is to this class of diseases that iodine is chiefly applicable, it is important that it should be to a certain extent cumulative and retained in the circulating blood for a sufficient length of time to exert its specific action upon diseased tissues. In glucose we have an agent capable of absorbing, or rather of occluding, free iodine so that this metalloid cannot be detected by either odor or taste, aud thus combined can be administered in much larger doses than formerly employed without producing unpleasant symptoms. Another advantage in giving iodine occluded by glucose is found in the fact that as this substance occurs normally in the contents of the small intestine, in the chyle after the use of amylaceous and saccharine food, in the blood of the hepatic veins, and in the tissue of the liver in the form of glycogen, it is probable that glucose in thus occluding free iodine is itself protected from chemical change during the process of digestion by the antifermentative quality of the latter, and hence may be readily absorbed into the circulation, carrying in its embrace the iodine to be liberated during the morphological changes that occur prior to the formation of new blood-corpuscles. In the formula, thirty grains of iodine are dissolved in four ounces of water by means of one hundred and fifty grains of potassium iodide; to this solution is added twelve ounces of syrup as prepared by the sugar-refineries and sold by grocers under the name of golden syrup, or sugar-house syrup, or molasses. This syrup contains glucose in combination with organic matter, and answers the purpose quite as well as glucose manufactured from starch by the action of sulphuric acid, or other glucosides furnishing this substance in the isomeric form. In the *Medical Record* for June 13, 1891, Dr. F. P. Mann gives the following formula as representing the best combination for iodine and glucose, with the caution that simple syrup must not be substituted, for this, containing entirely crystallizable sugar, will not take up the iodine, and the result will be

a strong solution of iodine, wich cannot be taken without serious inconvenience. Dr. Mann writes that he has produced the most satisfactory, even remarkable, results, where potassium iodide or syrup of the iodide of iron had signally failed, with the following formula:

℞ Iodinii.....3ss.
Potass. iodidi.....3iiss.
Aquæ puræ.....3iv.
Syrup. fuscus.....3xij.
Ess. gaultheriæ.....3ij. M. Fiat sol.
Sig Take a tablespoonful between each meal with a little water. (Syrupus simplex must not be used.)

He advises when using this formula to keep the preparation for about twenty-four hours before commencing its use, as from six to ten hours are required in which to completely occlude the free iodine. He adds that a larger proportion of the free iodine can be given than the above, and the preparation of the free iodine can still remain odorless and tasteless so far as free iodine is concerned; though where a stronger combination is employed it would be advisable to commence with a smaller dose and increase it gradually.—*Ther. Gaz.*

MEDICINE.

THE CARE OF THE THROAT AND EAR BEFORE AND DURING THE INFECTIOUS DISEASES.

In treating the throat lesions, Dr. E. E. Sattler writes, we must always take into consideration the age of the patient, the stage of the disease, the extent and thickness of the membrane formed. Antiseptic irrigations, sprays, or gargles, should be used every half hour or so in the manner and with the solution mentioned in the prophylactic treatment. This treatment must be kept up at night, as well as day, without fail. Whatever membrane comes off with gentle pressure can be removed, and the throat swabbed every few hours with a solution of bichloride of mercury in strengths from 1:500 to 1:1,000. I believe that this remedy will accomplish our aim best and has given the most uniformly good results. Strong caustics of all kinds must be handled with the greatest of care, and we must remember that by denuding or abrading healthy mucous membrane in proximity to the diphtheritic process, we run the risk of more extensive infection. In children, I think, strong caustic agents are absolutely contra-indicated. When the membrane is very thin we can rely on one or the other of the solvent remedies mentioned above, and then use the bichloride swab. Forcible separation of the false membrane, I think, is always uncalled for, and frequently acts in a detrimental way. Continuous cleansing of the infected nose, naso-pharnyx, and throat by antiseptic solutions, day and night, swabbing the throat with a solution of bichloride of mercury, eternal watchfulness, and constant vigilance constitute a rational treatment of the most common throat lesions. Of course, I do not mention the valuable assistance which we derive from internal medication in this disease, as it falls entirely outside the scope of these remarks. My purpose was simply to show what care should be taken of the throat, the *fons et origo* of these dreadful diseases.

When we come to consider the care of the ear before and during these affections, we come to a subject to which little attention has been paid, and which has been neglected by physicians generally. It has been estimated that 64 per cent. of middle-ear troubles are due directly to catarrhal troubles of the nose and naso-pharynx, and that 33 per cent. of the cases suffering from scarlatina develop an otitis media. By an early treatment of aural complications, no doubt this percentage could be materially reduced. But the methods of prophylaxis detailed above for the mucous membrane of the nose and throat, we are able indirectly to benefit the contiguous lining of the Eustachian tube and middle ear, and in this way prevent, or at least lessen, the extension of the inflammatory process inwards to the ear. In scarlet fever especially danger always threatens the ear, and it is the imperative duty of the physician to keep an eye on this delicate structure. A proper examination with good light at certain intervals is absolutely necessary. During the stage of desquamation especially, a sharp lookout must be kept, and sudden change for the worse, an elevation of temperature, increased fretfulness or severe pain, should call immediate attention to the ear. In older children the diagnosis of implication of the ear need not be so difficult; but in young children and infants it is often attended with uncertainty, and frequently the diagnosis is not made until the discharge of purulent matter is seen in the external meatus. It has become an old saying, and a good one too, that when you are called in to treat a crying child, and you do not know for what to treat it, treat it for the ear-ache. As a rule, however, before much treatment is instituted nature finds relief and an exit for the pent-up matter in the middle ear, by a perforation of the membrana tympani, and a more

or less profuse purulent discharge shows itself in the outer ear.

I cannot linger too long over details of treatment, as I know my time is almost up. It is my firm conviction, however, that a neglect to treat immediately the otitis media and the resulting otorrhœa constitutes an almost criminal action. To refuse to treat this discharge, to leave its arrest to nature, to belittle it by telling parents that their children will outgrow it, has been the means heretofore of more suffering and deafness in after years than all other troubles combined. In the dawn of the twentieth century such neglect, I hope, is a thing of the past. No other inflammation of the middle ear is followed by such quick destruction of the drum and contiguous parts of this sequela of scarlet fever. It requires immediate attention. When the drum has been perforated and this discharge is present in a greater or less quantity, gentle syringing with a lukewarm antiseptic solution, drying of the external meatus with the probe wrapped with cotton, the use of one or the other astringent remedies as the case may require, the gentle inflation of the middle ear by the Politzer method, is the treatment generally called for in ordinary cases. I, myself, am opposed to the careless and indiscriminate use of boracic acid or other powders, especially in the hands of general practitioners. This treatment must be continued as long as necessary, and of course in the hands of the specialists will be modified in a variety of ways for different cases.

In an early and rational treatment of this dreaded sequela of scarlet fever we must look for the benefit which will surely follow for the coming generation. May we hope that soon, with the intelligent and educated co-operation of the people and the physician, diphtheria and scarlet fever will be almost as radically stamped from the face of the globe as that one-time dreaded and frightful disease — small-pox. *Cincinnati Lancet Clinic.*

SOME RECENT CONTRIBUTIONS TO THE LITERATURE OF RAYNAUD'S DISEASE.

A most interesting and suggestive paper, entitled "A Contribution to the Diagnosis of Raynaud's Disease," was read before the New York Neurological Society, by Dr. Geo. W. Jacoby, on Jan. 6, 1891, and published in the *New York Medical Journal* of Feb. 7, 1891. He reviews the various theories advanced in explanation of the disease: viz., Raynaud's, that it is due to spasm of the vessels caused by a functional spinal irritation; the possibility that abnormal blood mixture might be the cause; the cases in which a neurotic origin seemed indicated by lesions found in the peripheral nerves and those occurring in acute infectious diseases. The main part of his paper consists in deductions drawn from a case of his own, which showed primarily typical Raynaud's disease, and which subsequently developed and died of chronic interstitial nephritis. This case is contrasted with others reported in syphilitic subjects by Klotz and Hutchinson, and the great clinical similarity insisted upon. Raynaud excluded from among his cases all those due to syphilis, but Dr. Jacoby says with great point: "This demand in itself shows the weak foundation upon which this diagnosis rests, for if in two different individuals all the symptoms of Raynaud's disease are present, without any other symptoms which might indicate the existence of anatomical disease of the arteries, we are asked in the one case to exclude the diagnosis of 'Raynaud's disease,' because the patient acknowledges having had syphilis, while in the other we must accept the diagnosis, because a syphilitic history is not obtainable. The difficulty in understanding these cases lies in the fact that the frequent occurrence of syphilitic disease of the peripheral vessels, excepting those of the brain, is not yet appreciated as it should be." As hinted in this quotation, the Doctor insists upon the probability of symmetrical gangrene being due, as has been proven in some cases, to obstruction of the end arteries by inflammatory processes in syphilitic cases, even when no lesion is apprciable in the large trunks, and of the probability of the same process existing in cases which are really syphilitic though not suspected or proven to be such. In his own case of symmetrical gangrene followed by cirrhotic kidney he regards the disease as probably due to non-syphilitic endarteritis, the arterio-capillary fibrosis of Gull and Sutton. The necessity of making a microscopical examination of the small arteries of affected areas in these cases is rightly insisted upon before the vascular origin of such processes can be excluded. Disease of large vessels may effect such lesions, but the absence of disease in the large vessels does not exclude the possibility of grave lesions in the terminal arteries.

His general summing up is as follows:

"From a consideration of the various data here adduced, from the nephritic as well as from the syphilitic cases, we are unavoidably forced to the conclusion that those authors who admit that an affection of the small arteries, be this an arteritis obliterans, or other change, does produce a similar clinical picture to that formed in Raynaud's disease, therein are right, but that these same authors are wrong when they contend that a differential diagnosis between the two affections can always be made. The points which are advanced by the various writers for the purpose of making the differential diagnosis are the following: Gangrene occurs in some cases of Raynaud's disease in places where endarteritis obliterans has thus far never been described (face, vulva, auricle, ear, nates, loins); the lesion in many cases of Raynaud's disease is confined to the superficial layers of the cutis, and this never occurs in endarteritis obliterans; the absence of those ætiological moments which produce vascular disease; absence of all palpable anatomical changes in the vessels; and, finally, the occurrence of symmetrical gangrene in neuropathic individuals only.

That these points are invalid and some of them erroneous becomes clear when we consider: (1) That it is probable that arteritis obliterans does occur in the vessels of the skin, as shown in the very excellent article of Klotz, entitled, "The Occurrence of Ulcers Resulting from Spontaneous Gangrene of the Skin during the Later Stages of Syphilis, and their Relation to Syphilis"; therefore, superficiality as well as location would not serve to exclude arteritis; (2) as regards the absence or presence of an ætiological moment (history of syphilis), I have already expressed myself at length; (3) if an arteritis occurs in the peripheral ramifications and spreads upward, then no anatomical change can be clinically detected; (4) that symmetrical gangrene occurs only in neuropathic individuals is a statement not supported by facts. It is true that nervous symptoms are frequently present, but these are often simply results of widespread vascular disease. We are, therefore, justified in concluding that the different diagnosis between Raynaud's disease and anatomical disease of the arteries can in many cases not be made *intra vitam*—in other words, many cases of so-called Raynaud's disease are really cases of arteritis.

The author's further contention that Raynaud's disease should be regarded as a symptom complex, and not as a distinct pathological entity, must commend itself to all who have investigated the subject.

In the *Sci.-J.-Kwai Medical Journal*, D. C. Haga announces that, as the result of the microscopical examination of thirteen cases of idiopathic gangrene, he had reached the result that it was due to arteritis obliterans of syphilitic origin. This article is unfortunately very brief, and would not on its face carry conviction to one who was not inclined to accept the results. As confirmatory of observations of other works in the same line, it is perhaps of value, but it seems a pity that such opportunities should have been apparently so inadequately utilized. The paper is of interest, especially in connection with Dr. Jacoby's.

In the *Lancet* of July 6, 1889, is recorded a case in which a transient attack of local asphyxia was determined by a dog-bite. The patient, a boy aged nine, was bitten on the left arm and hand. He was both anæmic and syphilitic. The coldness and lividity were most persistent in the left arm and hand, but the radial pulse being decidedly less full on that side than on the entirely unaffected right. The attack passed off in two hours entirely. Slight lividity of the ears was also noted. Slight attacks afterwards occurred, lasting on one occasion ten minutes, on another one hour. Once the left foot became cold and the toe blue after a warm bath. In spite of the co-existent syphilis, the shortness of the attacks, the final ultimate recovery after the wound was healed, and the existence of a well-marked peripheral irritation—all seem to indicate that this case was indeed due entirely to vascular spasm. It seems to the writer most plausible in the study of these cases to admit that the rapidly changing phenomena of typical cases of Raynaud's disease are due to vascular spasm. It is quite possible that the graver necrotic lesions are due to coincident vascular disease. It is quite possible that in infectious diseases, such as typhoid fever, symmetrical gangrene may be due to the inability of the feeble tissues to resist external irritants or infectious organisms by reason of general feebleness, interference with the trophic inervation or passing spasm of the vessels, independent of possible embolism. In the *Provincial Medical Journal*, Dr. W. Alexander cites a case as neurotic gangrene simulating Raynaud's disease in a boy of ten, who had an exanthem and fever prior to certain sloughs, which separated and healed when the boy got well.—*Epitome.*

THE ANAL REFLEX.

Rossolimo (*Neurologisches Centralblatt*, May 1st, 1891) says this reflex consists in a contraction of the anal sphincters in response to a stimulation of the skin and mucous membrane of the anus. It is invariably present in man in health. The branches of the inferior hæmorrhoidal, pudendal, and perineal nerves, on which this reflex depends, are connected with the third and fourth roots of the sacral plexus, which spring from nerve cells in the conus medullaris. This reflex can be obtained in the dog as well as in man, and Rossolimo cut the spinal cord across at different levels from above downwards; whenever the lumbar enlargement was cut across at the level of entry of the third sacral nerve, the anal reflex suddenly disappeared, from which it follows that the cells of the spinal cord which are connected with this reflex are situated in the third quarter of the lumbar enlargement, reckoning from above downwards. In another series of experiments the lumbar enlargement was exposed, and the sacral roots were cut one at a time. By this means it was proved that the anal reflex depended upon the integrity of the third and fourth sacral roots. This reflex therefore has its seat in the cord lower than any other reflexes. To obtain the anal reflex the patient may be either standing, the operator separating the glutei, or lying on his side with the legs drawn up. The skin and mucous membrane of the anus may be stimulated by stroking with a pin, a feather, a piece of paper, or some suitable object. The reflex is is shown by a contraction of the sphincter ani externus, and if it is very strong there is a drawing in of the whole anus, and even sometimes a contraction of the glutei. In women the testing of this reflex may be conveniently combined with a gynæcological examination. The author has examined this reflex in a great many conditions, and he comes to the following conclusions: It is increased in some cases of neurasthenia, in cases of myelitis high up in the cord, and in conditions in which there is a general exaltation of sensations. It is lost in multiple neuritis affecting the sacral plexus, in some cases of tabes, and in myelitis of the lower part of the cord, and in these cases there is generally also anæsthesia of the rectum, anus, and urethra. It remains normal in functional derangements of the bladder, the rectum, and the sexual apparatus.—*Brit. Med. Jour.*

NERVE STRETCHING.

M. Charcot related three successful cases of stretching of the sciatic nerve. A postman in going his rounds six years ago, fell on the right hip from a considerable height. Great pain along the sciatic nerve followed and lasted four months. Three years subsequently the suffering became again acute and resisted all medical treatment. M. Charcot tried what stretching would do, and a month after the operation all pain had disappeared, never to return. The second case was that of an artilleryman and the operation was equally successful, while the third was still more interesting. A young soldier suffered from sciatica of an absolutely rebellious nature. The operation produced immediate relief. In concluding, the speaker said he was surprised that elongation of the nerves was not more frequently resorted to. Out of 66 cases M. Lagrange reported 12 definite cures, 49 improvements, permanent or temporary, four totally unsuccessful cases and one death.—*Med. Press.*

THE HEALING OF TUBERCLES.

M. Virchow said: In order to be able to speak with precision of the healing of the tubercles and of the modifications consecutive to the injections of the liquid of Koch, it is necessary to distinguish the tissue which constitutes the tubercle itself (properly speaking, tuberculous tissue), on the one part, from the tissue which represents inflammatory exudate (catarrhal and caseous pneumonia), and which are not, strictly speaking, veritable tissues.

This admitted, there is reason to ask, on what does the remedy of Koch act? Does it act at once upon the three classes of pathological products? Without wishing to reply to this question by an absolute negative, I am able to say nevertheless that the visible effects of the injections, those that we are able to study directly, show that the action of Koch's remedy bears in an unequal manner upon the three pathological products already mentioned.

Let us first study the action of the remedy of Koch upon the tubercles properly speaking. If the remedy be really able to cause the resorption of the miliary and submiliary tubercles, this fact should have been proved in one way or another.

I have occupied myself much during my life in the research of cases where a resorption of the tubercles had been produced, but

I have never succeeded in getting together a number, though it be small, sufficient for observations of this species, and I ought to add that this number has by no means augmented since the use of the liquid of Koch.

With regard to the bacilli of tuberculosis, we know that Koch himself has declared that they are not attacked by his fluid.

For that which now concerns the neighboring tissues which are not tuberculous in the strict sense of that word, I am convinced by observations upon the living as upon the dead that it is upon these tissues, modified by irritation and inflammation, that the action of the remedy of Koch especially acts. In a certain sense this is a fact favorable for the patient; let it be understood that it implies the possibility of the elimination of the tubercles with the product of destruction of the neighboring tissues. But on the other hand it implies also the danger of an excessive irritation of these same tissues —danger of which we have several times seen examples.

I may not omit to remark that I have never spoken of the therapeutic value of the injections of the liquid of Koch. I do not say that it is dangerous. I have simply indicated the possibility of the danger without entering into any considerations upon the different cases and the circumstances in which this danger appears.

I desire to say to-day that in my opinion it is the tissue irritated or inflamed in the vicinity of the new formation which is the most influenced by the remedy of Koch. If we apply to the lungs and to the brain the action so well studied upon the skin in lupus and upon the laryngeal mucous membrane, there can be no doubt that the tissues bordering on the tubercles would become therefrom, after the injections, the seat of tumefaction, intense congestion, acute œdema, hæmorrhagic infiltration, immigration of leucocytes, nay, even of proliferation with formation of new tissue or of its elements.

With the exception of the cases of phlegmonous inflammation of an excessive intensity, of which I have presented to you the anatomical specimens, one can say that all the modifications produced by the remedy of Koch enter into the group of lesions already known, and are only some varied forms of the process of inflammation and of necrosis.

It has been observed, after some injections, that there is a diminution of the zone of thoracic hollow sounds, and this fact has been attributed to the action of the remedy of Koch on the tuberculous tissues. But it is evident that this phenomenon can only depend on a diminution of the catarrhal hepatization accompanying the tubercles, and ought not in any fashion to be placed to the account of the tuberculous tissues, properly speaking.

To sum up that which concerns the anatomical modification produced by the lymph of Koch, I will say that (1) we do not possess any evidence of destruction of the bacilli; (2) there does not exist any fact directly demonstrating the resolution of the tuberculous virus and the resorption of the tubercles; (3) we have already a whole series of observations to support the fact that the destruction of the tubercles and of the neighboring inflammatory tissues is accelerated by the method of Koch. Otherwise we know nothing still which is of a nature to demonstrate that the injections favor the process of induration and the encapsulation of the caseous masses. Quite to the contrary, there is reason to believe that the liquid of Koch is capable of mobilizing afresh some caseous masses already encapsulated, and of establishing in this manner some fresh centers of infection.

I will say in conclusion that I am far from considering my researches at an end. I acknowledge with pleasure that it will be very important to control the observations of M. M. Grabower and Flatau, in which some submiliary tubercles, appearing during the treatment by the method of Koch, have disappeared in the course of further injections. I do not consider this assertion as impossible, but M. Flatau will pardon me if I deem a little strange the disappearance of tubercles under the influence of a remedy that had provoked the eruption.—A. M. Gillett, in the *Amer. Pract.*

ACUTE PULMONARY CONGESTION OF A PSEUDOPLEURITIC TYPE.

M. Berthier (*Revue de Medecine*, April, 1891) says there is a form of pneumonia which gives the signs of pleural effusion, namely, complete dullness on percussion and absence of vocal vibrations and breath sounds. It has been termed by Professor Grancher "*pneumonie massive.*" The ramifications of the bronchial tubes up to the larger divisions are filled with exudation. M. Grancher has also described another form which yields similar physical signs, and which he has named "*spléno-pneumonie.*" He supposes it to be due to a sero-albuminous and epithelial inflammation. M. Berthier then reports a case occurring in a young man after influ-

enza. There were signs of fluid at the left base, but exploration with the needle was negative. The expectoration consisted at first of pure blood. On the fourth day the patient became much worse; he was cyanosed. Similar signs were found at the right base, with bronchial breathing and bronchophony at the angle of the scapula. Later, friction sounds were heard over the subspinous fossa, first on the right and later on the left side. The patient was discharged well in six weeks' time. M. Berthier remarks that the "congestion" was very intense in this patient; the parenchyma of the lung was infiltrated with blood, as also the smaller tubes. During the last epidemic of influenza, cases of pulmonary congestion —and that, too, of a peculiar kind—were frequent. Dry pleurisy was also a common complication.—*Brit. Med. Jour.*

CHLORIDE OF GOLD IN LUPUS.

Dr. J. Rüsin (*Meditzinskoie Obozrenie*, No. 5, 1891, p. 509) reports the case of a peasant woman, aged 40, with extensive lupus of thirteen years' standing, successfully treated by the subcutaneous injection of a 1 per cent. solution of chloride of gold in combination with a 1 per cent. solution of cyanide of potassium. Nearly the whole face, nose, and forehead were involved, the cheeks, forehead, chin, and hard palate being studded with ulcers, the discharge from which contained tubercle bacilli. In all, six injections were given in the course of eleven days, the total quantity of either of the salts amounting to $\frac{3}{100}$ grain, the individual doses of the chloride varying from $\frac{1}{1000}$ to $\frac{1}{100}$ grain, and those of the cyanide from $\frac{1}{1000}$ to $\frac{1}{125}$. On the second day of the treatment, the subjective state markedly improved; on the third, the swelling of the face subsided, some old scars began to shed cuticle, and a labial ulcer distinctly decreased; on the 6th, some ulcers on the cheeks and hard palate commenced to heal, while the facial tumefaction and pain disappeared altogether; on the twelfth, several ulcers soundly healed, and the remaining ones became clear and covered with healthy granulations. Of accessory phenomena, there were observed a kind of intoxication, drowsiness, rigor, and slight elevation of temperature. These symptoms made their appearance on the fourth day of the treatment, shortly after the injection of $1\frac{1}{25}$ grain. They disappeared spontaneously the next day.—*Brit. Med. Jour.*

SURGERY.

HARDENING PLASTER.

M. Julte has recently communicated to the French Academy of Sciences a process of hardening plaster so as to adapt it to the construction of flooring in place of wood, and to other purposes for which it cannot be used in its ordinary state, on account of its want of hardness and resistance to crushing. It is effected by intimately mixing six parts of plaster of good quality with one part of finely sifted, recently slaked white lime. This mixture is employed like ordinary plaster. After it has become thoroughly dry, the object manufactured from it is saturated with a solution of any sulphate whatever whose base is precipitated in an insoluble form by lime. The sulphates best adapted for the purpose, from every point of view, are those of iron and zinc.

With sulphate of zinc, the object at first greenish, finally assumes through desiccation the characteristic tint of the sesquioxide of iron. The hardest surfaces are obtained with iron, and the resistance to breakage is twenty times greater than that of ordinary plaster. In order to obtain a maximum of hardness and tenacity, it is necessary to temper the limed plaster well in as brief a space of time as possible, and with no more water than is strictly necessary.

The plaster cast, or other object to be hardened, should be very dry, so that the solution employed may penetrate it readily. The solution should be near the point of saturation, and the first immersion should not exceed two hours. If immersed too long, the plaster would become friable.

The proportions of the lime and plaster are arbitrary, and may be varied according to the results to be obtained; nevertheless the proportions of one to six have given the best results.—*Sanitarian.*

TREATMENT OF ENURESIS.

Dr. Sänger, of Leipsic, recommends a course of systematic dilatation of the urethra in cases of enuresis both in women and female children. His plan is to introduce a metal catheter well into the bladder, keeping the thumb over the aperture. The instrument is then firmly pressed backwards and to each side from eight to a dozen times. It is, of course, useless to make any pressure anteriorly, as the pubes lie immediately in front. Ten or twelve sittings are usually sufficient. During the treatment the patient is desired

to control the sphincter as much as possible by means of the will, to take but little to drink and to keep the abdomen warm. The good effects of this mechanical system of treatment are to be ascribed to increased power gained by the sphincter in consequence of its contractions after dilatation and stimulation. This method is useful where the paralysis is of central as well as where it is of peripheral origin. Where, however, the neck of the bladder and the whole urethra are of very large calibre, it is useless, and in such cases a plastic operation is required.—*Lancet.*

THE ETIOLOGY, PROPHYLAXIS AND THERAPEUTICS OF HÆMORRHAGES AFTER TONSILLOTOMY.

Although hæmorrhages following excision of the tonsils are of rare occurrence, they are of great interest to surgeons. The majority of patients are adults, in whom the hæmorrhage is due to the fact that the incised blood-vessels fail to retract and contract properly in the indurated tonsillar tissues. The bleeding never results from injury of the carotid artery, as was formerly believed, but comes from the enlarged tonsillar branch of the carotid or the ascending pharyngeal, from the pterygo-palatine artery, or from the ascending palatine in cases where the latter vessel is abnormally situated. Usually, however, the hæmorrhage is not arterial, but of parenchymatous character. It can be easily understood that in persons suffering from hæmophilia, tonsillotomy may give rise to an uncontrollable hæmorrhage.

As regards the prophylaxis, care should be taken in the performance of tonsillotomy not to draw the tonsils too far forward between the faucial pillars, because the surrounding folds of mucous membrane, and the vessels at their point of entrance in the tonsils, are exposed to injury. These accidents are most likely to happen if guillotine-shaped tonsillotomes or scissor-formed instruments are used. Especial care should be taken not to operate in the acute stage of inflammation, or in marked tonsillar hypertrophy, because these conditions favor the occurrence of secondary hæmorrhage. For the same reason the surgeon should content himself with excising only that portion of the tonsil which projects beyond the faucial pillars, the more so since the remaining part usually undergoes spontaneous shrinkage.

If a severe hæmorrhage occurs we should make use at first of styptics, which, in conjunction with compression, are usually sufficient to arrest the bleeding. The application of ice is an excellent hæmostatic. If these means fail, we resort to cauterization with nitrate of silver, or better still the Pacquelin cautery. In the severe cases ligation of the common carotid artery has been successfully performed. As a final resort, tracheotomy with tamponing of the pharynx may be entertained. Experience has shown that severe hæmorrhages are frequently arrested by the occurrence of vomiting or syncope, and these conditions may be artificially produced for the same purpose.—Dr. O. Von Holst in *Oest.-ungar, Centralbl f. d. Medicin. Wissenchaften, No.* 11, 1891.

COCAINE IN URETHRAL SURGERY.

In December, 1886, Dr. W. Frank Glenn, of Nashville, Tenn., introduced a bulbous bougie in a patient on whom he had cut a stricture three inches from the meatus; also enlarged the meatus. He prepared a fresh 8 per cent. solution of muriate of cocaine, and injected a small quantity (without measuring,) into the urethra. Ten seconds had nearly passed when patient excitedly asked, "Will that put a man asleep?" Dr. Glenn answered, No; that its effect was only local. By this time the patient was unconscious, muscles jerking, eyes rolling upward, mouth frothing, and every few seconds entirely ceasing to breathe. He was thoroughly and completely poisoned by the cocaine. It required the active work of three other physicians and himself one hour and fifteen minutes to prevent death. At last, however, he began to breathe naturally, and soon returned to consciousness without any ill effects whatever resulting therefrom. He then resolved to use cocaine (of any strength) no more on a recently cut or denuded urethra. He has since had no unpleasant results until September 24th, 1890. Seeing that Glück regarded a mixture of cocaine in a weak phenol solution as entirely void of any danger, he again tried it in a urethra which had been incised at the meatus just forty-eight hours previous.

The solution was prepared after Glück's formula with the exception that instead of adding ten grains of cocaine to the drachm, he only put two and one-half grains. He took a small quantity in a syringe and injected into the urethra, not holding it in, but allowing it to escape immediately. He turned to his instrument case, and immediately the patient raised up and asked, "What is this?" and fell back, going at once into the regular cocaine spasms, from

which in twenty or thirty minutes, Dr. Glenn feared he would lose his life. The symptoms were exactly those of his former patient, though not lasting so long.

These two experiences, with one other, in which the effects were well marked, but not alarming, will cause him to be very careful in the use of cocaine on absorptive surfaces. In the mildest case of the three, the urethra had not been incised at any point, but was ulcerated, and bled upon the slightest touch with an instrument.

From these cases, he draws the following conclusions:

1. Cocaine is a most potent and wonderful local anodyne, but not void of danger.
2. Its use should be positively forbidden in the recently cut or denuded urethra.
3. Prepared after the manner of Glück (with phenol), it is equally unsafe to apply to the abraded urethra.
4. The use of cocaine in the urethra is attended with more risk than when applied to any other part of the body.—*South. Pract.*, April, 1891.

TREATMENT OF SUPPURATIVE PANOPHTHALMITIS.

Boé (*Annales d' Oculistique*, January and February, 1891) gives the results of some further investigations which he made in order to ascertain the advisability of enucleating a suppurating eyeball. At the International Medical Congress last year, he read a paper in which he came to the conclusion that it was not expedient to enucleate or eviscerate a suppurating eyeball. He considers that the further investigations which he has made strengthen the opinions which he expressed at Berlin. In his earlier experiments he injected blood taken from a body several days after death into the vitreous of rabbits. This was followed by suppurative panophthalmitis and death. The *post-mortem* appearances were not very marked. White lines bordered by a reddish zone were observed on the surface of the liver. Microscopic examination revealed dilated capillaries plugged with streptococci. There was no appreciable meningitis, and no metastatic abscesses were discovered. It has not yet been shown that the streptococcus is the only or chief agent in all intraocular suppurations, and it is impossible to diagnose whether the inflammation in any given case is due to a microbe or not. The author is of opinion that all cases should be treated as if they were microbic in origin. He is strongly opposed to enucleation or evisceration in suppurating panophthalmitis. He recommends that when the pain becomes intolerable a free incision should be made into the eyeball, and the purulent contents evacuated. He objects to enucleation or evisceration on the grounds that either of these operations opens up numerous paths along which microbes might enter the system. He found in his experiments upon rabbits that general infection was more likely to occur if excision were performed soon after suppuration was established. Delay in operating lessened this danger, and for this there might be two explanations: either that the activity of the microbes had diminished, or that the veins and lymph channels had become plugged, and the entrance of the microbes into the general circulation was impeded.—*Brit. Med. Jour.*

"GUTTA-PERCHA PAPER" IN ULCERS OF THE LEGS.

Dr. Vasily P. Kürtchinsky, of Nejin (*Vratch*, No. 35, 1890), speaks highly of the so-called "gutta-percha paper" as the best means of rapidly curing even the most intractable ulcers of the leg. The diseased surface should be first carefully washed with a 4 per cent. boracic acid solution, and then gently dried with a piece of absorbent cotton-wool, after which a sufficiently large sheet of the "gutta-percha paper" (previously washed in the solution and dried between towels) should be applied, covered with a thin layer of cotton-wool, and lightly fixed by means of a muslin roller. The dressing should be changed every day. Under such simple treatment the ulcers are said to heal soundly in about five days in more or less recent cases, while those of older standing and greater severity are cured in two or three weeks. Pain, heat, tension, and disagreeable subjective sensations subside almost immediately after the first application. Similar excellent results are also obtained in all cutaneous affections which are characterized by an intense local irritation, such as dermatitis of various kinds, acute or chronic eczema, erythema, erosions or fissures, etc. The author adds that the application of Martin's india-rubber adhesive plaster is followed by identical beneficial effects. This material, however, is a good deal more expensive than gutta-percha paper. In either case the curative action must be attributed mainly to the powerful sedative and protective properties of the dressing material.—*Brit. Med. Jour.*

A HAIR-PIN IN THE NOSE.

Dr. Joseph C. Roth, writes in the *Medical Record* that on January 28, 1886, while he was doing night duty at the Out-Patient Department of Chambers Street Hospital, New York City, a policeman brought in his daughter, stating that she had a hair-pin up her nose, and that a physician had tried for an hour to remove it. Upon questioning how the accident happened, she said she had dry nasal catarrh, and frequently used the curved end of a hair-pin to loosen the crusts. On the evening of January 27th she attempted to cleanse her nose as usual, and introducing the pin too far, it eluded her grasp; all attempts at its removal merely seemed to push it still farther into the nose. On examination he found a hair-pin in the right nostril, the two points embedded in the mucous membrane of the bony septum and turbinated bone. He attempted extraction with forceps for some time, but being unsuccessful, and producing quite a free hæmorrhage, he wrapped cotton about a nasal probe, and pressing it against the inner side of the distal or curved end of the hair-pin, pushed it as far into the naso-pharynx as possible. He then, with his index and second fingers passed through her mouth and upward, back of palate, grasped the curved end of the hair-pin, and extracted the same through the mouth.

By removing the pin in this manner he was able to avoid all injury to the nose and throat, save what he had done while attempting its extraction through the anterior nares. The hair-pin was of the ordinary shape and size, measuring two and a half inches doubled, or about five inches from end to end.

GYNÆCOLOGY.

ENDO-UTERINE THERAPEUTICS.

Dr. More Madden in a paper on the above subject said, with regard to the methods of modern intra-uterine treatment and the conditions by which this is called for, his observations are founded on a clinical experience extending over many years, and embracing upwards of ten thousand gynæcological cases treated in his wards or in the extern department of the Mater Misericordiæ Hospital, Dublin. Of the cases admitted into those wards during the last fifteen years, endo-uterine treatment was found necessary in 35 per cent. The two essential points in all such treatment, are—first, that the orifice and cavity of the uterus, if not already sufficiently dilated, should be mechanically expanded; and secondly, that whatever application is resorted to should be brought into direct contact with the diseased endometrium. For the first purpose the slow, painful, and hazardous methods of dilatation by sponge or laminaria tents have been long abandoned by Dr. More Madden, who employs in their stead the rapid cervical dilator which Messrs. Arnold have brought out in accordance with his suggestion, and which he finds more effective and quicker in its action than Hegar's or other similar dilators. The second object is especially necessary as a preliminary to endo-uterine treatment in cases of congestive hypertrophy and chronic subinvolution, in which the lining membrane of the uterus is commonly overlaid by an inpervious pseudo-membranous albuminoid neoplasm envolved from the proliferating celia of the diseased surface. Or else the endometrium, in many cases, is so thickly bathed in the tenacious morbid secretion therefrom, as effectually to protect the underlining tissues from the action of any remedial agent introduced into the uterine cavity until that pseudo-membrane and secretion are removed by the curette. For these objects Dr. More Madden recommends, firstly, the use of Duke's cervical curette to cleanse out the entrance to the womb; and secondly, the employment of his own Adjustable Uterine Curette, by which the endometrium may be thoroughly denuded, and at the same time by the hæmorrhagic discharge thus occasioned the congestion of the hyperæmic and hypertrophied organ may be most effectually relieved.

In the treatment of subinvolation the author advocates the introduction, in some instances, of a small tampon saturated in a combination of tannic acid and turpentine, which he termed "Tanno-terebinth." This acts as an immediate stimulant and astringent on the uterine structures, and in suitable cases is allowed to remain in the cavity from 12 to 24 hours, unless sooner expelled from the then generally much contracted uterus. The vaginal glycerine saturated tampon commonly employed in cases of this kind, although unquestionahly serviceable in many instances, is messy and troublesome in its use both to patient and practitioner, and hence for some time past the writer has generally adopted the boric acid, or "dry treatment," recommended recently by Dr. Duke, and which he has found generally very satisfactory as a substitute for the older method of treatment. He also strongly

deprecates the employment of the ordinary syphon syringe for any endo-uterine purpose, and believes that this should be replaced by an irrigator such as the one he suggested many years ago, and which, having been since appropriated by others, without any acknowledgment is depicted in the paper of which this is an abstract. The foregoing measures must, however, be supplemented by more active agents in those more serious cases of long standing, fundal or corporeal endometritis and subinvolution, in which the disintegrated and eroded endo-uterine mucous membrane becomes the seat of various pathological changes, extending to the submucous structures and utricular glands, and often associated with those so-called fungosities resembling papillary epithelioma, which, if checked, may ultimately degenerate into that condition. In such cases it is that the cautery, actual or potential—the first in the form of igni-puncture, and the latter in the shape of stronger caustics, acid, nitrate of mercury, fuming nitric acid, or chromic acid, &c.—may be justifiably resorted to in endo-uterine treatment. In conclusion, Dr. More Madden briefly detailed the result of his clinical experience of these various applications, the circumstances that indicate their use, the dangers that may attend their abuse, and the methods of their employment.

It was also thought, in selecting dilators for use, the amount of dilatation required should be considered. In some cases it is only necessary to dilate to a small amount to admit a curette; in other cases a large amount of dilatation is required to admit the finger to explore the uterus. He wished to know in what case of chronic intra-uterine disease Dr. Madden recommended intra-uterine douching with hot water. After labor or abortion, or operations on the interior of the uterus, it is frequently done, but in these cases the cervical canal is patulous. In chronic cases the cervix should be kept in a state of sufficient dilatation to admit a Boazman's catheter, if uterine douching were carried out daily, as recommended by Dr. More Madden. As to the use of caustic, the most important point was to apply the caustic directly to the mucous membrane, which is frequently very difficult on account of the mucous secretion filling the uterus and cervical canal.—*Med. Press.*

PRURITUS ANI AND VULVÆ.

Dr. Augustin Gœlet (*Archives of Gynæcology, Obstet., and Pædiat.*, March, 1891) disparages the treatment of pruritus by simple application of any lotion. The vagina, he insists, should be daily cleansed with a solution of peroxide of hydrogen (1 part to 3 of water), best administered as a spray. The parts being dried with absorbent cotton, the whole vagina and vulva shouid be dusted with Squibb's pure boracic acid in fine powder. The neighborhood of the anus is, in cases of pruritus ani, to be cleansed with spray, dried and powdered in the same manner. The parts must not be washed with soap. After dusting the vulva and vagina, the medical attendant must place a thin layer of absorbent wool, which has been dusted with the same powder, between the folds of the labia and majora and between the nates, close to the anus and perineum so as to prevent the contact of two irritating surfaces. The wool must be changed directly it becomes moist. Dr. Gœlet says that the above treatment will effectually relieve the pruritus, but cannot prevent its return, as it does not cure the cause. Discharge from the vagina frequently causes pruritus ani in women, though the possibility of discharge from a fistula or some other rectal disease must not be overlooked. Pruritus vulvæ is most frequent in pregnant women with chronic endometritis and extensive erosion of the cervix. A few applications to the cervix of Churchill's tincture of iodine (which should be five times the strength of the ordinary tincture) every third day, and a douche twice a day of a solution of creolin, will frequently effect a speedy cure. The most prompt and effective method of treating endometritis, as well as erosion of the cervix, is by galvanic applications to the uterine canal, or to the cervix alone when the disease is confined to that part. Dr. Gœlet makes the above observations in a notice on a lotion recommended as a remedy for pruritus in the *Canada Medical Record.* The lotion consists of hypophosphite of sodium 1 drachm, carbolic acid half a drachm, glycerine 1 ounce, and Listerine 3 ounces.—*Brit. Med. Jour.*

OBSTETRICS.

RETENTION OF AN ALMOST FULL-TERM PLACENTA FOR TWO MONTHS.

In the *Indian Medical Record* of last month the editor, Dr. James R. Wallace, relates a very interesting case of retention of a placenta for nearly two months without any unfavorable symptoms supervening. The

facts are peculiar. He was called to attend a woman during her second delivery, which had come on at the eighth month. He found the head low down in the pelvis, and the expulsion of the child terminated naturally. While waiting for the uterine contractions to expel the placenta he received an urgent message, and left the midwife to see to the after-birth. He did not visit the patient again, but about two months afterwards he was called, to find her in great pain. There was some hæmorrhage, and on examination the uterus was as large as a child's head. The os was somewhat dilated, allowing two fingers to pass which touched a fibrous mass, found to be the placenta. On inquiry he ascertained that the midwife, finding that the after-birth did not come away within an hour, concluded that probably "everything had come away," and forthwith applied a bandage. The discharge ceased in about ten or twelve days, and the woman got up, going about her work without any discomfort, pain, or sense of weight. On applying compression over the fundus uteri, the placenta, quite fresh in appearance and without fetor, was expelled.—*Lancet.*

DOES ONE ATTACK OF PUERPERAL FEVER PREDISPOSE TO SUBSEQUENT ATTACKS?

Dr. B. E. Kings, (*Mass. Med. Jour.*) after a somewhat exhaustive and painstaking search in connection with this subject, is forced to say that in no work has he found a single reference made to the liability of puerperal fever to recur. His experience leads him to conclude that an attack of puerperal fever predisposes to subsequent attacks, and he attempts to substantiate this statement by the report of several cases gleaned, not only from his own practice, but also from the practice of others who were competent to diagnosticate puerperal fever.

He reports the cases of six women who between them have had fifteen attacks of puerperal fever. He asks: What is the cause of the recurrence of the fever? Does the poison remain latent in the system, ready to break out at any favorable moment? To this he cannot concur, knowing the rapidity of the action of septic poison, knowing that it will not remain dormant, and that it is not recognized as a chronic disease.

He also asks: Can there remain a low form of inflammation of the peritoneum that at the slightest provocation the inflammation is rekindled or are adhesions disturbed by changes that take place during pregnancy and confinement? In regard to old peritoneal trouble breaking out afresh, we all know how careful we have to be in operating in cases of old pelvic cellulitis, but still we must look further, for, in the only case in which he had a chance to observe the condition after death, no such adhesions were found.

Can the nervous system have a hand in the renewal of the fever? He says he can readily believe that a woman with a delicate nervous organization, under adverse circumstances, might be thrown into a condition favorable for the lighting up of a fever, as seen in one of his cases.

TUMORS OF THE DECIDUA.

Professor Sänger (*Centralb. f. Gynak.*, June 13, 1891) has collected a considerable number of cases of "deciduoma." A perfectly innocent form exists, which must not be mistaken for inflamed and degenerate relics of decidua left adherent to the uterine walls. Sänger and Chiari have observed a malignant deciduoma which gives rise to metastases—a true sarcoma of the decidua, in fact. Foul discharge and hæmorrhage follow delivery, and death occurs within six or seven months, after symptoms of disease in the bones, lungs, and other organs. The metastatic deposits in the lungs resemble decidua, bearing the characteristic cells. In the discussion on Professor Sänger's paper (reported in the *Union Medicale*, June 2), Dr. Müller stated that he had seen a case where masses of decidua-like tissue were found in the uterus and metastatic deposits developed in the vagina, abdomen, and nates. Dr. Veit believed that these cases were simply instances of pregnancy during cancer of the uterus.—*Brit. Med. Jour.*

PATHOLOGICAL ANATOMY OF ECLAMPSIA.

In fifteen cases of eclampsia, Schmorl (*Centralblat fur Gynakologie*, No. 29, 1891) found necroses in the liver in almost every case. He divides them by their microscopic and macroscopic characteristics into hemorrhagic and anæmic, the first being much the more frequent. In five cases in which the heart and pancreas were also examined, necrotic patches were found mostly anæmic in the pancreas, mostly hemorrhagic in the heart. In the kidneys there was invariably more or less of a degenerative process to be seen in the epithelium, and frequently hem-

orrhages along the boundary line of the cortex. In almost all the cases hemorrhages could be discovered in the brain, some macroscopic, but most microscopic. Pathological conditions were also found in the blood-vessels. There were numerous ruptures of smaller vessels which the writer ascribed partly to the compression of internal organs by the muscular spasms, partly by the contraction of the vessels themselves which accompanied the convulsions. There was noted, moreover, a separation of the endothelium in good-sized shreds, which led to embolic obstruction of the vessels. This was also favored by the rupture of small vessels and the entrance into the circulation of parenchymatous cells. There were found not only emboli of liver-cells, as observed previously by Jürgens and Klebs, but also indubitable renal cells, and cells of placental origin in the circulatory system. The presence of these cells not only stopped up small vessels, but also gave rise to thrombus formations and consequently to grave disturbance of the circulation. The whole pathological picture, says the writer, points to some poison in the maternal blood. Curiously enough, he would ascribe this poison to the decomposition of the parenchymatous cells within the blood; instead of giving the obviously correct view, that the poison emanates from the fœtal body and is not excreted because the maternal kidneys have become, from some cause, insufficient to do their work of excretion.—*Univ. Med. Mag.*

PÆDIATRICS.

TREATMENT OF HYDROCEPHALUS.

Broca says (*Rev. Mens. des Mal. de l'Enf.*, March, 1891,) there are some cases of this disease in which surgery is powerless. Thus, when one finds post mortem that a subject had tubercle or a neoplasm of any kind in the cerebellum, or the cerebrum, which, by compression, had caused an effusion of fluid, it is certain that no surgical procedure would have been of any benefit whatsoever. The external cause of pressure might be removed and the symptoms be relieved for a time, but the initial cause would remain. There are cases, however, in which so serious a cause is not present, and which under previous conditions of surgery have been looked upon as hopeless. At the present time it is believed that for some of these cases relief can be obtained by the evacuation of the intracranial fluid. A cure may not result, but improvement may occur. Such a result might be hoped for in cases in which the condition was of syphilitic origin. Before the antiseptic era, the results of puncture in these cases were bad. One was afraid to trephine, and if a trocar were used it was more than likely to be septic, and in a few days the result would be death from suppurative meningitis.

At the present time the cranium, the meninges, and the brain itself all show extreme tolerance to aseptic instruments, and Keen has proposed measures for the drainage of the cerebral ventricles. Clinical and anatomical investigations have led Keen to the conclusion that the surest way of entrance to the distended lateral ventricle and the best track for drainage was by a lateral opening, the crown of the trephine being applied three centimetres behind and three centimetres above the external auditory meatus. The brain should then be perforated by the trocar, the latter entering from three to six centimetres above the external auditory meatus and penetrating directly to the ventricle. No injury could be done by such wound to any vital portion of the brain. Keen has thus operated in three cases, Mayo Robson in two, and Thiriar in one. The author has also found the method one of extreme ease and rapidity. The ventricle should not be at once emptied, but progressively, and Keen recommends the use of a horse-hair drain. The brain will bear such an injury, and the drain may be left in position several days. Keen even advises irrigation of the track and the ventricles with boiled water, and in one case after an interval of several days trephined on the opposite side of the skull, put in a drain, and established thorough drainage. The patient died, but there was no evidence of inflammatory reaction about the wounds.

The principal danger in all the recorded cases seems to have been from the too rapid evacuation of the cephalo-rhachidian fluid; in the first of Keen's cases death did not occur until the forty-fifth day, and then was attributable to a tumor of the cerebellum. In another case death followed within a few hours of the operation as the result of a unilateral tubercular meningitis. In order to produce a cure in certain cases of congenital hydrocephalus it will be necessary to operate early, before the fontanelles have closed. The author has operated, however, in one case in which the child was three and one-half years old. The five months which have elapsed since the operation have shown marked improvement in the child's physical condition, but the author does not speak

hopefully concerning his intellectual future. Mayo Robson also punctured an acquired hydrocephalus in a child ten years old, the wound being closed without drainage. All the bad symptoms disappeared, and the child to all appearances made a complete recovery.—*Archives Pædiatrics.*

TETANOID CONVULSIONS IN AN INFANT; OPERATION; RECOVERY.

Ronaldson (*Canadian Practitioner*) recently reported a case that arose when the child was nine days old. It was considered to be one of tetanus, whose starting-point seemed to be the neglected or badly-taken-care-of umbilicus. At first the convulsions were confined to the left side of the body; restlessness led on to tonic muscular contraction, and that was succeeded by well-marked clonic convulsions. Between the attacks the child was apparently well. The convulsions increased to the number of 204 in the twenty-four hours, while during their occurrence the tongue became blue-black, and at times well-marked opisthotones supervened. On one occasion they were never absent for one whole hour, and for a period of nine hours the child was unable to suck, in consequence of the frequency of the fits. When they did not come too rapidly, it took its nourishment greedily. They varied in frequency from about 100 to 204 in the twenty-four hours, but not in such a way as to warrant us in believing that treatment, local or general, had any beneficial effect.

Dr. Brakenridge, who saw the child, and subsequently confirmed the diagnosis, gave it as his opinion that the convulsions were not due to any disease originating in the brain, but that they were peripheral in their origin, and probably had the umbilicus as their starting-point.

Excision of the umbilicus was performed, and at once there was improvement, and the fits gradually decreased.

They returned later in a lesser degree, but were controlled by sulpho-carbolate of soda, and the child perfectly recovered. Microscopic examination of the excised umbilicus did not detect any special organism in it.

NOCTURNAL ENURESIS.

A correspondent of the *Lancet* advises for this trouble that the old-fashioned remedy of a birch-rod be employed shortly before the boy is put to bed, six not severe strokes repeated for two or three nights at the outside will effect a cure. The birching should be regarded by all parties not as punishment for the past, but as treatment for the future —a very different thing. The *rationale*, he thinks, is (1) that it wakes up a desire to avoid wetting the bed; (2) that it draws the blood to the surface for a few hours, and thus relieves the pelvic organs; (3) that it stimulates the lumbar centre, controlling micturition through the nerves distributed to the upper gluteal region; and (4) that it prevents the patient lying on his back.

HYGIENE.

THE PREVENTION OF THE SPREAD OF CONSUMPTION.

Dr. Samuel G. Dixon, in his address before the State Board of Health of Pennsylvania said: As there is nothing that affects the wealth and happiness of the people of this great State more than ill-health, and as there is no one poison that interferes more with health than tuberculosis, which not only too often robs us of those in the prime of manhood and womanhood, but renders thousands upon thousands a burden to themselves and their families for years, yet it is happily a preventible disease, and this Board should be armed with authority and means to enforce and carry out sanitary laws essential to that end.

To accomplish this most important. work it must be evident, after what we have reviewed this evening, that you should have legislation regarding the disinfection and destruction of tuberculous material, especially human tuberculous sputum.

There should be a law compelling passenger transportation companies to furnish receptacles containing either water or a germicide for sputum, both in their cars and stations. The same law should apply to all places where large numbers of persons gather together either for the purpose of work or amusement.

To enforce the expulsion of dust in our factories and workshops.

To compel the thorough sprinkling of the public highways immediately before cleansing.

To forbid spitting on the sidewalks.

To compel the draininge of damp soils before permits for building dwellings are granted.

Rules should be formulated for air space and ventilation of all buildings, and the builders and architects required to submit their plans and specifications before the

work of building can be commenced. This certainly is quite as necessary and practicable as the present law in Philadelphia and other cities regarding plumbing.

Not only must we have a law requiring a certain air space and ventilation in our buildings, but also around our dwellings, workshops, etc.

The width of all new streets and passageways should be of a sufficient breadth. Every block of buildings should have a complementary garden or park. Every building should be accompanied by a certain air space.

Such topographical regulations must be insisted upon in our growing cities, if we mean to reduce the present alarming death-rate and suffering from phthisis.

This ventilation of our cities and towns by the laying out of wide and diagonal streets and reservations of open spaces for gardens and parks, is essential for the successful ventilation of our buildings.

A pure and constantly renewed atmosphere is requisite for the prevention of consumption. This is well known and universally admitted beyond doubt or controversy.

All knives, forks, spoons, cups, and other eating utensils should be thrown into scalding water immediately after using, otherwise the tuberculous sputum will be carried from one person to another.

Dentists and physicians should be required to disinfect their instruments according to a law of the State, and be subject to inspection and a heavy fine for a violation of the same.

The cleansing of all public conveyances should be regulated by law.

We should have laws regulating the ventilation of our animal stables. Cows, like men, require physical exercise and pure air and light to enable them to resist tuberculosis.

The hot, close, dark and dirty stables throughout our State are important factors in promoting tuberculosis in our cattle; therefore, regulations should be formulated for ventilation, light, and cleanliness of animal sheds and stables. These should be under the inspection of competent and honorable inspectors.

Soiling of cattle should be forbidden by law.

As there are at present so many cows predisposed to tuberculosis, and as it is more than probable that interbreeding intensifies predisposition, it should be defined and forbidden.

All consumptive animals should be condemned and killed after having been valued and paid for by the State. The vending of the meat of such animals should be made criminal.

At present cows suffering with this disease are constantly being sold in our markets for the manufacture of mince-meat and sausages.

The breeding of tuberculous animals, the killing of which, at any time, should be delayed for the want of a sufficient appropriation to pay for the same, should not be permitted.

The sale of the milk of such animals should be forbidden under a heavy penalty.

As tuberculosis, actinomycosis, lymphadenomo and rheumatism with enlargement of the joints would frequently be taken the one for the other by the laymen, competent government inspectors should be appointed to make periodical and special inspection of all home cattle as well as those about to be brought into the State.

All butter and milk imported into the State should be subject to inspection for tuberculous material. All meat exposed for sale in our markets ought to be subject to inspection and condemnation.

The law should require physicians to report tubercular cases.

The proved transmissibility of tuberculosis from one person to another brings us face to face with the necessity of considering the question of admitting to our country tuberculous immigrants.

MEDICAL CHEMISTRY.

QUINA LAROCHE—A PERFECT WINE OF CINCHONA.

This celebrated French proprietary is said (*Bulletin de la Société Royale de Bruxelles*) to be prepared as follows:

Macerate 100 gm. quinquina succirubra coarsely powdered, for thirty minutes, in 100 ccm. of boiling water. Strain off the liquid and set aside. Macerate for several hours the residual magma in 1,000 gm. Malaga wine, and again strain off the liquid and set aside. Finally, macerate the magma in 500 gm. alcohol of 50°; strain off, and wash the residue with a little water to recover all the alcoholic tincture. Unite all the liquids, let stand for twenty-four hours, and filter.

To the filtrate add 800 gm. loaf sugar with the aid of a gentle heat, and again filter. The product is the *Vin de Quina Laroche.*

The *Vin de Quina Ferrugineux Laroche* (ferrated wine of cinchona, Laroche) is prepared by dissolving in 1,000 parts of the above wine 1 part of citro-ammoniacal pyrophosphate of iron.

THE COLOR OF OXYGEN.

Till now oxygen was believed to be as colorless in the liquid form as it is in the gaseous. But the Polish chemist, Olszewski, shows that it is only because thin layers of it have been examined that liquid oxygen has been believed to be without color. He has succeeded in getting a layer of it 30 millimeters thick, and he finds that it has a bright sky-blue color. The discovery is very important in point of view of the absorption spectrum of oxygen.

REGREENING OF PEAS AND BEANS WITH SALTS OF COPPER.

According to the *British Medical Journal*, the Health Committee of Glasgow have notified the dealers in colored peas that they will institute proceedings for the sale of such articles, whenever the circumstances are sufficient to warrant a prosecution.

The medical officer of health, in a report to the Health Committee, says: "The process of regreening is essentially fraudulent in its intention and commercial results; that regreening with sulphate of copper certainly does not make vegetables more wholesome—probably always makes them less wholesome, and in some proportions undoubtedly does so; and the public ought, in purchasing preserved vegetables, to ask for ungreened, or at least for vegetables free from copper."

The report then gives the history of this industry in France, the seat of the practice, showing that since 1853 the practice has been prohibited in Paris, and since 1860 throughout France; that commission after commission have reaffirmed the decision, until in 1889, when the Consulting Committee of Hygiene adopted a report of M. Grimaux to the effect that "in the position of our information as to the noxious influence of salts of copper, there is no ground for prohibiting the practice of regreening with salts of copper."

There is a law in Germany against the coloring of food-stuffs, as also in Massachusetts; and as the French government have finally yielded to the wishes of the manufacturers, the consumers must now look out for themselves.

NEWS AND MISCELLANY.

PROF. J. C. WILSON.

Dr. James C. Wilson was elected by the Board of Trustees of Jefferson Medical College to the chair of practice of clinical medicine, to succeed Dr. J. M. Da Costa, who resigned last Spring.

MEETING OF TRI-STATE MEDICAL ASSOCIATION OF GEORGIA, ALABAMA AND TENNESSEE.

The third annual meeting of the Tri-State Medical Association of Georgia, Alabama and Tennessee, which will be held in Chattanooga Tuesday, Wednesday and Thursday, Oct. 27th, 28th and 29th, at Turner Hall, Nos. 616 and 618 Cherry Street.

DR. FRANK TRESTER SMITH,
Secretary.

SEVENTEENTH ANNUAL SESSION OF THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

In the preliminary announcement of the programme for the seventeenth annual session of the Mississippi Valley Medical Association, to be held in St. Louis October 14th, 15th, and 16th, 1891, nearly fifty papers on various topics of interest to the general practitioner are listed to be read.

A regular classified programme will be issued and sent to members and the profession generally at an early date.

UNION MEETING OF THE DISTRICT MEDICAL SOCIETIES OF NORTHERN OHIO.

The Joint Committee appointed by the following Societies, to hold a Union Meeting of the North Western, the North Eastern and the North Central Ohio Medical Societies, at Mansfield, O., on Thursday, Friday and Saturday, Nov. 5th, 6th and 7th.

On Thursday evening the members will be entertained by a reception given in honor of the Association by the Hon. John Sherman, and on Friday evening by a reception given by the Hon. M. D. Harter. Every arrangement has been made to make this meeting a pleasant and profitable one, and we trust that a full attendance may be had.

Ample hotel accommodations will be arranged for; and an effort will be made to secure reduced rates on all the railroads of Ohio.

The following Committee of Arrangements have been appointed: Dr. R. Harvey Reed, Dr. J. W. Craig and Dr. George Mitchell, all of Mansfield.

AMERICAN PUBLIC HEALTH ASSOCIATION.

The 19th annual meeting will be held at Kansas City, October 20th to the 24th, 1891. The Local Committee of Arrangements announces that all the railway passenger associations of the county, have granted a one and one-third fare rate for the round trip on the usual certificate plan, that is:

(1). Procure a certificate of attendance from the agent at the starting point by paying full fare to Kansas City.

(2). Have the certificate of attendance signed by the proper officer of the Association at Kansas City. This certificate will then procure return ticket for one-third fare. All the leading hotels of Kansas City will give special rates to delegates. Arrangements are being perfected for an excursion into Kansas, as one of the features of the entertainment of the Association. For any information as to the meeting, address

DR. E. R. LEWIS, Chairman, or
DR. JOSEPH SHARP, Secretary.
Local Committee of Arrangements, Kansas City, Mo.

IN PRAISE OF WOMEN.

O woman, in our hours of ease
Uncertain, coy and hard to please,
When pain and anguish wring the brow,
Then none so cheaply pleased as thou!
We've only to submit to take
Hot rhubard tea and anti-ache,
And gizzard oil and ipecac,
And porous plasters on the back,
A flaxseed poultice, catnip tea,
And Quackem's pet discovery,
Hot water bags, and sweats beside,
And camphor nasally applied,
And castor oil and vaseline,
And coals with feathers burnt between,
And soothing syrup, paregoric,
Cold-water cloths and drinks caloric,
And all the housewife's category—
'Tis then we see her in her glory,
Needing, to make her bliss complete,
But mustard plasters on our feet.

C. F. L. in Harper's Bazar.

WHAT ANTISEPSIS HAS DONE.

The generation of surgeons whose medical birth and bringing up date back no more than ten or a dozen years, have little conception of the trials that beset surgeons before the discoveries of Pasteur and Lister and the results that have flowed from them. As little, perhaps, as those of older growth have of the ante-anæsthetic times, when patients were poisoned with tobacco in order to produce muscular relaxation and were strapped to the table to keep them quiet while under the surgeon's knife, and when skill and speed were nearly synonymous terms in recounting the qualifications of an operator. We compare the results now obtained with those of fifteen or twenty years ago and are prone to forget the tremendous advantages we have, and to plume ourselves with scant reason on being better surgeons than we were in those days or than others were before us.

These reflections have been called forth while reading Sir James Paget's "Studies of Old Case Books," to which we have already referred, and observing the fatal course of many cases which nowadays would scarcely be looked upon as in any sense serious or demanding more than ordinary care and attention on the surgeon's part. We may believe that the author's cases could nowhere have received better care than they did in his hands, yet he relates a number of instances similar to the following in which a fatal termination in these days would seem almost inexcusable. The case was one of abscess, which was opened and discharged a large amount of pus ". . . and then the case went on after the usual manner of the time, nearly thirty years ago, and the patient died about five months after the accident, exhausted with suppuration, hectic, blocked femoral and iliac veins and bed-sores."

In almost any surgical work of those times and in the files of old journals the same story can be read. It was not that the surgeons were incompetent, far from it, for there were giants in those days, but because asepsis and antisepsis were unknown and unpracticed. We certainly have cause to congratulate ourselves and our patients as well, or more, that we live and work in the days of anæsthetics and of antiseptics. But who would not give much for a peep ahead to see what surgeons of fifty years hence will be doing, what wonders they will be able to accomplish, and what by us undreamt of methods will then be in daily and hourly use?—*Medical Record.*

A NEW METHOD OF STAINING THE BACILLI OF LEPROSY AND TUBERCULOSIS.

Unna (*Monatshefte für prakt. Dermatol.*, June 1, 1891) proposes a new method of staining the bacilli of leprosy and of tuberculosis. By carrying out the following procedures the bacilli are stained brownish-red upon a colorless background.

1. Stain for five minutes in an aqueous borax-methylene-blue solution (1 : 1 : 100).
2. Wash in water.
3. Iodize for five minutes in a 5 per cent. solution of potassium iodide, containing a crystal of iodine.
4. Wash in absolute alcohol until blue clouds are given off.
5. Differentiate in creasol from a few seconds to a half minute.
6. Fix in rectified oil of turpentine.
7. Mount in balsam (a solution of yellow resin in oil of turpentine).

The method may be modified in the following manner for staining tissues:

1. Stain for five minutes in an aqueous solution of borax-methylene-blue (1 : 1 : 100).
2. Wash in water.
3. Iodize for five minutes in a 5 per cent. solution of potassium iodide.
4. Wash in absolute alcohol.
5. Differentiate from ten to thirty seconds in a solution of equal parts of glacial acetic acid, absolute alcohol and ether.
6. Harden and smooth by immersing in absolute alcohol.
7. Fix in rectified oil of turpentine.
8. Mount in balsam (a solution of yellow resin in oil of turpentine).

Good results may be obtained by omitting the fifth and sixth manipulations.—*News.*

A RUSSIAN PILL FOR ANTI-VACCINATIONISTS.

Riga is a city of some 180,000 inhabitants, comprising 6,500 "orthodox" Russians who object *conscientiæ causæ* to vaccination, and reside in one quarter of the town. Between the years 1882–87 the average mortality from small-pox was 108 annually. From December, 1886, to the end of March, 1887, about four months, there were 155 deaths from this cause, owing to a slight epidemic during that period. Of this number 71 occurred among the orthodox population, equal to 109 per 10,000, while the deaths among the remaining inhabitants only numbered 84, equal to 4.8 per 10,000. Down to the year 1887, as stated above, the average number of deaths annually from small-pox was 108. After this epidemic, vaccination and re-vaccination were largely enforced, with the result that from 108 the annual number of deaths due to this disease fell at once to 8.

MIDWIVES IN TURKEY.

The following is the text of a recent irad promulgated in Turkey, regulating the practice of midwifery. 1.° Midwives who are called to attend upon lying-in-women are held to give the greatest attention to cleanliness; they must wear clean garments, and carefully trim and brush their finger nails and wash their hands. Under no pretext whatever must they keep the soiled linen of lying-in-women, or other soiled objects. 2°. After having trimmed and brushed their nails, and washed their hands, they must employ a disinfectant whose formula has been given to all the pharmacies. 3°. As soon as a widwife perceives symptoms of disease in a lying-in woman, and medical diagnosis shows it to be puerperal fever, the midwife must not attend any other parturient woman, without first having taken baths and changed her underwear and clothing. 4°. Any infraction of these rules will subject the midwife to severe punishment.

And yet some say that the Ottoman Empire is composed of barbarians. Our own Boards of Health could read with profit the sanitary regulations of the sons of Othman.—*St. Louis Med. Surg. Jour.*

ETHER-DRINKING IN NORWAY.

The theory has been more than once advanced that the origin of ether-drinking in Ireland can be traced to the success of Father Mathew's crusade against drunkenness in its ordinary forms. Alcoholic nature, driven out by the pitchfork of his eloquence, returned in a new disguise, and the last state of the victims was as bad as the first. This theory has been called in question, but it receives accidental confirmation from what is at present happening in Norway. As English travelers know, the sale of ardent liquors is, in that happy country, encompassed about with more restrictions than that of the most deadly poisons is with us; temperance, in fact, is the law of the land in Norway, as Lord Eldon declared that Christianity was in England. But, alas! these people made sober by Act of Parliament have now discovered how to get drunk without violating the law. Ether-drinking, according to a

Norwegian contemporary, is becoming quite common in certain districts. The farmers buy it in considerable quantities, especially at Christmas-time and on other festive occasions, and they treat each other and get drunk on ether, as they formerly did on potato or barley brandy. Ether is said to be drunk by young and old men and women, rich and poor, by society belles as a "pick-me-up" after a night's dancing, and by starving wretches, to make them, like Tam o' Shanter, "o'er a' the ills of life victorious." If this be true, it seems to point a moral which perhaps thorough-going temperance advocates have not taken sufficiently into account. Is there, after all, a grain of truth in Byron's thesis (which, by the way, found a scientific supporter in no less a person than Justus von Liebig) that "man being reasonable must get drunk," and can the moderate use of ordinary stimulants be suppressed only at the risk of the evil spirit, which has been cast out, coming back after the house has been swept and garnished, bringing with him seven devils worse than himself? The facts are disheartening.—*Brit. Med. Jour.*

THE POISON OF TOADS AND SALAMANDERS.

The skin of toads and salamanders has lately been submitted to microscopical examination by Mr. Schulz, who finds that there are two kinds of glands present in the skin of these animals, viz., mucous and poisonous glands. The former are present all over the body; the latter are confined to the back of the body and limbs and the ear region behind the eyes; and in the salamander are present at an angle of the jaw. The poison glands are larger than the mucous glands in the salamander, are oval, and have a dark granular appearance, due to strongly refractive drops of poison, a good reagent for which is copper hæmatoxylin. The poison is secreted by epithelial cells lining the glands, and, when the animal is stimulated by electricity, it is exuded slowly in drops by the toad, but discharged in a fine jet, sometimes to the distance of a foot or more, by the salamander. The anæsthetic action of the poison of the toad and the use to which it is put in medicine by the Chinese has frequently been pointed out.—*Monthly Journal of Pharmacy.*

MISTAKES OF A PHYSICIAN.

First—To promise a patient you will cure him.

Second—To promise to call at an exact specified time.

Third—To promise that the malady will not return.

Fourth—To promise that you can render more efficient service than your fellow practitioner.

Fifth—To promise that your pills are not bitter or that the knife will not hurt.

Sixth—To promise that the chill or fever will not rage so high to-morrow.

Seventh—To allow your patient to dictate methods of treatment or remedies.

Eighth—To allow yourself to be agitated by the criticisms or praises of the patient's friends.

Ninth—To allow yourself to buoy the patient when the case is hopeless.

Tenth—To allow yourself to make a display of your instruments.

Eleventh—To allow yourself to experiment or exhibit your skill uncalled for.

Twelfth—To allow yourself by look or action in a consultation to show that you are displeased and that if you had been called first matters would have been different.

Thirteenth—To allow yourself to indulge in intoxicating beverages.

Fourteenth—To allow yourself to rely wholly upon the subjective symptoms for your diagnosis.

Fifteenth—To allow yourself to tell the patient you are perscribing saccharum album when you are giving calomel.

Sixteenth—To allow yourself to give arsenic and quinine when a bread and water placebo will answer.

Seventeenth—To allow yourself to tell Mr. Smith the weak places and irregularities of habit in Mr. Jones' family.

Eighteenth—To allow yourself to give your services or an opinion without a reasonable fee or a reasonable expectancy.—*Kansas Med. Jour.*

EXPERIMENTS ON ANIMALS.

The return made to the House of Commons by Dr. G. V. Poore, the inspector under the Act 39 and 40 Victoria, has just been issued. The report gives the names of all persons who have held licenses or special certificates during the year 1890, and the total number of experiments performed by them. The total number of licensees is 110, of whom thirty-three performed no experiments. There were forty-eight licensing places in thirty-three different institutions in England and Scotland. The return shows that licenses and certificates were granted and

allowed only upon the recommendation of persons of high scientific standing, and that the licensees were persons who by their training and education were fitted to undertake experimental work and to profit by it. The total number of experiments performed in 1890 was 2102, and they are subdivided into the tables according to the nature of the experiments. Thus there were 920 in which the animal suffered no pain, because complete anæsthesia was maintained from before the commencement of the experiment until the animal was killed. In 857 other experiments the pain was trivial, simply a hypodermic injection or inoculation, it being a condition of the certificate granted in such cases that the animal shall be killed if pain result. In 316 cases the animal was anæsthetised during the operation, but was allowed to recover, care being taken to ensure the painless healing of the wounds by antiseptic dressings. The inspector states that in his visits to the various licensed places he has never seen a single animal which appeared to be in bodily pain. "As regards the nature of the experiments, 765 were physiological, 976 were pathological, and 361 were therapeutical or pharmacological. In the domain of pathology investigations have been made concerning tuberculosis, cancer, diphtheria, pneumonia, tetanus, acute necrosis, malaria, lead poisoning, rabies, distemper, grouse disease, anthrax, 'black quarter,' 'pink eye,' &c. In the department of physiology the questions of animal heat, circulation, respiration, secretion, and the action of the central nervous system have been investigated; while among the therapeutical questions which have been here examined are the action of chloroform, morphia, nicotine, salicylic acid, strophanthus, and many other bodies which are new or less widely known, together with investigations into the protective and other powers of bacteria and ferments." Dr. Poore refers to his appointments in the spring of 1890 to succeed Professor Erichsen in the office of inspector, and the appointment in August of Dr. J. A. Russell of Edinburgh as assistant inspector. Dr. Thornley Stoker furnishes the report for Ireland, where three persons hold licenses, and they performed seventy-eight experiments, of which fifty-nine were physiological and nineteen therapeutic.

SHOULD YOUNG DOCTORS WRITE?

When a young man begins his medical career the question sometimes arises whether he ought to write articles for medical journals. The first and instinctive response is in the negative. He has had but little experience, and he cannot possibly add anything to the sum of medical knowledge. But this view of the matter is, in fact, not entirely correct. For, in the first place, the capacity for literary work, and of putting ideas in written words has to be developed early in life. To the vast majority of men writing is a mighty task because the habit was never acquired during the plastic season of youth. If a man does not begin to write before he is forty he will never do it at all. The practice of writing, therefore, though it may be acquired at the expense of a good deal of indifferent work, helps the physician in his maturer years to embody results that are of great importance and interest. There are, as everyone knows, in all large cities a number of medical men of brilliant attainments, large experience—acute, practical, and successful. But they cannot write; and the profession is but little the better for their labors. Usually such gentlemen speak lightly of literary work and do not believe in "rushing into print." As a matter of fact they only do not do it because they cannot.

The kind and amount of literary work which young men can wisely undertake is limited, and this fact should be steadily borne in mind. Reporting cases must be done very little. The case should either be unique in kind or of positive interest therapeutically or pathologically. Experimental work in physiological or pathological laboratories is a kind always open to young men, and almost always gives results in some increment to medical knowledge.

A field of literary labor also in which young men can usually work profitably is that of collating and digesting critically all contributions upon certain subjects. Such articles, if prepared carefully in connection with personal observations, are often of great service to older and busier men.

Many young men make the mistake in pursuing a certain task, of attempting to prove too much or of investigating too wide a field. It is much better to settle a little matter positively and forever, than to bombard a large subject with inconsequential results.

Finally, we would remind young men that therapeutical problems are the most difficult to solve; and that books should never be written by the immature.—*Medical Record.*

Clinical Lecture.

THE NATURE AND TREATMENT OF ORGANIC STRICTURE OF THE URETHRA IN THE MALE.*

BY JOHN H. BRINTON, M. D.,

PROFESSOR OF THE PRACTICE OF SURGERY AND OF CLINICAL SURGERY, AT THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

Gentlemen:—In the ensuing lectures I propose to present a summary of the treatment of organic stricture of the male urethra, as you have seen it practiced by me in this arena. In so doing, I shall confine myself to purely clinical considerations, and shall refrain from entering upon foreign theoretical discussion.

Organic stricture consists, as you know, in a deposit of lymph beneath and around the urethral mucous membrane. This takes place in the form of plates and encircling bands, of varying size, density, and resistance. Its exciting cause is pre-existing inflammation, generally gonorrhœal, and violence or injury. The obstructions or strictures thus formed, by their gradual increase, firmness, and contraction, interfere with the flow of urine, and give rise to urethral and often vesical irritation. Strictures have been variously classified. We have *first*, the *linear*, bridle, cord-like or thread-like stricture; and then the *annular* stricture, more or less broad, varieties of the *ring-like* contraction, which surround the canal and are met with in the most perfect form in the spongy urethra; *secondly*, the resilient or elastic stricture, which, when dilated or stretched, evinces a constant and persistent tendency to contract; *thirdly*, the *irritable* stricture; this is characterized by marked sensitiveness, and pain on the slightest manipulation, with a disposition to bleeding, inflammation, local, vesical, and often general irritation. This irritability may be met with in almost any form of stricture, and in any locality. It seems to depend rather upon an individual sensitiveness than on any special pathological formation. It largely influences the determination and results of treatment, and its existence or development must be carefully watched and respected.

Strictures of *large* and *small* calibre; these terms are of constant application, and are somewhat arbitrarily used. By a stricture of *large* calibre, is usually meant, one with a circumference of more than fifteen or sixteen millimetres, while one below that standard is described as a stricture of *small* calibre. As a rule, strictures of the anterior or pendulous urethra, especially when of long duration, and annular, are resistant to a far greater extent than those of other portions of the canal. In the opinion of Professor Longstreth this condition is due to the fact that the submucous connective tissue of the anterior urethra is more homogenous, and its fibres are more closely felted than in that of the posterior portion. It contains also more connective tissue and fewer glandular elements than the latter, or bulbo-membranous portion, in which the paucity of connective tissue and the preponderance of glandular elements favor a more frequent development of stricture, and at the same time renders it less resistant. Strictures may be *single* or *multiple*. A *tortuous* stricture is the result of two or more neighboring strictures, whose irregular openings and canals collectively form a distorted and twisted passage.

The symptoms of stricture, I need only refer to. Micturition is difficult, imperfect, painful, strained, and usually frequent. The stream is altered, being narrowed, flattened, forked, twisted, irregular, and intermittent, even to drops, with often, a gleety discharge from behind the stricture. There is impairment of propulsive force in the stream,

*First Lecture.—Two Clinical Lectures delivered at the Jefferson Medical College Hospital.

although this can usually be increased by straining, and there is a sense of imperfect voidance of urine, with dribbling, after voluntary urination is completed. Shooting pains in the loins, and limbs, and reflex and sexual disturbances are not infrequent. If severe and deep urethritis occur, more or less suppuration may result, with dilatation of the urethra behind the seat of stricture, rupture, extravasation of urine, abscess and fistula. In other cases, cystitis may follow, with involvement of the ureters and kidneys, and disorganization of the latter.

Stricture most commonly follows gonorrhœa, although it may result from simple urethritis, from masturbation, and perhaps from prolonged and inordinate or ungratified venereal excitement. It is also caused by the application of caustic and irritating agents, by unskilful and rough manipulations, and generally, by traumatism. Its development, I believe, is sometimes favored by extra urethral pressure or hindrance to the flow of urine in micturition, particularly when the urethra is congested or inflamed. Such an impediment may be produced by the corded edge of a pair of drawers, made high in the crotch, and which press externally against the lower wall of the urethra during urination in the erect posture. This idea is strengthened by the alleged rarity of stricture in Oriental nations, who, I have been informed, urinate not in the upright, but in the squatting position. If this be true, stricture, ethnologically speaking, would seem to be more frequent in "him who pisseth against the wall," to use the language of the Old Testament.

As a rule, organic stricture, the result of gonorrhœa, occurs almost always in front of the membranous urethra, and involves the bulbous and spongy portion of the canal. It is rarely met with in the membranous part, except as the result of falls, kicks, and other traumatic violence, in which must be included rough surgical manipulations. It probably never occurs idiopathically in the prostatic urethra. When an organic stricture has once formed, it remains, in a greater or less degree, for life; it is not absorbed, and does not disappear. Yet under proper treatment, the canal, at one time narrowed, may be kept largely pervious, and the stricture may thus be deprived of its malevolence and cease to be a source of annoyance. If neglected, or if after having been once relieved by dilatation in any of its forms or by incision and division, either internal or external, it be left to itself, it will almost certainly recur, and sooner or later, revive the ancient memories of its possessor. I think however, that in all cases, organic urethral stricture, if taken in time, will prove amenable to judicious surgical treatment, and with this object in view, I wish to recall and formularize your clinical experiences of the last few months.

In approaching a suspected case of stricture, the first object of the surgeon, is to arrive at a certain and satisfactory diagnosis. This can best be accomplished by an exploration of the urethra, by means of the acorn tipped bougie with a rectangular shoulder, the bougie a-boule. This instrument may be either flexible, or metallic, but I prefer the former for a first examination. The presence, number, locality, and calibre of the narrowed points, can thus be accurately determined. Their resistance and firmness can be estimated, by means of the slightly conical metallic Thompson's sound. All urethral instrumentation should be conducted under full antiseptic precaution. Every instrument should be thoroughly cleansed with soap and hot water, both before, and after use, and should also, before introduction be dipped in the sublimate solution of 1–1000, or 2000. As an additional precaution, it is well to brighten all steel urethral instruments with a small piece of well used, fine, oiled emory cloth, before boiling and disinfecting them. We can not be too careful in regard to surgical cleanliness in the urethra, and by attention in this respect, you may find, perhaps to your surprise, that very considerable surgical interference can be tolerated, almost with impunity. This increased tolerance has forcibly impressed me, on mental comparison of the results of my urethral operations during the last few years, with those of the period preceding an antiseptic practice.

When inserting urethral instruments, I advise you always to place the patient on his back; and in employing metallic ones, invariably to follow a uniform method. Thus, stand on the left side of the patient, grasp the penis behind the corona with the left middle and ring finger, and with the thumb and index finger, cause the meatus to gape; and insert the point of the bougie or catheter, the shank of which rests over the patient's left groin. Then gently draw the head of the penis and meatus upwards on the instrument, and keeping the point at first downwards so as to avoid the lacuna magna, slowly carry the handle to the middle line of the body, then by a delicate pushing motion advance the point, and at the same time raise the handle of the instrument so that it shall

be at a right angle, or perpendicular to the axis of the body. Its point will then be immediately beneath the pubal arch. Next *raise* the instrument slightly, so as to lift its point towards the upper urethral wall, and prevent it from entering into, and being arrested by the sinus of the bulb. By a continuance of the sliding motion (which should never be intermitted) the point will traverse the membranous and prostatic urethra, enter the bladder, and the handle of the instrument will descend between the patient's thighs. By following this formula, pernicious leverage with the point of the sound is prevented, the danger of bruising or tearing the urethral wall is avoided, and the operator at all times knows exactly where the end of his instrument is. In most cases, the urethra rapidly becomes tolerant of gentle catheterism.

With regard to the character of the stricture, and its size, calibre, or want of dilatability, much has been said, and perhaps the subject has even been somewhat obscured by the very minuteness of classification. Stricture undoubtedly occurs in every degree, from the slightest impediment of the urine flow, to a narrowing, which will not much more than pass a filiform,—strictures of large and small calibre. The gravity of the symptoms is however, often disproportionate to the degree of the stricture, for one of large calibre, if resilient may cause more inconvenience than one which is comparatively tight. It would seem indeed as if the resiliency and irritability of the stricture, its age, or length of continuance, and the amount of involvement of the deep urethra and bladder, rather than a mere degree of tightness, influence its clinical features, and dominate its treatment.

In the *treatment* of stricture, the first and most natural process, is gradual dilatation. It is readily applied, and is attended with comparatively little danger. As Sir Henry Thompson has told us, "it is always to be tried first, because it is the safest and easiest mode." Theoretically it is a perfect procedure, but unfortunately it is not always applicable. How then will you know when to resort to it? This question can be best answered from clinical experience. In strictures occuring near the meatus, and for two or three inches back in the pendulous urethra, the obstruction is usually more or less resistant, and when dilated, by any process, even if largely overstretched, is apt to recur rapidly and obstinately. Strictures occurring in this portion can without doubt, be more efficiently treated, by internal incision or division, or internal urethotomy as it is called. This division of the stricture should be followed by the introduction of straight or curved metallic sounds to prevent recontraction. Internal urethotomy may be effected by the urethrotomes of Maisonneuve or Civiale. The former cuts from before backwards, the latter from behind the stricture forwards. In this Charriere model, the two instruments are combined, it cuts both forward and backwards. Here is the urethrotome of Otis, by which dilatation of the stricturing band is added to its section. Any of these instruments can be safely used in strictures of the anterior portion of the urethra. It must be remembered however, that in cutting from behind forwards, the stricture must first be dilated up to number ten or eleven of the French scale, so as to permit the passage of the instrument, before the blade is sprung.

In advising the division of stricture of the anterior urethra, and especially of the meatus, I must nevertheless, caution you against the indiscriminate and excessive cutting, which has become the fashion of the day. It is unquestionably right to perform meatomy to relieve a mechanical impediment to micturition, or to facilitate the insertion of large instruments for vesical or urethral operations. It must however, always be borne in mind, that the meatus urinarius is a point of normal urethral narrowing. It plays, in this respect, the same part as does the nozzle of a garden hose, which increases the propulsive force of the stream of water. In like manner, the physiological function of the normal meatus is to accelerate, and lend force to the fluid issuing therefrom, be it urine or semen. It is manifest that surgeons should not needlessly disturb, or attempt to improve this arrangement of nature, and should refrain from changing the slit-like aperture of the meatus, into an expanded bell-shaped opening, as too often happens. In this latter condition, dribbling after urination may ensue, and what is perhaps more important, a possible impairment of the life-giving function.

Leaving for the present those anterior strictures which demand and admit a cutting instrument, let me next direct your attention to those deep strictures of really narrow calibre, such as cannot be traversed by an ordinary instrument. These are often spoken of as impermeable or impassible. On this point I will speak positively, and I ask you not to misunderstand me. I do not believe that any idiopathic stricture is ever impermeable. By idiopathic stricture I mean

one which has resulted from urethitis, and not from traumatism or surgical operation or manipulation. Surgical violence, you will comprehend, may readily change an idiophathic into a traumatic stricture. With this limitation, I believe, that in all deep non-traumatic strictures, through which the urine can pass, if only in trickling drops, a filiform whalebone can be carried into the bladder.

I am also certain that over this whalebone, dilating instruments can be guided through any stricture into the bladder, and that the stricture, however tight, can be dilated and by over-distension brought to a comparative cure. as effectively and more safely than by any of the cutting processes. .

I am quite aware that you may read and be told differently, and that you may be led to think that in many cases the stricture may be so tight as to defy all attempts at instrumental passage, and demand division by the knife. Yet I cannot but hope that your observations, in this room, and the testimony of those who have assisted in this clinic for many years, may go to sustain the truth of my assertions. as to permeability and dilatability of these deep, tight strictures.

The instruments necessary for the performance of rapid dilatation, are six or eight capillary whalebone filiforms, a Thompson's dilator, a Gross dilator, and a set of metallic sounds, numbers 20 to 35. For a slower dilatation, to relieve retention the result of aggravated stricture, the same whalebone will be required, also two of double lengths, four or five ordinary English gum catheters, calibre six to twelve French, and an equal number of Gouley's tunelled catheters, beginning with the smallest. The starting point of your manipulations will be the possession of proper whalebone filiforms—filiform bougies as they are often called. Each whalebone should be thirteen inches long, and at its greatest diameter of shaft be so fine that it will readily slide through the number two opening of the French scale. The lower two-and-three-quarter inches should gradually taper until it becomes absolutely capillary, and should terminate in an olive-shaped end or tip.

I advise you to make these instruments yourself. They are essential to your success, and as all those in the market, which I have seen, are coarse, stiff and practically useless, at the risk of being prolix, I will tell you how to make them. A dozen will last a lifetime, for if you know how to insert them nicely, you will not break or destroy them. Buy from your instrument maker a few fine round whalebones †of the thickness of number two French scale. Each length is twenty-six inches, and will therefore make two filiforms of ordinary size. Prepare them thus: Paste a half sheet of fine emory paper on a thin board, then, having cut the end of the whalebone transversely with a sharp knife, place it perpendicularly on the emory and draw it to and fro so as to smoothly round the tip. Next, let the end rest horizontally in a shallow grove on the board, and rotating it between your fingers, scrape it quickly with the knife, from the tip so as to give it the olive shape. Then draw the knife blade edge downward over the whalebone until the latter is sufficiently and evenly thinned, taking especial care to taper the last two-and-three quarter inches, down to the olive end. Do not use glass for scraping the bones, or a file. If you do so it will destroy the fibre and render the filiform untrustworthy and friable. Do everything with the knife-blade. Finish the instrument by drawing it frequently forwards and backwards through the tunnel of a smallest Gouley's catheter and that of Thompson's dilator. This will insure the ready passage at all times of the metallic instruments along the whalebone. The whalebones thus fashioned are very delicate and perfectly straight. I never use those with spiral or twisted ends, as I have found them uncertain in their action, and deceptive in the information they furnish. After whalebones have been used, they should always be immersed for a few moments in very hot water and then dried with a cloth. If they have become twisted by use they should be placed between the leaves of a large book, and allowed to dry. Twists and kinks are thus removed and the bone preserved straight, uninjured and in good condition for fresh use. Filiforms should be kept in a reed or tin quiver.

You have now an efficient filiform, and you must learn to use it properly. Therefore, bear in mind this cardinal rule, never to attack with a filiform, a stricture, especially a tight one, *after* the use on the same day of any catheter, bougie, or explorer. The chances are against success if you do. The filiform should always be used *first*, as any other instrument, soft or hard, especially if of larger size, is apt to press or ram the aperture of the stricture or its walls together. Its opening is thus distorted and rendered difficult of access, and the stricture becomes

† These whalebones are manufactured in New York at Nos. 161, 80 and 82 Duane St., for hatters' use. The mercantile gauge is No. 20, and the price about $5.00 or $6.00 a gross of 144 pieces, full length.

for the time impermeable to instrumentation, although passable by urine. Remember this and you may save yourself discouragement and mortification. You have seen me in public decline a filiform attempt after previous skilful and continuous instrumentation, and I did so because I knew my efforts must be futile. In an endeavor to pass a so-called impassable obstruction, you must take every precaution and give yourself every chance.

COMMUNICATIONS.

COLPO-PERINEORRHAPHY.*

BY JOHN W. GROFF, M. D.,
HARLEYSVILLE, PENNA.

Partial laceration or rupture of the perineum, and more especially of the vaginal portion, thus producing what has been called a skin perineum, the neglect of that laceration, with the consequent development of a rectocele, prolapse of the uterus, cystocele, etc., including all its attendant horrors, and the necessity for this operation of colpo-perineorrhaphy, or possibly for either operation separately, is, I am convinced, a not infrequent one, judging by my experience in medical practice.

Meeting, as I do, with many a case in which this accident occurred, it may be years ago, patiently listening to the long history of sorrow and suffering upon the part of the patient, provided you choose to, which will be given forth in volumes, give your time and attention to the recital in all its detail; guided and directed by this experience, I have taken it to heart and resolved to profit thereby.

All this as the result of the parturient act —the only painful process, physiologically, in nature. Perhaps in many cases due to misguided or misdirected efforts upon the part of the attending accoucheur, or in other cases, to a want of any effort at all upon the accoucheur's part,—a mere acting by catalysis, as it were—which I heard thus expressed upon one occasion, and which to my mind should be self-condemnatory; for the accoucheur's duties are sufficiently clear and obvious, to at once destroy this catalytic theory altogether.

*Read before The Montgomery County Medical Society, on July 22, 1891.

I recall that but a few short weeks ago, I was sent for to see a patient—Mrs. B., 68 years of age, who had been stricken with a slight apoplectic seizure. After developing the history of the trouble for which I had been summoned, I made inquiry in regard to other bodily functions, as is my usual rule, and thus touched upon the condition of her bowels, past and present. The facts developed were, that, 41 years ago, she was attended in her second confinement by Dr., afterward Professor Blank, we will name him. From what I learned in this and other cases like it, it appears that the Professor was not in the habit of devoting much time to his obstetric cases, but, on the contrary, gave ergot with a free hand, and applied the forceps early, thus making it appear that his life, if not his practice, depended upon his getting away at as early an hour as possible, upon all such occasions, regardless of consequences.

The result of this method of obstetric practice is well attested by the number of sickly women, who escaped with their lives, at the hands of this obstretrician, and who remained, and some of whom are *still* remaining, a living testimony unto the dreadfulness of such work and the results which followed therefrom.

In this case, the patient suffered a partial rupture of the perineum, which was neglected, and thus in time there developed all those attendant conditions, which render the life of such a patient miserable, together with a large rectocele. At present, she has frequent desire to evacuate the bowels, with utter inability to do so, except by the employment of purgatives, in order to produce loose and watery evacuations. I told her of the operative measures, which might be instituted in a younger person, but that in view of her age and infirmity, that would be out of the question in her case, and that she would have to bear her bodily affliction until relieved by the Angel of Death, palliative measures being the only ones applicable in her case.

Thus I might repeat, case after case, but a partial history of this one, together with that of the one in which an operation was performed and which I will treat somewhat in detail, will be sufficient for the purpose of the present paper.

In regard to partial rupture, Thomas in his work on *Diseases of Women*, says:

"Complete rupture presents such serious discomforts as a consequence, that partial rupture is by many viewed as a trivial circumstance. So it is by com-

parison, but so likely is it to be followed by prolapse of one or both vaginal walls, that it should never be undervalued. As soon as such prolapse occurs, uterine, vesical and rectal troubles become almost inevitable."

It is not my intention to touch upon the subject of complete rupture of the perineum at all in this writing.

It has been maintained by some one, that, in the progress and development of the human race, the brain itself has become larger and heavier—more developed, and consequently requires a larger brain-case or calvarium to contain it. Hence labors have become more difficult, painful and dangerous in order to give birth to larger heads, and that this will become still more so in the future, I will not attempt either to affirm or to deny this idea, but will leave it to the anthropologist to decide. Simply by this means desiring to call attention, more forcibly perhaps, to the great value and importance of anæsthesia in labor. I am an ardent advocate of the administration of an anæsthetic agent, during the process of parturition. It is now an almost invariable rule with me, when called to attend a case of child-birth, to take with me a can of Squibb's ether, for inhalation, and offer it to the patient as the best, surest and safest means of assisting her, in passing through the perils and tortures of child-birth. The pain is without a doubt, acute, the suffering agonizing, and why not make use of an agent, which is capable of almost extinguishing that suffering, and of allowing her to pass through the ordeal, undaunted and undismayed.

Many a surgical operation is performed, in which the pain to be endured would bear no comparison whatever to that of a severe case of labor, where full anæsthesia is employed, and which would be considered criminal nowadays, were such agent not made use of under the circumstances.

I have administered ether in labor with none save the best effects and the happiest results, and I now give it with a confidence, born of some experience, and perhaps a good deal of enthusiasm. The fact that it has been of immense service to me, will stimulate me to its continued employment in the future.

And further, the point which I wish to make is, that lacerations of the perineum are, I believe, far less frequent when such an agent is made use of properly, than under other circumstances.

Anæsthetics relax muscular and other tissues, thus allowing the birth canal and perineum to relax or stretch more readily. It relieves the pain, and hence more time can be allowed for the parts to stretch, instead of to tear. Besides, by using an anæsthetic in this way, it will not be found necessary to resort to the forceps nearly as frequently as is done by many practitioners, thus again diminishing the liability to tears, the forceps being in my opinion an admirable instrument, the more admirable, the less used.

City practice differs very essentially from country practice, and one community may, and undoubtedly does differ, it may be, very materially, from another. In the scope of country in which I have the honor to hold forth as a practitioner of medicine, the gynæcologist finds comparatively little work to do. Not that the necessity for his calling does not exist, but, because the majority of patients will object and many refuse any examination for the diagnosis of diseases of the genital organs, much less as a rule, consent to any operation. At times, in some instances, it is only after years of suffering, or by being brought, as it were, almost to the verge of the grave, that they will submit to examination, and if necessary, operation. Such was the case with the patient whose history I am about to detail, an extreme one of its class. To me, it was full of interest, doubly interesting on account of the very marked relief afforded by the operation, after the condition had existed for so many years. The patient, Mrs. Samuel H., first came under my observation during the month of January, 1889. I was called in with the hope of being able to afford her some relief, during a severe attack of sick-headache, and for procuring means to ward off future returns of the trouble, or at least to render them much less frequent and distressing.

These occurrences and especially the concomitant conditions, I may as well describe right here in the beginning. She was subject to sick headache, the assaults being violent in character, and occurring quite frequently, at times, their duration being various, in many instances continuing several days. The pain was very severe, rendering her as feeble and helpless as a little child. Invariably accompanied by vomiting, and when this feature broke in upon the scene, the poetry of the occasion became manifest, it was truly pathetic. When the nausea became distressing, indicating the advent of vomiting, she was compelled to assume a rather anomalous position, so it required two receptacles to receive and retain the discharges, one at either of two rather distant extremities. She was unable to retain her urine, this fluid gushing forth in volumes,

during the violent retching, which formed a part of each attack.

Her inability to control the outlet of this reservoir, was a very distressing feature with her, even when free from headache. In walking she was compelled to be very cautious, not to step too high, nor to indulge in laughter, for all these alike would bring forth a gush of urine, caused by the sphincter relaxing its feeble grip upon the contents within.

The vomiting and retching were violent in character concerning both of which she complained bitterly. These attacks of headache occurred frequently, their recurrence being promoted by the highly unsatisfactory condition of the gastro-intestinal tract, this feature being dependent upon the anatomico-pathological condition, to which I am about to refer, and for the restoration of which an operation was performed, which I will presently describe.

At the time of the operation, the patient was 51 years of age, medium in size and stature but of a highly neurotic temperament. In part, on account of inherited nervous predisposition, and in part, due to long-suffering, she had become excessively irritable and despondent, in fact she became a "household tyrant" long since.

Menstruation was still regular in recurrence, this function continuing its regularity until the summer of 1890, about one year after the operation, when she entered the period of the grand climacteric. She had been comparatively free from disease, with the exception of the neurotic element and the violent headaches.

Somewhat more than twenty-four years previous to the time of the operation, she became pregnant for the first time. Labor came on, the case did not advance as rapidly as thought desirable, and thus the attending physician saw fit to apply the forceps. The application was made high up, I have been informed, the delivery was accomplished, and as a sequel, she sustained a partial laceration of the perineum. This rupture was of such a nature as to be misleading, one of a kind which I think Prof. Goodell very aptly designates a skin perineum, the cutaneous portion being but slightly ruptured, or at least only to a limited extent, while within the vulval opening there was extensive separation of the tissues.

In those days, I fancy, operations for the restoration of lacerated cervices and lacerated perinæi, were not as common, nor as frequently performed, as within more recent years, or at the present day. At least, in this instance, nothing was done, no attempt having been made to restore the parts to a normal condition.

Right here in the occurrence of this laceration, and the subsequent neglect, in allowing the case to drag along, without performing an operation for the restoration of the parts to their previous condition, the foundation was laid for many years of dreadful, silent suffering. Silent, I said, for not a few women would rather suffer in silence for years and years than approach a medical man upon a subject which appertains to their sexual organs. In this case the lady was especially modest and retiring in her disposition. During the years immediately following the reception of the injury, comparatively little discomfort or inconvenience was experienced, but as the years rolled by, little by little, the difficulty increased and thus there developed a condition of affairs deplorable to the victim and direful to the beholder. This wretched state was connected with the act of defecation, and the manner in which this important process of nature was accomplished, or at times only partly so, I will depict, first giving the results of physical exploration.

Upon examination I found the cutaneous surface of the perineum but slightly ruptured. Within the vulval opening and extending upward upon the posterior vaginal wall, the tissues were separated very considerably, thus making the canal much larger and wider than natural.

When in the recumbent posture by bearing down, this being unnecessary when erect, there would bulge forward an immense tumor-like formation, due to enormous dilatation of the rectum—a huge rectocele. The separation of the tissues above noted, took away a wall or support for the rectum and then the patient, by bad habits, want of attention to personal hygiene, allowing herself to become constipated, with consequent straining at stool, gradually paved the way which brought about the formation of this immense rectal pouch. Thomas says that the tumor thus formed will sometimes equal in size a man's fist. I am quite positive that in this instance it was fully that large, thus making the case an extreme one of its class.

As would be expected, the uterus was displaced posteriorly with descent. The bladder may have been involved somewhat—cystocele—but this was of little account; there was no difficulty in passing water, the trouble was in retaining it. Under the influence of the operation and the subsequent

treatment this was entirely relieved. The point which overshadowed all others was the immense rectocele.

And now as to the manner in which the act of defecation was accomplished, this having been the trouble for many years. In the ordinary position, it was impossible for her to accomplish anything in the way of extruding fœcal matter. The fœces would collect in this pouch in one solid mass. The rectocele would bulge forward into the vagina, and by sufficient straining would protrude through the vulval opening, and over the perineum, it may be, and thus she would be utterly unable to attain any result. So she would push this mass back, replace it as best she could, bring her thighs in the closest juxtaposition possible while squatting, and then receive an injection of a considerable quantity of water (probably half a gallon) into the rectum, followed by straining—in this way she would generally be enabled to clear out her lower bowel. Even these measures at times failed, and so weakened had she become from long suffering, that, occasionally, she would be unable to go through this performance, but would sink to the floor utterly exhausted, without having completed the evacuation.

We now come to the operation itself.

With this patient, the point of chief importance was the immense rectocele; the other conditions were in comparison to this one, but slight, and hence were practically disregarded. The patient was anxious for relief, and hence my sole purpose and desire was to do an operation which would meet the indications and thus relieve her. I cared but little as to whether I should perform the classical operation of Sims, or of Emmet, upon the posterior wall, or any of the other set operations described in our text-books.

Friday, August 2d, 1889, I operated, assisted by my colleague, Dr. Keeler, and my father. The patient was anæsthetized and placed upon her back upon the table. The thighs were flexed upon the abdomen, and held there by two assistants, the lateral walls of the vagina being retracted by right-angled retractors.

Previously, the rectum had been thoroughly emptied, first giving a purgative, then flushing it with water to clear away all debris.

With a pair of scissors, I then proceeded to make the denudation, which I did from below upward, first upon the perineum and then upon the posterior vaginal wall toward the uterus. I made it sufficiently wide, so as to grasp plenty of tissue in passing the sutures, in order to obtain a firm cicatrix after the healing process had finished, and thus afford a firm wall for the bowel to press against during the act of defecation, the vagina being large and relaxed, thus affording plenty of room for so doing. The denudation was given somewhat the shape of a triangle, with the apex of the triangle up and the base down, this being in imitation of Hegar's operation, I find, although I was not aware of it at the time of so doing. The sutures were then inserted into the vaginal portion first, catgut being used for this part; for the perineum, I made use of silver wire, silk being used to draw the silver sutures into position, then drawn tight, and retained by compressed shot.

In regard to after-treatment, the patient was put to bed and kept as quiet as possible, in the horizontal position, but without any bandaging of the knees or thighs. The parts were kept as clean as possible, by the daily use of antiseptic injections of bichloride, 1 to 2000. The catheter was employed for the first few days for removing the urine. The bowels were kept soluble, to prevent any accumulation, and thus distension where this had existed so long and to prevent any straining upon the part of the patient, and thus possibly separation of the freshly-united surfaces.

Part of the silver sutures—every alternate one—were removed at about the end of a week, the remaining ones a few days subsequently. The catgut sutures required no attention.

The parts healed very rapidly, and, as far as I was able to ascertain, there was no pus whatever formed during the reparative process. Convalesence was rapid and the result of the operation thus far—now nearly two years—has been all that could be expected or even desired. With proper care and attention to the condition of her bowels, she is now able to move them, to attend to this function of nature, with as much comfort as prior to the accident, which induced the morbid condition. In fact, the patient was transferred from a condition of torment upon the one hand to a state of Elysium upon the other.

After the operation, the patient was placed upon general tonic treatment, which has been continued with occasional intervals up to the present time.

Collodion of Salol, useful in acute rheumatism, is obtained by dissolving salol 4 in ether 4, and adding to collodion 30 parts.

AMPUTATION OF THE CERVIX UTERI.[1]

BY J. D. CUMMINGS, M. D.,
AUSTIN, TEXAS.

Thomas in his work on the "Diseases of Women" says that "Ambrose Paré was the first surgeon who advised amputation of the cervix. In 1802 the operation was systematized by Osiander, who performed it twenty-three times, and after this it was resorted to by Dupuytren, Recamiér, Hervez de Chegion, and others. Lisfranc later on reported 99 cases with only two deaths. Huguier reports thirteen operations and no deaths; Sims over fifty operations and one death."

Thomas further says that by the galvano-cautery much better results are obtained. Out of the large experience of Dr. Byrne, of Brooklyn, with it no fatal cases are reported. The writer has not access to later cases of the operation except for carcinoma of the neck of the womb. This same authority reports twenty cases with no bad results. I am also apprised that so high an authority in uterine surgery as Dr. T. A. Emmett has said that this operation is only indicated in some cases of malignant or cancerous disease of the cervix. Many leading authorities, among them Barnes, of London, Thomas, of New York, and J. Marion Sims recommend amputation of the cervix for not only malignant diseases, but for enlargement of the cervix, from inflammation increasing the connective and other tissues of this part of the uterus; elongation of the cervix, whether congenital or due to disease; conical cervix, whether with or without elongation; granular or cystic degeneration, whether of the cervix or os of long standing and not remedial by other procedures. I will add to this list certain cases of lacerated cervix where the tissue has been deeply involved in the laceration, leaving a hard cicatrix, which often gives rise to multiform symptoms and general bad health. Also ragged eating ulcers, not yet cancerous in their nature, but liable to become so if not relieved. Again, whenever there is no doubt that the neck of the womb presses on the bladder so as to interfere with the proper performance of the function of this organ, not easily remedied by other means, undue induration of the cervix, leading to suspicion of ensuing cancer. In any case where the indurated or elongated cervix interferes with conception if it is desirable to have offspring, whether necessary as an addition to dilatation of the internal or external os uteri or not. In these cases very often where women have been married for years without having conceived, the external os will be found very narrow as well as the internal os. It is the opinion of the writer that the elongated or enlarged cervix is often the source of much trouble in malpositions of the womb, if malposition does not often follow as an effect. In the conical elongated cervix retroflexion of the womb necessarily follows. In such cases removing the redundancy allows nature to effect and maintain the proper relation of the pelvic parts. As an aid to relieve severe cases of anteflexion, requiring operations of various kinds for straightening the uterine canal, it is believed by the writer that a thorough amputation of the neck of the womb would be one of the best preliminary operations, if it does not relieve the trouble entirely. Different modes of performing this operation have been recommended. Among them I may mention the galvano-cautery, scissors, ecraseur and knife. I have used the knife and have had no bad results. Sims for a time would take off one lip and wait several months and then remove the remaining one. He, however, found this procedure unnecessary. With modern means of controlling hæmorrhage and its rare occurrence in this operation, I am induced only to mention it as one of the possible dangers following the same. Under antiseptic precautions, sepsis will rarely follow. As to cutting higher than is anticipated, and thereby opening up the peritoneal cavity, we may remark that we would be liable only in removing large malignant or other tumors, and should this complication arise proper drainage and antiseptic measures would probably insure complete recovery from the operation.

From the foregoing considerations it would follow that we would expect almost every case operated on in a proper manner to recover from the effects of the operation. As to any ultimate harm following the operation to the patient, it is the opinion of the writer that it cannot be shown. It certainly does not prevent conception, but, on the other hand, is liable to be followed by it. In two out of three cases that have come under my observation several children followed in the usual succession in each case.

Case I.—Mrs. J., operated on July 12, 1882. There existed general bad health. Examination showed a conical cervix and a narrow os. No untoward symptoms fol-

[1] Read before the Austin District Medical Society, June 25, 1891.

lowed the operation. Good health followed and several children.

Case II.—Mrs. P., was operated on about the same time; she had had one child. There existed a ragged eating ulcer, which failed to heal from ordinary applications, such as nitrate of silver, iodine, etc. Amputation of the cervix uteri resulted in complete recovery of the patient, and she has been confined repeatedly since.

Case III was operated on recently. She had been in bad health since marriage eight or ten years ago; has had no children, but has been treated by several physicians at times with some benefit, but with no permanent relief. One of the chief complications was frequent and painful micturition, accompanied with much burning, and a milky, cloudy condition of the urine, showing irritation of the bladder. On examining the womb, the external os was very small, and the neck was conical in shape and somewhat elongated; more or less hardness of the neck also existed. The internal os was very narrow, hardly admitting the smallest sized sound. Retroversion existed in a marked degree. The sound had to be bent backwards in order to enter the body of the womb at all. An attempt to replace the organ and internal appplications of Churchill's tincture of iodine were made but no relief followed. Amputation of the cervix was then recommended and assented to by the patient. May 9th she came in from the country prepared to remain until the operation and its effects were over. Drs. Mathews and Pointon assisted me in the operation. The knife was used and a Λ-shaped piece of the neck, including the anterior and posterior lips of the womb was removed. The point of the Λ-extended nearly to the internal os. Two stitches of silk, one on either side of the external os, sufficed to bring the parts under good cover of healthy tissue. The bladder symptoms persisted for several days, but have since entirely disappeared. The general health has very much improved. While the internal os on first examination after the operation seemed to be sufficiently pervious, yet some pain accompanied the first menstrual period. Since the patient has visited me at my office, and I found a very much contracted condition of the internal os, and later I incised the same and fully dilated both the internal and external os. The last report from the case was very favorable indeed.

In the subject chosen for this paper I am aware that I am treading upon ground that may be said to be forbidden by some, and that in the recommendation of this operation I cannot be said to be in the fashion. Yet, at one time, not many years ago, when our lamented Sims so ably defended this procedure, then it was popular. Since his death, lacerated cervix with its accompanying operation has had its day, and has run what may be said to have been a very popular course, and numbers with its victims probably more failures than any other operation ever done in so short a time. Since laparotomy for diseased ovaries and tubes may have swung too far in the extreme, many ovaries and tubes having been extracted that would have rendered their victims more happy by letting them alone, yet with all this, many otherwise doomed would have been relieved of long and excruciating suffering by the removal of their diseased ovaries and tubes. Painful os uteri have been remedied by well directed operations for repair of lacerated cervix, and the writer must contend that amputation of the cervix has its proper field of usefulness, and it extends farther than narrowly limiting it to removal of cancerous cervices.

ALIMENTATION AND ARTIFICIAL FOODS.*

BY F. C. HERR, M. D.,

OTTOWA, KANSAS.

Prior to the time that physiologists came to regard life processes as an even balance between constructive and destructive metamorphosis in the tissues—the blood included—the problem of scientific feeding did not seriously enter into the subject-matter of the physician's thought. The inspiration of the practitioner then was the empiricism of the past, and to deplete our ensanguinated system, to rouse into activity a torpid liver, to lull pain and soothe disquiet with strong opiates, fulfilled the indications of scientific therapeusis. But the evolution of a great science has changed all this; the tyranny which that opinion exercised over the professional mind was abolished by the genius of a man whom we all honor in our daily professional life. I refer to Dr. Robert Graves. He made the world his debtor when he said to his pupils, "If you are at a loss for an epitaph to inscribe on my tomb, you may use these words: 'He Fed Fevers.'" It is

* Read before the Kansas State Medical Society, at Wichita, May 15th, 1891.

well sometimes to go back and look over the work of the masters, to impress more firmly upon the mind those great principles of our science which constitute the corner-stone of rational and scientific medicine. Dr. Graves saw, in advance of other men, the disasters of protracted abstinence, and in language strong and eloquent he urged systematic feeding as the sheet-anchor of the physician's hope in exhausting disease.

I quote one brief passage from the work of Dr. Graves: "Now, in a person laboring under the effects of fever and protracted abstinence, when sensibilities are blunted, and where functions are deranged, it is not at all improbable that such a person, perhaps also suffering from delirium and stupor, will not call for food, though requiring it; and that if you do not press it on him and give it as a medicine, symptoms like those which arise from starvation in the healthy subject may supervene, and you may have gastro-enteric inflammation or cerebral disease, as the consequence of protracted abstinence.

"You may perhaps think that it is unnecessary to give food, as the patient appears to have no appetite, and does not care for it. You might as well allow the urine to accumulate in the bladder, because the patient feels no desire to pass it. You are called on to interfere when the sensibility is impaired, and the natural appetite is dormant, and you are not to permit your patient to encounter the horrible consequences of inanition because he does not ask for nutriment."

What a splendid plea for enforced feeding. It has proved an inspiration to medical teachers, and has filled with new hope and endowed with new resource the medical practitioner.

The dynamic forces of life are preserved through the maintenance of effective nutrition. It is an axiom of physiology that, not what we eat, but what we digest and assimilate, conduces to the up-building of the body and the support of life. "From the food the blood is fed; from the blood the tissues are fed." A simple proposition is this, but it embodies a vast deal of medical philosophy. Roughly stated, it might be said that the order of sequence in the construction of a vigorous body is good food, good blood, good tissues.

The progress of knowledge has disclosed this vital truth in relation to organic functions, namely, diseased action is not exalted vital force, and the paramount indication in all forms of disorder is the maintenance of the highest possible degree of healthful nutritive activity. To fail to take cognizance of this is to abandon the most potential lever that science furnishes for the successful combat of disease.

As that ensemble of physiological phenomena which we call life is the resultant of chemico-vital changes in the food, primarily it follows as a corollary that too great care cannot be exercised in the selection of nutriment. In it are the potentialities of life; in it may lie concealed, in unassimilable elements, the possibilities of gradual, but inevitable decay. Dr. Lander Brunton affirms that the mal-products of nutrition are positive depressant poisons. Physiological experiment confirms this, and the observations of the clinician give equal strength to the statement. Lives have been sacrificed to ignorant and injudicious feeding, and the administration of drugs often does not so much tax the skill and knowledge of the physician as the administration of food.

Here I am confronted with the very practical question of specific form and variety of food. And I may premise what may follow with the statement that a variety of elements enter the inter-question of suitable food. First, the quantity of food as to purity and freedom from adulterations; second, its nutritive value; third, its digestibility; fourth, its palatibility. Looking carefully over this order of arrangement in the essential qualities of suitable food I am reminded that palatibility is an element of such vast importance that it should perhaps be given in the first place, in order. The therapeutist has indicated the necessity for good foods, and the chemist's art has placed at his disposal one after another of much vaunted nutrients, and still the question confronts us: Has science furnished us with a food that will meet the indications for nutriment in a wide range of morbid states—a reliable food—easy of digestion, readily assimilable, agreeable to the taste, and with all such in nutritive material.

The dietetics of the sick-room like all things else, change. It is within the memory of men young in the profession when beef-tea and beef-essence, in the minds of the laity, possessed more importance than the physician with all his resources. And a prejudice still lingers with many people, and with some physicians, in favor of these once much used and much esteemed aliments. But the educated physician sees in them little more than the merits of a placebo and the concensus of enlightened judgment, is in favor of forms of artificial food that have been shown by analysis to possess in large degree, and in readily assimilable form, all

the constituent elements of the human body. The busy life of the average practitioner does not afford time nor opportunity for the investigation of these special subjects, and in the belief that the ends of scientific medicine will be there subserved I desire to submit to your consideration some facts which I have collated respecting the comparative merits of a variety of artificial foods. In doing this I desire to emphasize one obvious truth, namely, that all artificial foods are made with the paramount design to sell.

And it is the hope of their manufacturers that the medical profession will find in them enough of merit to justify their endorsement. The interest of the physician lies in restoring health to the sick and afflicted; the interest of the manufacturing chemist in creating a market for his products whether they be good, bad or indifferent.

I have an abiding conviction that the highest interests of our patients are often sacrificed to a credulity which compromises our best judgment in these matters. The best medicine is not a whit too good for our poorest patient, and only the best food should receive our endorsement. It is furthermore incumbent upon us as educated men, charged with grave responsibilities, to know that what we do use is the best obtainable.

But what is the best? In regard to the matter of foods I have secured the analysis of nine varieties or brands of artificial food, the Mosquera's Beef-Meal, Armour's Ext. of Beef, Liebig's Ext. of Beef, Beef Peptonoids, Wyeth's Beef Juice, Valentine's Meat Juice, Cibil's Fld. Ext. of Beef, Bush's Bovinine, and Murdock's Liquid Food. These foods comprise the best known and most favored preparations upon the market. They are all candidates for our support. They come to us highly lauded—all of them—by their manufacturers. Some are good, some indifferent, some worthless. Some will render great service in times of dire need, others, with much of promise, and more of parade, will be found barren of life-giving qualities.

The mal-products of nutrition—as Dr. Brunton observes are depressant poisons. Urea, whether elaborated within or without the system, is a physiological poison. The same is true of creatin.

A reference to the attached table will show that Liebig's Ext. of Beef, and Armour's Ext. of Beef contain nine and a fraction per cent. of nitrogen—a very fair percentage. But it would be an error to accept this as representing the actual percentage of *available* nitrogen in these pro-

Brand.	Moisture.	Fat.	Mineral matter.	Phosphoric acid.	Total nitrogen.	Total proteid or albuminous matter.	Peptone.	Contents, (weight) of each package.	Retail price.	Comparative value, based on total albuminous matter.	Equivalent of each package in raw beef, based on total albuminous matter.

ducts. In the Liebig process of manufacture the meat is simply treated with either cold or warm water, and the extracted matters contained in the resulting solution are subjected to evaporation, leaving a paste containing all the soluble constituents of the meat without any or very little of the proteid matter. The percentage of nitrogen designated in the table is, therefore, misleading, as it exists in the form of urea and creatin largely. The Armour's Ext. of Beef is prepared in the same way, and contains the same effete nitrogenized constituents. Dr. Fothergill has cast deserved imputation upon this class of foods, by declaring that they did not possess much more nutritive value than concentrated urine. But, in addition to the unavailable nitrogen these extracts contain a large percentage of moisture and mineral matter, and are devoid of fat and peptones. These forms of artificial food possess a nutritive value in weight twice perhaps in excess of lean meat or beef.

The beef peptonoids of Carnwick are shown by analysis to be a most inferior food. They have always stood in favor with the profession. The suave emissaries who so generously enlighten us upon these matters always assure us that beef peptonoids represent five times their weight of nutritive value in beef and milk. The table shows that it is free from peptone, hence its albumen, from whatever source it is derived, is in a crude condition, and has never been subjected to a peptonizing process.

In the percentage of proteid matter beef peptonoids compare unfavorably with other preparations of the list, while more than 50 per cent. of the preparation is soluble in water, and resembles dextrine—plainly indicating that the starch has been largely converted—no matter from what source derived, and probably by cooking ordinary wheat flour. Beef peptonoids are inferior in real nutritive value to the foods made after the Baron Liebig process.

I do not feel that much could be gained by elaborating upon the individual articles named in the table. It indicates at a glance the comparative nutritive value of these foods. But I cannot dismiss the subject without a reference to powdered beef, and Mosquera's beef-meal and beef-cocao. You are quite well aware that powdered beef is simply the residue left after extracting the meat with water.

In the manufacture of Liebig's extract a vast quantity of material accumulates, and the profitable disposition of this has lead to the production of powdered beef. This preparation has the endorsement of some eminent therapeutists, among them Dujardin Beaumetz, and in reality it is a concentrated food, differing from beef, which contains 75 per cent. of moisture, it containing none, while at the same time it is free from the inorganic salts which are so essential in the digestive process. It is just as much of a tax upon the digestive functions as pure beef, and all things considered, it is less desirable as a food, especially in conditions of enfeebled and disordered digestion.

Mosquera's beef-meal and beef-cocao are among the newer candidates for professional favor. They have already received the endorsement of reliable, and competent observers. Prof. Crittenden, of Yale College has made a careful analysis of beef-meal, and he estimates its nutritive value at least six times its weight in lean beef.

Dr. Martin, chemist of the Health Board in New York, as also Dr. Justus Wolfe of the same city, estimates it to be ten times as nutritious as the natural meat. Prof. John Atfield, London, England, testifies that a personal examination made by him of beef-meal shows that it is superior to any preparation to which his attention has been called.

Here let me remark that beef-meal is not a ready prepared food. It is entirely wanting in flavor and seasoning. These you must supply just as you would in the case of beef-steak. Your mastery of the cuisine will determine in a large degree the measure of utility in this food as it is not contraindicated in any condition of morbidity—it is equally applicable in simple indigestion, and in typhoid fever. The mode of preparation of this food is opposed to the Baron Liebig process which assumes that the extracted and soluble principles represent the nutritive wealth of the beef. The fact is that the nutritive value of these extracts has never been established by analysis until now, and their clinical worth has been wholly a matter of assumption.

When the residue, left after extraction by the Liebig process, is subjected to the action of pepsin and pancreatin it is dissolved and converted into peptone—thus showing that nature meant it for a food, and that it is in reality the nutritive portion of the beef.

In the preparation of beef meal nothing is taken from the beef but water, and nothing is added to it except a small percentage of extractive matter contained in the juice of the plant used in the peptonization of the albuminous constituents of the meat.

As in most forms of sickness the balance

between waste and repair is lost, the consumption of tissue accelerated and emaciation with prostration ensues, it becomes imperative to supply the economy with such food as will repair the waste, give strength to the enfeebled tissues, and furnish fuel for the consuming fire. I do not know of any food that will do this in the same measure that Mosquera's beef meal will. The comparative value of this food is shown in the table.

My attention was called to the Mosquera foods early in the history of their introduction, and I have faithfully tried them in a variety of disorders—always with good results—sometimes with surprising ones. I have no hesitation in affirming that as a food, and a medicine in all forms of dyspeptic derangement beef-cocao has no equal. Not that it will speedily and certainly restore to health every subject of these disorders, but that it will in the majority of cases afford relief, and in a large percentage effect a cure.

If after your accustomed morning meal you go to your labor with a feeling of languor and apathy; if you feel as the dyspectic usually does, borne down by an invisible load of something, just mix with a cup of hot milk one tablespoonful of beef-cocao for your breakfast meal, and you will go to your daily task with a clear head and a light heart.

A great multitude of slight ailments are directly traceable to enfeebled digestion and impaired assimilation. The pathogenic condition here is sub-normal nutrition—the result of excessive ingestion of coarse and non-assimilable food. Here beef-meal alternated with beef-cocao will soon change the complexion of things. I cannot stop to consider or indicate these special conditions; they are legion, but Dr. Lionel S. Beals, in his "Slight Ailments" has passed them all in review, and had he known then that the plodding scientist would soon place at our disposal such foods as these he would have urged their use.

You are all aware that nutriment may be furnished to the body, and life sustained, without the use of the digestive organs proper. The mode of alimentation by enemata, since the introduction of beef-meal, has grown to be a most satifactory method, indeed. The Mosquera foods are so thoroughly adapted to every purpose of easy assimilation that nutrition is accomplished by absorption, as distinguished from digestion with surprising facility.

I am well aware that the employment of nitrogenized food in febrile diseases is hardly in consonance with the orthodox practice. But we are not obligated to orthodoxy. Besides, the latest scientific and clinical researches refute the theory that animal foods are contra-indicated in febrile states. The excretion of nitrogenous products is much increased in all forms of pyrexia, and reasoning a priori the conclusion would be inevitable that as nitrogenous metabolism is already excessive it would be injudicious to introduce into the systen yet more nitrogen. But the experiments of Immerman, confirmed later by Bauer and Kunstle, entirely subvert this theory, and expose the fallacy of such reasoning. These investigators have shown that in typhoid fever albuminous food is beneficial, not because it diminishes the excretion of nitrogen, but because it supplies this element to the fevered tissues, and "nitrogenious foods alone are capable of being converted into the albumin and fibrin of the blood, and thus assimilated by the tissues."

In all forms, therefore, of protracted pyrexia, Mosquera's foods are invaluable. Small quantities of beef-meal frequently administered will supply to the economy a large percentage of tissue-forming elements, and it will be demonstrated in the near future that not only must fevers be fed, but the food supplied must be of the character here indicated in order to achieve the best results. Let not the bias of early teaching stand in the way of accepting new doctrine. If men always conformed to precedent and experience the march of progress would be slow indeed.

In the manifold forms of bowel derangement so common in miasmatic regions, these foods will be found available. In actual dysentery I have employed them with excellent results. Being largely predigested and easy of assimilation, they are not contra-indicated in any condition. Only one exaction do they make of the physician, namely, that they shall be seasoned to be made acceptable to the patient. The same is true of almost every other food, and while this labor and skill is being expended, it is as well to expend it upon foods of superior merit. In current medical literature I see reports of cases of pulmonary consumption treated by Profs. Gibbes and Shurly with iodine, and gold and sodium chloride hypodermically, and chlorine gas locally, with a reliance upon Mosquera's foods for adequate nutriment. Whatever influence any system of medication may have upon the pathology of tubercle, all will admit that the profound disturbance in the nutritive processes in this disease appeals to our knowledge and skill

for prompt and efficient relief. And to-day, if I were placed in charge of consumptive patients exclusively, and given my choice between drugs and foods as exclusive agents in their management, I would say give me the foods.

What are the diatheses and cachexia that haunt the doctor's mind? What do they require at our hands for their eradication? Medicine? I imagine not. More of sunlight, more of fresh air, more of judicious exercise, and, greater than all, *more* of *good food* is the *sine qua non* of substantial amendment in them. So the good results obtained by Profs. Gibbes and Shurly might, perhaps, with strict propriety, be ascribed to the judicious use of good food.

After all, what is every disease but some modification of nutritive function; in its final analysis every morbid process is some derangement, slight or grave, in the up-building forces of the economy.

Dr. Frederick L. Knight, before the Climatological Association at the 1890 session, said, "at present, the usual preparation of food is so bad that after one has found out the class of nutriment a patient requires it is well-nigh impossible to secure it."

It is beyond question that these foods—beef-meal and beef-cocao—are the best artificial foods yet offered for use.

As the table shows only the composition of beef-meal, it may be here remarked that beef-cocao comprises equal parts of beef-meal, sugar, and Dutch chocolate, so that it is about one-third the food-value of beef-meal.

In nursing women, beef-cocao meets the indications of an ideal food.

In surgical practice, where the problem of dietetics is important, these foods must find a wide range of applicability.

In the multiform neurasthenic conditions of women they are highly serviceable where tissue-waste exceeds repair, and where repugnance to food appears a constitutional quality.

The physician can choose from a multitude of drugs and foods that which he will use, but duty bids him to employ only those that *are* good—duty to the sick and suffering and confiding public.

The natives of the New Hebrides smear the points of their arrows with a swamp earth, the poisonous agent in which, according to Dr. Ledantec, is the septic vibrio of the tetanus bacillus.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

THE TWELFTH ANNUAL MEETING OF THE ASSOCIATION WAS HELD IN WASHINGTON, D. C., SEPTEMBER 22, 23, 24, AND 25, 1891.

TUESDAY—FIRST DAY.

The Association was called to order by the President, Dr. Claudius H. Mastin, of Mobile, who delivered the Presidential address.

The next paper was by Dr. D. Hayes Agnew, an abstract of which follows:

PRESENT STATUS OF BRAIN SURGERY BASED ON THE PRACTICE OF PHILADELPHIA SURGEONS.

What is the present position of brain surgery and what practical lessons can be deduced from a review of the recorded results in this department of surgery? The object of the author was not to glean the entire field, but to confine himself to the work done by Philadelphia surgeons in trephining for epilepsy, traumatic and Jacksonian intracranial abscess, hemorrhage, hydrocephalus, cephalalgia, microcephalus, and neoplasms.

Traumatic epilepsy.—Fifty-seven cases were recorded. Of this number forty-one recovered from the operation. Four died, and of twelve the result is not given. Thirty-two experienced temporary relief, nine obtained no benefit, four passed out of observation, and four were operated on too recently to permit of the result being determined, and four are reported cured. In one of the cases reported cured, the patient has been free from attacks for twenty-eight months, in two for ten months, and in the fourth a branch of the great occipital nerve was found imprisoned in the bone cicatrix. While the results in these cases have not been satisfactory, it by no means follows that surgery holds out no hope against epilepsy. It is not saying too much to assume that surgery is responsible for the great majority of traumatic epileptics, though this statement does not by any means criminate the surgeon of an early day. Whenever the profession can accept the doctrine that all depressed fractures, however slight the depression, and entirely irrespective of pressure symptoms, are proper subjects for trephining, then will traumatic epilepsy largely disappear from

the list of surgical diseases. It is not improbable, in view of the greatly diminished risk of trephining, that the operation will be extended even to cases of simple fracture or fissure of the skull.

Jacksonian epilepsy.—The table contains fourteen cases. In all the discharging centre was removed. Nine recovered and four died. Of those recovering, three had less frequent and less violent attacks, one realized slight benefit, one disappeared shortly after operation, and in two no benefit was observed. One is reported as cured, and in that case the operation was done during the present year.

Abscess.—Eighteen cases of this nature have been collected. Six had had fracture of the skull, two had syphilitic necrosis, in one a foreign body had entered the brain, in nine the abscess was due to middle ear disease, and in two there had been a severe blow without fracture of the skull. All the patients died in less than fourteen days.

Five cases of trephining for intracranial traumatic hemorrhage are recorded in each instance. The symptoms necessitating operation developed within twelve hours after the reception of the injury. Four of the five cases recovered not only from the operation, but with the restoration of the suspended functions.

Of trephining for acute and chronic hydrocephalus, five cases are reported. All the cases died, one living to the forty-fifth day. As hydrocephalus is usually due to tubercular disease or to morbid growth, it is difficult to understand on what ground such operations are undertaken.

Cephalalgia.—Five cases are given, in each of which the focus of pain was referred to the neighborhood of a scar on the scalp. In four of the cases complete relief was afforded.

Trephining for microcephalus. — Seven cases are reported, of which four died and three recovered from the operation. One of the deaths, however, was due to scarlet fever, occurring shortly after the operation. The result in the successful cases is reported as "moderate improvement." From the results obtained from the education of idiots, the author thought it wiser to relegate these unfortunates to special training schools, rather than to the trephine and rongeur. The debatable cases would be those accompanied with athetosis, in which condition some improvement might be obtained.

Brain tumors.—Only four operations for brain tumors have been done by Philadelphia surgeons. In one the growth was a fibroma weighing four ounces. The operation was done by Dr. Keen, December 15th, 1887, since which time the patient has had only six epileptic seizures. In the second case, done by the same operator, the tumor was in the occipital lobe and not removable. The patient died the following day from shock and hæmorrhage. In the third case no tumor was found, and in the fourth a cyst occupying the cuneus was found and emptied. The patient died in thirty-six hours, and at the autopsy a large sarcoma was found occupying the temporal sphenoidal lobe.

The deductions presented by the author are as follows:

1. That all fractures of the skull attended with depression, however slight and entirely irrespective of symptoms, should, in view of the late after effects, be subjected to the trephine.

2. That trephining for traumatic epilepsy promises only palliation at best.

3. That trephining for Jacksonian epilepsy is to be regarded as only affording temporary benefit.

4. That trephining for abscess, in view of the fact that all such cases left alone almost invariably terminate fatally, is entirely proper, and that the earlier such operation is done the better.

5. That trephining for intracranial traumatic hæmorrhage is both an imperative and highly promising operation.

6. That trephining for cephalalgia or traumatism, medical measures having failed, should be undertaken with every prospect of success.

7. That trephining for hydrocephalus is a useless operation.

8. That trephining for microcephalus, independent of athetosis, confers no credit upon surgery.

9. That it is more than probable that, as our observations multiply, the sphere of the trephine as a preliminary for the removal of brain tumors will be lessened rather than be amplified.

DISCUSSION.

Dr. John Chiene, of Edinburgh, did not take the same depressing view in regard to traumatic epilepsy. He referred to three cases in which decided benefit had followed operation. He agreed fully with what had been said in regard to operation in depressed fracture whether symptoms be present. As regards methods, he spoke of simple measures for locating the fissure of Rolando. The upper extremity may be located by means of a piece of string, being one-half

inch behind the middle. The angle may be secured by folding a square piece of paper into four, around one of the angles. Three of these parts will give the proper angle. The purification of the scalp is a difficult matter but may be accomplished by shaving and soaking with carbolic lotion for three days. For opening the skull he advises as safer than the traphine, the gauge and mallet. For enlarging the opening the gauge forceps fill a useful purpose. For puncturing the dura and the brain he uses a Græfe knife. Hæmorrhage from the bone may be checked by plugging with a match, bleeding from the brain, by hot water. Stress was laid upon the necessity of constant watching of brain cases and illustration cases cited. In one case of supposed injury to the head (but which later proved to be a case of apoplexy,) in which the patient was in a dying condition, great improvement eventuating in practical recovery followed trephining.

Dr. W. W. Keen held that every case of depressed fracture should be operated upon even in young children. A blow upon the head not sufficient to cause fracture may produce laceration of the dura or of the cortex. In regard to linear fracture, however, he was disposed not to accept the views that operation should be performed. In regard to tapping of the ventricles, he thought that further experience and animproved technique would lead to better results. In epilepsy he suggested the use of the bromides after operation had been done. In many cases of brain tumor, where there is no hope of removing the growth, great comfort may be afforded the patient by removal of bone.

Dr. Charles D. Nancrede, Ann Arbor, reported cases in which cure had followed operation for traumatic epilepsy, in one the case was of ten year's duration. Often cases that are reported as failures, soon after the operation prove to be cures when followed for a longer time. The operation removes only one of the elements that is causing the epilepsy. In speaking of these operations he stated that hæmorrhage from the skull could be checked by forcing in the diploe. In regard to simple fissued fracture he asked how the diagnosis could be made.

Dr. Roswell Park, Buffalo, differed from the author as regards the results of operations for epilepsy. He had himself had cases in which decided benefit was afforded. In order to determine the effect, time must elapse so that the epileptic habit may disappear. The operation removes the anatomical cause, but ordinary therapeutic measures are needed to counteract the secondary condition. Reference was also made to the relief afforded in brain tumors even when the removal of the growth was not contemplated. He reported two cases of craniotomy for microcephalus in which benefit had followed.

Dr. H. C. Wood, Philadelphia, thought that we should wait before coming to any conclusions as to the result of treatment either medicinal or surgical. He referred to one case in which under medicinal treatment the attacks remained absent for seven years and then returned. He advised that in these cases before the contemplated operation was performed, a mock operation should be done and the effect noted. He cited cases in which such measures had been followed by benefit.

Dr. J. J. Putnam, Berlin, thought that a simple smooth depressed fracture would not be likely to cause any symptoms. The presence of a sharp spicula of bone probably will cause irritation. Probably the most important element in the causation of trouble is the results of the original injury to the cortex. The interstitial changes in the cortex takes the form of sclerosis and it seems *a priori* doubtful that removal of the bone would materially affect it. The operation may not prove indifferent for the cicatrization of the wound may lead to harm.

Mr. Thomas Bryant, London, had been much struck with the emphasis with which Professor Agnew had insisted upon the treatment to be followed in depressed fracture. As a practical rule he was disposed to agree with him, but there are certain exceptions ; he did not think it wise to encourage the practitioner to trephine and elevate every case of depressed fracture. He could recall many cases of depressed fracture followed for years in which no symptoms followed. Depression of the lateral aspects of the skull are not so apt to be followed by symptoms as depression of the vault of the skull. From these remarks, he said, it would naturally follow that he disagreed with the observation that in every case of fissure of the skull, operation should be done. He wished Dr. Agnew had gone more thoroughly into the reason for this statement. If there has been no brain symptoms, although the blow may have been sufficient to cause fracture, it would not be wise to insist that we should at once proceed to explore to see if there is fracture. It is better to wait and watch for symptoms, being ready to operate as soon as there is a suggestion of something wrong. Although the risk of explorating operation may be slight, yet it must be admitted that it is attended with some danger.

Dr. D. Hayes Agnew:—In traumatic epilepsy I did not condemn operation, but curative results should not be expected from it. Its result is only one of amelioration. He could not withdraw his statement made in the paper, for in many of the cases of traumatic epilepsy, there has been no history of unconsciousness or other symptom. There has been a blow on the head and many years later epilepsy has appeared. It is impossible to determine the condition of the internal table of the skull by inspection of the external table. He had seen a simple crack in the skull with the internal plate forced downwards some distance.

A paper on Resection of the Wrist, by Dr. Rafael Lavista, of Mexico City, Mexico, was presented and read by title.

REPORT OF A COMMITTEE ON THE RESULTS OF TREATMENT OF SIMPLE FRACTURE OF THE FEMUR, BY STEPHEN SMITH, M. D., NEW YORK.

At the meeting of the American Surgical Association held May 15, 1890, the following preamble and resolution was adopted:

WHEREAS, In the treatment of fracture of the shaft of the femur, the question often arises as to what is a satisfactory result in a given case, therefore

Resolved, That a committee be appointed by the President, to report at the next meeting of the Association, what in their judgment under the methods of treatment, would be considered as satisfactory results.

The following committee was appointed: Dr. Stephen Smith, New York; Dr. D. Hayes Agnew, Philadelphia; Dr. David W. Cheever, Boston; Dr. D. W. Yandell, Louisville; Dr. Chas. T. Parker, Chicago; Dr. P. S. Conner, Cincinnatti; Dr. Charles B. Nancrede, of Ann Arbor and Dr. Hunter M'Guire, Richmond, Va.

The question referred to your committee has an important bearing upon the jurisprudence of surgical practice. One of the most frequent causes of prosecution of surgeons is the alleged maltreatment of fractures of the femur.

The following circular was sent by the committee to the members, "What should be considered as a satisfactory result (other than perfect union) in the treatment of a simple fracture of the shaft of the femur." The committee has reviewed the several questions raised and endeavored to secure a common ground on which the Association can take its position, and on which members can individually stand before the courts.

1. Bony union: The necessity of firm bony union does not admit of discussion. The amount of callus should not be taken as a criterion of the success of treatment.

2. Relation of long axis of the fragments. While it is the aim of the surgeon to restore the normal relation of the long axis of the fragments, yet it is generally impossible to secure exact apposition of the fractured surfaces, nor can the normal long axial line be restored with mathematical precision.

3. Correspondence of the anterior surfaces of the fragments. On this depends the position of the foot. The result of treatment to be satisfactory requires that the anterior surface be in the same plane.

4. Length of limb. This was formerly regarded as the test of success of treatment. The records of the past shows that shortening was the universal rule. The discovery of the natural discrepancy in the length of the lower limbs has considerably modified our estimate of this test 90 per cent. of healthy, uninjured persons have lower limbs of unequal lengths. In 35.8 per cent. the right limb is the longer; in 54.3 the left is the longer. If the amount of shortening does not exceed the average natural difference in the length of the limbs, viz: about one-half an inch, the result will be in accordance with the laws of nature in the conformation of the lower extremities. If the shortening does not exceed the extreme limit of difference in the lengths of the natural limbs, viz: about one inch, the result should be considered satisfactory. An unsatisfactory result as regards shortening exists only when the amount of shortening exceeds one inch.

5. Lameness: This is a symptom of variable importance. Some will have a limp with one-fourth inch shortening while others will not limp with one-half or one inch shortening. In many cases the limp disappears with time, or if it continues it is the result of careless habits of the patient.

6. Restoration of function. Essential to the function of the femur is strength of the femur at the seat of fracture, free and unimpeded action of the muscles and proper motion of the knee-joint. The determination of the degree of restoration of function can not be made for at least one year after the cessation of treatment.

7. Conditional results. There is a class of cases in which our estimate of results must be based upon a careful study of the special circumstances connected with the treatment

of each case. Results widely different from those already given, must be regarded as satisfactory when we consider the circumstances under which the treatment is necessarily pursued. The treatment may have been conducted under circumstances in which it was impossssble to secure proper apparatus, or the injury may have involved other parts so as to prevent the patient from taking the necessary position, or the patient may have suffered from delirium or other malady.

The following conclusions were presented: A satisfactory result has been obtained in the treatment of fracture of the shaft of the femur when—

1. Firm bony union exists.
2. The long axis of the lower fragment is either directly continuous with that of the upper fragment or the axes are nearly parallel lines, thus preventing augular deformity.
3. The anterior surface of the lower fragments maintains nearly its normal relation to the plane of the upper fragment, thus preventing undue deviation of the food from its normal position.
4. The length of the limb is either exactly equal to that of its fellow, or the degree of shortening falls within the limits found to exist in 90 per cent of healthy limbs, viz: from one-eighth of an inch to one inch.
5. Lameness, if present, is not due to more than one inch of shortening.
6. The conditions attending the treatment prevent other results than those obtained.

Adjourned.

WEDNESDAY MORNING—ASEPTIC AND ANTISEPTIC DETAILS IN SURGERY, BY DR. A. G. GERSTER, NEW YORK.

Personal cleanliness and cleansing of the field of operation are to be accomplished by mechanical measures, rather than by disinfectants. The dirt and oily matter of the skin is removed by emollient potash soap and stiff brush. This is followed by the germicidal lotion. The hands of the surgeon may be sterilized in the following manner. The nails are trimmed short, the hands scrubbed with soap and brush in hot water for one minute. The nails are then cleaned and the hands immersed in strong alcohol, and then washed in 1 : 1000 corrosive sublimate solution. Brushes require careful attention. They may be sterilized by boiling for five minutes in water containing 1 per cent. of washing soda. They should be kept in 1 : 1000 bichloride solution.

Instruments are sterilized by boiling for five minutes in soda solution, in a covered vessel. The addition of the soda prevents formation of rust.

Dressings are rendered absorbent and sterilized by steam. Strong antiseptic agents in dressings are objectional from their action in the skin. Dressings may also be sterilized by boiling in soda or potash lye.

The use of Florida sponges was recommended, as owing to their cheapness they can be used once and then thrown away. Boiling of sponges is to be condemned. Sponges are best prepared by heating, followed by immersion in dilute muriatic acid. Acid is removed by washing. Then immersed in water for two days to permit the spores to germinate. Each sponge is then kneaded in hot water for one minute with potash or soft soap. They are then placed in 5 per cent. carbolic solutions for 24 hours. As a substitute for the large flat sponges used in laparotomy he recommended the substitution of pads of absorbent gauze.

In operating, few instruments, sponges and assistants should be employed. The dissections should be clean, the tissues being cut rather than torn. Irrigation should not be employed except when special indications present.

In the abdominal cavity irrigation was condemned. When the peritoneal cavity is contaminated by pus, etc., simple wiping away of the matter is sufficient.

In perfectly aseptic operations, no drainage is required. Iodoform gauze can often be substituted for the use of tubes. Drainage by tubes is required where there is progressive suppuration.

In combating septic morbid processes, mechanical measures such as incision, drainage and irrigation are of more importance than chemical measures.

DISCUSSION.

Dr. J. Collins Warren, Boston, described the details of operative surgery as practiced in the Boston City Hospital. The Massachusetts General Hospital and the Children's Hospital.

Dr. J. William White, Philadelphia, thought that the time had not yet arrived when the use of antiseptics could be dispensed with. He preferred an antiseptic dressing in all cases except where the wound is absolutely sterile and where no discharge is to be expected. While in a general way he agreed as to the value of mechanical measures in cleansing the skin he saw no good reason for throwing aside entirely the

use of the weaker chemical solutions. There are so many cases in which we can not be sure that the wound is aseptic, antiseptic dressings become of importance. He had tried the gauze substitute for sponges in abdominal work, but had found it objectional from the fact that when the gauze remains long in contact with the intestines, threads of *the gauze adhere to the intestine.*

Dr. Joseph Ransohoff, Cincinnati, said that in some cases it was absolutely impossible to render the part aseptic and cited cases illustrating this point. In cases where it becomes clear that the wound is infected, he removes the dressings and soaks the part in hot water. He had discarded the use of sponges altogether. In the majority of cases he employs the aseptic dressing, but could see no harm in the use of antiseptic dressings. Dressings, etc., in private practice may well be sterilized by heating in the oven. He thought that tight closing of the wound should be practiced oftener than it now is. Drainage is rarely used except in wounds already septic. He often uses catgut for drainage. In the septic cases he thought that probably the surgeon was often responsible for the infection of the wound. By clean incisions, cutting far away from the disease, and by not using the sharp spoon too freely, infection of the wound in suppurating cases can often be prevented.

Dr. E. M. Moore, Rochester, asked what objection was there to irrigation? In amputations for instance irrigation in the 1 : 1000 bichloride solution affords a ready means of removing clots, etc. The clots are removed and the wound can be left in a dry state. If this irrigation does no harm, why not use it? Dr. Gerster had condemned it, but he had not given his reasons for such condemnation. In certain cases of abdominal section, especially, where there was oozing of blood the use of hot irrigation of aseptic water was of great service.

Dr. Gerster, in including, said that he did not condemn antiseptic methods. He employed both methods. In its proper place asepticism is infinitely superior to antisepticism, but the cases must be properly selected. Teachers must be careful not to go too far in advance of the rest of the profession. Those who have not learned the details should be warned to stick to the older methods and work up the higher methods.

THE SURGERY OF THE SPINE, BY J. WILLIAM WHITE, M. D., PHILADELPHIA.

The conditions discussed were, congenital deformities, tuberculosis of the spine, neoplasms and traumatisms. Under the first head, spina bifida is the only condition requiring consideration. In this, injection by an iodo-glycerine solution offers the greater prospect of ultimate recovery with the least immediate danger.

In tuberculosis of the spine the indications for interference are the evacuation of pus, removal of a sequestram or of a focus of carious bone, and relief of the cord from pressure.

There are records of 14 operations upon the bodies of vertebræ for abscess, with 8 cures, 5 cases improved and one death which had no relation to the operation. There have been 40 cases of operation on the spine for the relief of pressure. In 22 there was either improvement or cure. The effect of suspension in the treatment of Pott's paralysis has been so favorable that it should occupy a prominent position.

Conclusions in regard to operative treatment of spinal tuberculosis with symptoms of pressure on the cord were:

1. The paralysis in Pott's diseases is not as a rule, due to a transverse myelitis or hopeless degeneration and is not usually due to the pressure of the carious or displaced vertebræ; but is in the majority of cases the result of an external pachymeningitis which results in the formation of an extra-dural connective tissue tumor.

2. Speaking generally, a favorable prognosis is to be given, especially in children in cases of Pott's paralysis, in which the abscess, if any exists, can be evacuated; the treatment by extension and with plaster jacket can be employed and the patient can be put under the most favorable hygienic conditions.

3. In cases in which all this has been tried unsuccessfully or in those which disease is slowly but steadily progressing to an unfavorable termination; where with more or less complete loss of motion and sensation below the level of the lesion, there are incontinence of urine and fæces and the development of bed sores, and especially when acute symptoms threaten life, resection becomes entirely justifiable.

4. Operation having been decided upon for any or all of the above reasons, the prognosis will be favorable in direct proportion to the youth and strength of the patient, the absence of generalized tuberculosis and the nearness of the lesions to the base of the brain.

5. When the tuberculosis process affects the arches, and there is paraplegia, we may

sometimes operate, hoping not only to free the cord, but at the same time remove the focus of disease. This double indication may also be fulfilled in those cases where, without bony disease there is posterior pachymeningitis or a tuberculoma occupying the canal.

6. If the lesion of the bodies of the vertebræ is in the lumbar region at a point where these bodies are accessible, it might be possible in certain cases to expose the cord from the back, by removal of the laminæ, with the object not only of removing pressure, but of reaching and taking away the diseased bone and tubercular granulation.

7. In tuberculosis of the body of a vertebræ and compression of the cord by anterior pachymeningitis, we can fulfil only one indication—liberate the cord from pressure. We should operate only in grave cases where acute compression, the appearance of respiratory complications, the rapid development of degenerative processes force us to interfere, or where the course of a chronic case is steadily toward a fatal termination, although no advanced visceral tuberculous lesions are present.

In regard to neoplasms, it was said that every case of focal spinal lesion, thought to depend on a tumor and not distinctly a malignant and generalized disease, should be regarded as amenable to operative interference, no matter how marked the symptoms of pressure may be, nor how long continued.

Traumatism.—The indications and contra-indications for trephining in spinal fractures are based on the following points: 1. The nature of the vertebral lesion and the nature and extent of the medullary lesion. 2. The time which has elapsed since the traumatism. 3. The regional level of the medullary lesion.

The following conclusions were presented:

1. Some objections urged against operative interference in spinal traumatisms—*i. e.*, hæmorrhage, frequency of absolute destruction of the cord, pressure from inaccessible fragments of bone, etc., have been shown to be unsupported by clinical facts; others were largely due to a well-founded dread of *a*, the shock, in those cases operated on in pre-anæsthetic times, and *b*, consecutive inflammation, suppuration, and pyæmia in pre-antiseptic periods.

2. Some results of recent operative interference in properly selected cases of fractures of the spine are encouraging and should lead to the more frequent employment of resection of the posterior arches and laminæ; *a*, in all cases in which depression of those portions either from fracture or dislocation is obvious; *b*, in some cases in which, after fracture, rapidly progressive degenerative changes manifest themselves; *c*, in all cases in which there is compression of the cauda equina from any cause, whether from anterior or posterior fracture or from cicatricial tissue; *d*, in the presence of characteristic symptoms of spinal hæmorrhage, intra or extra medullary.

3. Operation is contra-indicated by a history of such severe crushing force as would be likely to cause disorganization of the cord. The question which will remain in doubt previous to operation will usually be that of the extent of damage done to the cord, and the possibility of its taking on a reparative action. As to this, the safest rule is that which has been formulated by Lauenstein, namely, that if after the lapse of six or ten weeks there is incontinence of urine or incontinence of fæces, and especially if there is also the development and spreading of bed-sores, but little is to be hoped for from the unaided efforts of nature. If, however, these symptoms are absent and if there be the least improvement it will be proper for the surgeon to delay operative interference still longer.

DISCUSSION.

Dr. H. H. Mudd, of St. Louis, dwelt upon the importance of remembering the liability of severe shock in these spinal operations. He reported three cases of bullet wounds of the spinal column, one of which ended fatally.

Dr. John B. Roberts, Philadelphia, insisted that injuries and diseases of the spine of a surgical kind should be treated as we treat injuries of the cranial cavity. Cases of Pott's disease, with angular curvature, have been referred to, but sufficient stress has not been laid upon the fact that many of these cases with motor paralysis improve under ordinary remedies, the inflammatory exudation being absorbed. In traumatism of the spine we should explore the spine as we should explore the brain. In severe injuries, with fracture, spciulæ of bone are often driven down on the cord.

Dr. J. J. Putnam, of Boston, thought that the dangers of inflammation had not been sufficiently dwelt upon. Some cases of spinal injury after one to four years show some improvement. In such cases an operation may add to the improvement.

Dr. James M'Cann, reported two cases of spinal injury in which operation had been

performed. In one death followed. In the other there was great improvement.

THE TREATMENT OF TUBERCULOSIS OF BONES AND JOINTS BY PARENCHYMATOUS AND INTRA-ARTICULAR INJECTIONS, BY DR. J. N. SENN, CHICAGO.

The following conclusions were presented.

1. Parenchymatous and intra-articular injections of safe anti-bacillary substances are indicated in all subcutaneous tubercular lesions of bones and joints accessible to this treatment.

2. Of all substances, so far employed in this method of treatment, iodoform has yielded the best results.

3. The curative effect of iodoform in the treatment of local tuberculosis is due to its anti-bacillary effect and its stimulating action on the healthy tissues adjacent to the tubercular product.

4. A ten per cent. emulsion in glycerine or pure olive oil is the best form in which this remedy should be administered subcutaneously.

5. The ethereal solution should never be employed as it is liable to cause necrosis of the tissues overlying the abscess or iodoform intoxication.

6. Tubercular abscesses and joints containing synovial fluid or tubercular pus should always be washed out thoroughly with a three to five per cent. solution of boracic acid before the injection is made.

7. Injections should be made at intervals of one or two weeks and their use persisted in until the indications point to the cessation of tubercular inflammation and the substitution for it of a satisfactory process of repair or until the result of this treatment has shown its inefficacy and indications present themselves of the necessity of resorting to operative interference.

8. If the treatment promises to be successful, symptoms pointing to improvement manifest themselves not later than after the second or third injection.

9. In tubercular empyema of joints and tubercular abscess, gradual diminution of the contents of the joint or abscess at each successive tapping, lessening of the solid contents of the fluid and increase of its vicidity, are the conditions which indicate unerringly that the injections are proving useful and that in all probability a cure will result from their further use.

10. Moderate use of limb is compatible with this method of treatment, provided the disease has not resulted in deformities which would be aggravated by further use of the limb. In such cases correction of the deformity should be postponed until the primary joint affection has been cured by the injections.

11. Para-chymentrim and intra-articular medication with anti-bacillary material, has yielded the best results in tubercular spondylitis attended by abscess formation and tuberculosis of the knee and wrist joints.

12. This treatment may prove successful in primary osseous tuberculosis followed by involvement of the joint, provided the osseous foci are small.

13. Extensive sequestrums of articular ends with secondary tubercular synovitis, always necessitates resection, but preliminary treatment by iodoform injection into the affected joints constitutes a valuable preparatory treatment to the operation and adds to the certainty of a favorable result.

14. In open tubercular affections of joints, incision, scraping, disinfection, iodoformization, iodoform gauze tampon, suturing and subsequent injection of iodoform emulsion is advised, and yields excellent results, and should be employed in all cases in which a more formidable operation can be avoided.

15. Balsam of Peru ranks next to iodoform in the treatment of tubercular affections of bone and joints, and if the latter remedy for any reason can not be employed or has failed in effecting the desired result, it should be given a fair trial, if operative treatment is not urgently indicated. Adjourned.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO, (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by postal note, money order or registered letter.

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount earned, received and due in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

AN ANALYSIS OF 1008 CASES OF SCARLET FEVER ADMITTED INTO THE SOUTH-WESTERN FEVER HOSPITAL DURING THE YEAR 1890.

Since the publication in 1887 of the monograph of Dr. Astley Gresswell on the *Natural History of Scarlet Fever*, in which was studied 375 cases of scarlet fever treated in the South-Western Hospital, of London, we have been fortunate in having been furnished from this same Hospital some exceedingly valuable data. Dr. F. Foord Caiger, believing that a brief record of a considerable number of cases of this disease successfully treated under conditions favorable for observation would be of value, contributes, in the *Lancet* of June 13, 1891, an analysis of 1008 cases admitted to the Hospital in 1890. In this paper he considers: (1) Seasonal Prevalence, (2) District Prevalence, (3) Age, (4) Sex, (5) Mortality, (6) Complications, (7) Period and Extent of Desquamation, (8) Treatment.

I.—SEASONAL PREVALENCE.—This seasonal prevalence of the disease, as evidenced by the monthly admissions, was in accord with that observed in London during the last seventeen years. The admissions were at their lowest during the first quarter of the year. A slight rise was observed in May, and was maintained during the summer. A rapid increase was noted in September, and reached its highest point in October. After this the numbers fell rapidly until the end of the year. The curve of scarlet fever admissions into this hospital in the main corresponds with that of the total admissions into the hospitals of the Metropolitan Asylums Board. They numbered for the year 6565, and represent about 43 per cent. of the notified scarlet fever in London.

II.—DISTRICT.—Of these cases the parish of Lambeth contributed 585, or 58 per cent.; Wandsworth, 334, or 33 per cent.; other parishes, 89, or 9 per cent. The district from which they are drawn is not without its influence upon the case mortality. It is a

recognized fact that the poverty-stricken inhabitants of the poorer neighborhoods, in consequence of their lower vitality, show a much weaker power of resistance to the attack of scarlatina than those who are better housed and better fed. In this respect, though a large proportion of the patients came from the poorest parts of Vauxhall, Waterloo, and Battersea, they were not so badly off in the aggregate as those entirely drawn from the East-end districts. With this reservation there was nothing noteworthy in the type of disease observed throughout the year.

III.—Age Distribution.—The largest number of admissions fell within the second quinquennium of life; 449, or 44.5 per cent., of the total were between five and ten years. The first quinquennium furnished the next largest number; 314, or 31.1 per cent., were aged from one to five years. If these groups be examined more in detail, it will be seen that the number of admissions regularly increased with each year of life up to the fifth year, at which age they reached their maximum, after which they fell somewhat more gradually until ten years was reached. After ten years each quinquennium showed a progressively decreasing number until forty years was reached, after which age only two were admitted. It will be seen that after ten years the drop in the number of admissions at each quinquennium until twenty-five years was reached was considerable. These charts may be taken as characteristic of the total scarlet fever admissions under the Metropolitan Asylum Board for many years past.

IV.—Sex.—The numbers for the two sexes were nearly equal. Males, 509; females, 499. Under five years the males exceeded the females in the proportion of 7 to 6; whereas over five years the preponderance was slightly in favor of the females.

V.—Mortality.—The death-rate, calculated according to the Registrar-General's formula, comes out at 4.67, a very satisfactory figure when it is remembered that the mortality was 32.48.

VI.—Complications.—The following figures give the percentage incidence of the various complications observed in cases completed during the year arranged in their order of frequency:—Otitis occurred in 12.9 per cent. of cases, adenitis in 7.1 per cent., rhinitis in 6 per cent., eczema in 3.3 per cent. albuminuria (simple) in 3.1 per cent., ulcerative stomatitis in 2.8 per cent., nephritis in 2.7 per cent., rheumatism in 2.7 per cent., bronchitis in 2.08 per cent., conjunctivitis in 1.35 per cent., tonsillitis (secondary) in 1.24 per cent.

Otitis, attended with a purulent discharge, was the most frequent complication. It occurred in 124 cases, mainly in young children. The younger the child the greater its apparent liability to the disease. In most instances it began with earache, and more or less fever and restlessness, lasting from one to three days, which symptoms rapidly subsided on the appearance of the discharge. Though the majority were due to otitis media with perforation of the tympanum some few were apparently caused by a simple inflammation of the external auditory canal. There seemed to be a direct connection between the severity of the scarlatinal attack and the early development of the affection. The milder cases were attacked less frequently, and usually at a later period of their illness, occasionally several weeks after the subsidence of the fever. The continuance of the discharge varied from three or four days to three or four months. Most cases were clear within two weeks. All were detained in Hospitals until the discharge had entirely ceased. This was usually effected by means of simple treatment. In three instances suppuration occurred over the mastoid process, but by means of early incision down to the bone possible suppuration of the mastoid cells was averted. In only one case did there appear to be very marked impairment of hearing at the time of discharge from the Hospital, but to obtain accurate knowledge on this point was difficult owing to the extreme youth of the majority of the patients. Only one case of otorrhœa occurred in a patient over ten years of age. No case of meningitis or

pyæmia developed during their stay, and as all discharges were cured before the patients were sent home, there is some hope for an immunity in the future. It is a point worth bearing in mind that extreme fetor of discharge in otitis media is not necessarily dependent on bone disease.

Adenitis occurred in 69 cases, and was the next in order of frequency. The adenitis here alluded to is a distinct affection, and does not include the glandular swelling directly associated with the faucial inflammation which, though in some instances so slight as to be hardly noticeable, in others assumes such proportions as to deserve the name "bull neck," a symptom of the gravest omen, being associated with extensive ulceration of the fauces, a fetid discharge from mouth and nose, and symptoms of a pyæmic type. The affection referred to is a rapid swelling of one or more of the glands of the neck, usually at the angle of the jaw, sometimes beneath the sterno-mastoid, attended with a fresh rise of temperature, quite apart from the original febrile attack, from which it may be separated by an interval of from one to three or more weeks. It either more or less rapidly resolves, or it suppurates, often with little or no reddening of skin or periadenitis. Of the 69 cases, 17, or about one-third, suppurated, necessitating surgical interference.

Rhinitis, with a more or less purulent discharge, occurred in 58 cases. It was frequently associated with otorrhœa, and was relatively more common in young children. In recording instances of this complication Dr. Caiger has endeavored to eliminate as much as possible those cases in which the discharge appeared in the first week, during the height of the fever, at which time, in common with several others, it is a *symptom* of grave prognostic value. It is always a difficult matter to determine where the line should be drawn between symptoms and early complications. It would be well if the field could be cleared of any such assumed distinctions, but in the present state of our knowledge some such empirical distinction is at least a matter of convenience.

Eczema was noted in thirty-two cases. Its most frequent seat was at the junction of the alæ nasi and upper lip, behind the ears and on the ear itself, especially at the external auditory meatus and within the groove of the helix. It seemed in many instances dependent on the presence of an irritant discharge from the nose or ear, and, from the fact that it is very difficult to prevent young children from picking a sore spot, its extension in an impetiginous form to neighboring parts of the face frequently occurred. Young children showed a greater liability than older ones, and its incidence was most marked in cold weather and on patients taking a meat diet. In some cases it necessitated a prolonged detention in Hospital. Several cases of eczema capitis were very tedious in their convalescence.

Albuminuria was recorded in thirty cases. This small number does not pretend to include all cases in which faint and transient traces were present at one time or another. Those showing a faint cloud during the pyrexial stage of the attack and those cases in which a faint haze with picric acid was observed for not more than three consecutive days are not included in the list.

Dr. Gresswell states that he found albumen in the urines of 93 per cent. of his cases, and in the months of October and November in every one, the urines usually being tested every other day, and a neutral saturated solution of picric acid the reagent employed. Difference of season and epidemic type may doubtless, in some degree, account for the discrepancy; moreover, the individuality of the observer and the nature of the test he employs are not without their influence. The cases were treated in the same wards, and with practically the same environment. The only variation lay in the matter of treatment. The diet *scale* remained the same in the two series. Dr. Gresswell's ordinary cases appear to have been kept on "low diet," consisting of beef-tea, milk, and two eggs (in the case of children over ten years four eggs) for a period of three weeks, during which time no baths were given. In the cases under discussion in this paper the

patients were put on a meat or fish diet with no eggs (in the case of children over ten one boiled egg,) and were ordered baths on the day following that on which the temperature had reached the normal. This usually occurred about the end of the first week. Both series of patients were kept in bed for three weeks after admission. Their treatment, therefore, during the second and third weeks differed in this respect. Dr. Gresswell's cases were taking a diet rich in highly diffusible albumen without any baths; Dr. Caiger's cases own a much less proportion of easily diffused albumen and frequent baths, and it was during the first three weeks that Dr. Gresswell found albumen in 100 per cent. of of his October and November cases.

With the exception of a slightly higher rate during the October and November cases, the albuminuria has been spread nearly uniformly over the year. Young children were affected in larger proportion than their elders; 93 per cent. occurred in children under ten, the relative admissions for that age period being 75.

Ulcerative Stomatitis occurred in twenty-seven cases. They varied in severity from the mildest form of surface ulceration on the lips, tongue, and buccal surface of cheek, arising in connection with spongy gums and carious teeth, to a rapidly necrotic form of deep ulceration, attended with extensive sloughing of cheek and gum. In this latter form the teeth soon become loose and fall out. Cases of all degrees of severity are attended with a distinctive fetor of breath, a dirty coated tongue, and rapid incrustation of the teeth with a black putrefactive deposit. Under suitable treatment, and, in the severe cases, very radical treatment, all recovered. Half-measures are of no use. If the disease does not almost at once yield to mild measures, fuming nitric acid, if necessary under chloroform, should be freely applied to the whole of the diseased surface. Within thirty-six hours the whole process will have changed.

Nephritis supervened in twenty-six cases. Though nearly equally distributed throughout the year, they were relatively slightly more frequent during the summer months. Twenty-three of these cases occurred within the first three weeks of illness. The incidence of nephritis was therefore very small—viz., 2.7 per cent. This is in marked contrast with the statement which appears in the article on "Scarlet Fever" in Roberts' Theory and Practice of Medicine, 1890—viz., that the most frequent and important complication and the one that requires special notice is acute nephritis and its consequences.

Rheumatism of sufficient distinction to cause a rise of temperature, and obvious joint tenderness was seen in twenty-six instances. In two instances the pericardium was affected, in two an apparently valvular murmur developed, but one of these had probably been the subject of antecedent endocarditis. Pleurisy in connection with rheumatism was seen in only two instances. The joints most frequently affected were those of the extremities, the arms more frequently than the legs, and the wrists, elbows, and ankles, than the shoulders, hips, or knees.

Scarlatinal rheumatism most frequently occurs at the end of the first or beginning of the second week, at a time when the rash is just disappearing and the temperature reaching the normal. There seems to be a greater liability in patients who have had a copious rash, followed by profuse desquamation. It is comparatively more frequent in adults and in older children, and shows but little tendency to affect the heart, pericardium, or pleura. Its incidence seems to be independent of season. It is relatively as frequent during the summer and autumn as during the colder months.

Bronchitis occurred in twenty instances. It was mild in character, and almost invariably appeared during the febrile stage. It was relatively more frequent during the cold weather.

Conjunctivitis of a mild muco-purulent type occurred in thirteen instances. It was mainly an affection of convalescence, and readily yielded to treatment. No case terminated in corneal ulcer or serious eye mischief.

Secondary tonsillitis sufficient to cause a

rise of temperature occurred in twelve cases. They all made a rapid recovery.

It is satisfactory to note that in no instance did diphtheria, either faucial or laryngeal, make its appearance among the scarlatina convalescents.

Relapse or recrudescence of the disease was seen in six instances. Great care should be taken in recording such instances to eliminate all cases in which there exists any reasonable doubt as to the genuineness of either attack, as it may be suggested that either the initial or the second one may not have been an instance of true scarlatina. In four cases out of the six the symptoms in each attack were so distinctive that if their genuineness be in dispute it can only be urged that we have, then, no reliable criteria of an attack of scarlatina. Rash, throat, tongue, the course of the temperature and peeling were in each instance characteristic of the disease. Three of the relapses occurred during the second and third week of illness—viz., on the twelfth, fourteenth, and seventeenth days; two in the fifth week, and one in the seventh week. In three of them—viz., those occurring on the twelfth day, fifth week and seventh week respectively, the relapse, in one case complicated with nephritis, was of greater severity than the primary attack.

VII.—Desquamation.—The period and extent of desquamation varied in different cases within wide limits. In some instances, mainly in adults and very young children, it was completed in less than six weeks. In others it was prolonged to twelve, or even sixteen weeks. With the exception of a few in whom a condition of xeroderma was natural, no case was sent home until all sign of peeling had disappeared, discharges from mucous cavities and sores had ceased, and the urine been for several weeks free from albumen. In infants, as is usual, peeling was but slight and transient. The average detention in hospital was slightly over nine weeks.

VIII.—Treatment.—In the large majority of cases no special treatment was indicated, symptoms being dealt with as they arose. In those with severe throat and glandular affection, frequent syringing out of the fauces and nares with a solution of chlorine or boracic acid was most useful as serving to clear away offensive secretions and lessen discomfort. In such cases the frequent application of hot poultices was of great service. In restlessness and sustained pyrexia cold and tepid spongings were useful to promote sleep, and sulphonal in some instances proved a valuable hypnotic. The cases were treated in bright and well ventilated wards, maintained at a temperature of 56° to 60° F., the average cubic space per bed being about 2,000 ft. The diet during the pyrexial stage consisted of milk, beef tea, eggs, and ice, after which a more solid diet of milk pudding, bread and butter, with fish or meat, was given, and at the same time baths were ordered on alternate days. Stimulants were only employed in severe cases, usually in the form of brandy or champagne. Uncomplicated cases were allowed to get up at the end of the third week, and except in wet weather, sent out of doors for several hours usually each day, due care being taken that flannel was worn next the skin and the clothing otherwise warm and generally sufficient. Complications were dealt with as they arose, and, with the exception of otorrhœa, were rarely seen after the third week.

With reference to the treatment of scarlatinal nephritis, Dr. Cagney was not in the habit of using drugs in ordinary cases. A death from scarlatinal nephritis in his hands is an event of the greatest rarity. In this series of over 1,000 cases of scarlatina only one death occurred from scarlatinal nephritis, the child being admitted with nephritis, and dying a few days after in convulsions.

Correspondence.

GASTRALGIA CURED BY ARSENIC.

To the Editor of the Medical and Surgical Reporter:—Ten drops of Fowler's Solution of Arsenic three times a day for three days would probably have cured the case of gastralgia reported by Dr.

Alice McLean Ross in a previous number of the REPORTER. It will now in all probability prevent its recurrence. This is what cured (in 6 drop doses) Dr. Valentine Mott of severe neuralgia of the stomach, occurring immediately after a four months course of lectures, his last, in his 78th year.

For fissured nipples I notice several remedies in your journal.

The worst case I ever saw, was cured speedily by the application of oil of eggs, immediately after nursing, to the dried nipple, then covered with a bees-wax shield to protect it from the clothing. This I used successfully at home, and in many other cases after all other things failed. This is Sherman's Celebrated Nipple Oil. I gave him the receipt which is as follows: Break two fresh eggs in a frying pan, wiping the pan clean of grease, place it over a smart coal fire. They will cook, dry, char and remain like charcoal, for perhaps an hour or more, then turn to a blackish antiseptic oil, which will not get rancid in twenty years; this I know by leaving a small bottle open from which I used the oil.

EDW. VANDERPOOL, M. D.

BOOK REVIEWS.

PULMONARY CONSUMPTION, A NERVOUS DISEASE: considered as such from a practical, a clinical, and a therapeutic standpoint. By THOS. J. MAYS, M. D, Professor of Diseases of the Chest in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. Geo. S. Davis, Detroit, Mich., 1891. 16 mo., 185 pp. Paper, 25 cents; Cloth, 50 cents.

In this volume of the Physician's Leisure Hour Series, the author endeavors to show that the principle causes and nature of pulmonary consumption are of direct neurotic origin. In other words, he looks upon consumption as a neurosis, and evidently wishes to discard entirely the bacillary origin of this disease. His chief reason for belittleing or abolishing a dependence on bacilli is apparent in his preface, in which he states that "Any one who takes a calm and impartial retrospect of the whole situation must own that never was an *ignis fatuus* pursued which left more promises broken and greater anticipations unfulfilled than the bacillus theory in so far as it stands related to the therapeutics of this disease." To decry a theory of the origin of a disease because that theory has not benefited the therapeutics of the disease is illogical and an absurdity. For the same reason the author's asserted neurotic origin may be attacked.

To any one who will unbiasedly read these pages, it will be apparent that the author starts out with such preconceived opinions that he does not fairly consider the data before him; but, indeed, really makes deductions which are directly opposed to the matter he recites. This assumption of the neurotic origin of tuberculosis seems to us to be one of the familiar instances, where, because a certain lesion was found in one case, the argument is that a similar lesion must exist in all cases of the same class. There are no doubt cases of pulmonary tuberculosis primarily of neurotic origin, so, too, are there those primarily of bacillary origin, but to say that consumption is in all cases primarily a neurosis, or, on the other hand, that all are primarily of bacillary origin is absolutely unwarranted.

The author's arguments rest on such unstable ground that it seems apparent he will have few adherents to his beliefs.

ESSENTIALS OF PHYSIOLOGY, ARRANGED IN THE FORM OF QUESTIONS AND ANSWERS, PREPARED ESPECIALLY FOR STUDENTS OF MEDICINE, BY H. A. HARE, B. Sc., M. D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, of Philadelphia, etc. Third edition, thoroughly revised and enlarged by the addition of a series of handsome plate illustrations taken from the celebrated "*Incones Nervorum Capitas*" of Arnold. Philadelphia; W. B. Saunders, 12 mo., 193 pp., cloth $1; interleaved for taking notes, $1.25.

In this edition of this excellent compend we find as the chief change the insertion of a number of plates which the student will find of great benefit in the studies of the deep and superficial origins, the modes of exit, the distribution and the functions of the cranial nerves. The plates are well executed, and the book creditable both to author and publisher.

ESSENTIALS OF ANATOMY AND MANUAL OF PRACTICAL DISSECTION, TOGETHER WITH THE ANATOMY OF THE VISCERA. Prepared especially for students of medicine, By CHARLES B. NANCREDE, M. D., Professor of Surgery and of Clinical Surgery in the University of Michigan, etc. Fourth edition, revised and enlarged by an appendix containing *Hints on Dissection*, by J. Chalmers Da Costa, M. D., Philadelphia; W. B. Saunders. 12 mo., 388 pp. Price, in cloth, $2; sheep, $2.50.

This edition presents evidences of decided and gratifying changes. The former editions have been very popular, and in the present issue an effort has been made to extend the usefulness of the work by the addition of a

series of 30 excellent full-page lithographic plates, in colors, taken from the works of Maclise, Savage, Nuhn and Hirschfeld. Besides these there are 188 fine wood cuts. The student will find this a very handy and trustworthy work in the dissecting room.

PERISCOPE.

THERAPEUTICS.

SOMNAL.

1. Somnal induces sleep through a direct action on the brain.

2. The sleep is preceded by disturbances in co-ordination of movements, which is dependent upon the drug's action on the central nerve system.

3. Somnal diminishes the irritability both of the psychomotor centres and the spinal cord.

4. It lowers reflexes, acting directly on the spinal reflex centres.

5. When applied locally, it depresses the excitability of the peripheral endings of sensory nerves.

6. It does not seem to exercise any influence on the peripheral terminations of motor nerves.

7. It lowers the blood-tension, the fall resulting from the drug acting both on the vasomotor centres and the vascular walls themselves.

8. It manifests an inhibitory influence on the central, but increases the irritability of the peripheral endings of the vagus.

9. It decreases the excitability of the respiratory centres.

10. It lowers the bodily temperature.

11. When administered in toxic doses, the drug kills the animal through inducing asphyxia.

12. On the whole, with regard to its physiological effects, somnal stands midway between chloral hydrate and urethan.

13. The action of somnal on the heart is a trifle less depressing, and hypodermic injections of the drug slightly less painful than those of hydrate of chloral.

14. In comparison with urethan, somnal cannot possibly claim even those advantages, since the former *a.* does not manifest any injurious influence on the heart; *b.* does not depress the arterial pressure; *c.* has a more unpleasant taste; *d.* even a 30 per cent. solution of urethan does not cause any pain in hypodermic injections.

15. Whatever somnal might prove—a definite chemical compound, or simply a solution of chloral and urethan in ethylic alcohol—all the same the new hypnotic does not offer any appreciable practical advantages over its components.

16. In view of *a.* the latter circumstance, *b.* the mysteriousness of the chemical composition, and *c.* the fact that the proprietor keeps in darkness and monooplizes the preparation, somnal should be discarded from the list of legitimate therapeutical means.—*St. Louis Med. and Surg. Jour.*

THE ROLLER BANDAGE FOR THE PAINS OF TABES DORSALIS.

Dr. Joseph Leidy publishes a note in the *Medical News* for the purpose of drawing attention to the results of a simple method for the relief of pain during the course of spinal disease, and especially tabes dorsalis.

Warmth, in the form of the warm bath, has long been recognized as of considerable utility in the treatment of this symptom.

He has frequently observed the relief afforded by the firm application of a roller bandage in the spasmodic and painful conditions so common in the extremities following traumatism. It occurred to him that the application of such a bandage (flannel or hose) to the part the seat of pain in locomotor ataxia might be of some service in mitigating the suffering. He found that the firm application of a bandage (flannel) from the toes to the upper third of the thigh was attended with great relief. During the past six months this method of treatment has been employed with most encouraging results. For the girdle pains a bandage, similar to the abdominal binder, firmly applied at the level of the abnormal sensations, afforded almost instant relief. The cases under observation had been treated with galvanism, with absolute rest, and the usual therapeutic measures, the majority of which had failed. The usefulness of this method depends principally upon the pressure and warmth that the bandage affords, combined with rest. It is worthy of further trial, if only as a substitute for morphia. In one case the removal of the chest-binder was in several hours followed by a return of the girdle sensations. Two other patients invariably suffered a return of pain in the lower extremity on the removal of the bandage. In suitable cases the elastic stocking may, with advantage, be substituted for the bandage, as it does not interfere with locomotion.

The application of a roller bandage about the seat of pain was equally useful in several instances in which the area of pain was localized.

The method of treatment indicated will commend itself for its simplicity, with the advantage of acting as a substitute for drugs.

INFLUENCE OF DRUGS ON THE HEART.

Professor German Sée's second paper on this subject was read at the last meeting of the Academy of Medicine. He gave some further notes on the action of sparteine, digitalin, iodide of potassium, caffeine, etc., explaining and adding to what was reported June 13. He likewise examined at length: 1. Strophantine, which is a very strong contracting agent; it only increases the heart's action indirectly and momentarily. 2. Convallamarine is a weak diuretic, producing extreme effects similar to digitalin; convallamarine and sparteine are indispensable auxiliaries and succedaneums to strophantine, iodide of potassium, and digitalin. 3. Lactose is a renal diuretic, without producing the least agitation on the heart and its vessels. The learned professor's ill health necessitated the postponement of the discussion which was to follow this paper.

THE ELIMINATION OF ANTIPYRIN.

The rapidity of elimination of antipyrin has been experimentally worked out by Perret and Givre (*Lyon Médical*, June 7, 1891). The marked tolerance of this drug by young children, and their almost complete exemption from the not infrequent accidents observed after its use by adults, have suggested the idea that elimination of this substance in children is much more rapid than in older patients. The presence of antipyrin in the urine can be detected by the addition of perchloride of iron, which forms a beautiful deep red color. This test is sufficiently delicate to show the presence of one part of the drug in 5,000 parts of urine. The results of this investigation show that (1) the elimination of antipyrin, in all doses, in both children and adults, commences at the same time—about three-quarters to one hour after ingestion; (2) the the child eliminates the same dose more rapidily than does the adult, and he, in turn, more rapidly than the old man. Seven and a half grains given to a child continue to appear in the urine for fifteen to twenty hours, while the same quantity in the adult requires twenty-four to thirty hours for elimination, and a somewhat longer time in an aged person. Larger doses considerably prolong the period of elimination. Sixty grains, in a single dose, administered to an adult, continued to appear in the urine for seventy-two hours.—*Univ. Med. Mag.*

SULFONAL IN AFFECTIONS OF THE NERVOUS SYSTEM.

Dr. Græme M. Hammond, in the *Jour. Nervous Mental Diseases*, writes: Sulfonal is one of the most serviceable drugs in the treatment of nervous diseases which modern chemical research has added to the pharmacopœia. It cannot, in any sense, be considered as a remedy which, by its persistent administration, causes the resolution of pathological conditions. It is a hypnotic, pure and simple. On account of its tastelessness, the refreshing, apparently natural, sleep which follows its administration, and the freedom from unpleasant after-effects, he regards it as a remedy of the highest order. Though he has frequently prescribed sulfonal in large doses nightly, he has never observed any tendency on the part of the patient to form a sulfonal habit.

Of course, being a hypnotic, its use is confined principally to those affections in which insomnia constitutes an important feature. He does not believe that sulfonal ever cures insomnia, except in rare instances. Where wakefulness, moderate in degree and in duration, has been induced by anxiety or worry, and still persists after the exciting cause has been removed, he has sometimes found that fifteen or twenty grains of sulfonal, given every evening for four or five consecutive days, entirely dissipates the insomnia without any other remedial measures being adopted. But it is also serviceable in the preliminary treatment of persistent insomnia. The remedies which relieve insomnia, by the arrest and removal of those morbid conditions which have developed the cerebral hyper-excitability, necessarily act slowly. Under the most favorable conditions, two or three days at least elapse before wakefulness gradually yields to sleep. In such cases a sufficient dose of sulfonal, given for two or three consecutive nights, insures that much-needed sleep which will be continued without the sulfonal when the effect of the remedies aimed at the morbid condition inducing the insomnia becomes manifest.

In certain forms or insanity, in which the constant mental activity frequently induces

nights of wakefulness, sulfonal can be used with benefit. It is far preferable to narcotics, as it secures the desired rest without any apparent pernicious after-effect.

The dose of sulfonal varies greatly for different individuals, depending principally upon the degree of insomnia and the condition of mental excitability. In mild cases, fifteen or twenty grains will be enough, but he has seen several cases in which fifty or sixty grains at a dose were required before even a moderate amount of sleep could be obtained. These cases were all sufferers from insomnia depending upon cerebral irritation of undoubted organic origin, such as epilepsy, cerebral tumors, etc.

There are certain individuals who undoubtedly evince a decided intoleration for sulfonal.

In one case, that of a woman, fifty years of age, who was suffering from insomnia coincident with cerebral embolism, the administration of fifteen grains of sulfonal was almost immediately followed by vertigo, stupor and marked delirium, which persisted for several hours. A few days later the same symptoms followed almost immediately after the same quantity of sulfonal was taken. As a usual thing the effects of sulfonal rarely show themselves until three or four hours after the drug is taken. It could not have been the age of the patient which caused the unpleasant symptoms, for he has frequently given doses of fifty or sixty grains to persons of sixty or seventy years of age. One case—a man, sixty-five years of age, who suffered from frequent epileptic attacks—took sixty grains of sulfonal nightly for a month without any unpleasant symptoms whatever. Another patient, after taking twenty grains of sulfonal, complained of similar symptoms to those previously mentioned, besides which the patient felt weak and suffered from vertigo for the following twenty-four hours. These are the only two instances he has met with in which any decided intoleration for the drug has been shown.

To obtain the best effects of sulfonal, it should be given as nearly in solution as possible. Hot water or hot milk are, in my opinion, preferable as vehicles for the solution or suspension of the drug. Sulfonal is readily soluble in alcohol, and it is often recommended, therefore, to give it dissolved in wine or in some other fluid containing alcohol. But alcohol, being a cerebral stimulant, is contraindicated in most cases of insomnia. It may be given dissolved in soup, in tea, or in coffee, and will be tasteless, unless the dissolving fluid contains grease, as soups frequently do, when a decidedly bitter taste will at once be remarked.

Sulfonal given in powders has in his experience proved more efficacious and efficient than when administered in the form of compressed tablets. Whether it is that the latter, being more insoluble than the former, pass into the lower portion of the alimentary tract before they become completely absorbed, he does not know; but he has frequently observed that when equal quantities of sulfonal, in tablets and in powders, have been taken by the same individual, that the duration of sleep produced by the powders greatly exceeded that induced by the tablets.

The cases in which sulfonal gives rise to unpleasant symptoms are so infrequent—only two such instances having come under his observation—that we may readily regard it as a safe and valuable hypnotic—not as a remedy which will cure insomnia, but as a temporary means of bringing refreshing sleep to an exhausted or over-excited brain.

INTRAVENOUS INJECTIONS OF SODA IN ANEMIA.

Castellino (*Gaz. d. Ospit.*, No. 20), at the clinic of Maragliano, at Genoa, has studied in cases of anemia the results of intravenous injections of from fourteen to sixteen ounces of a ¾ per cent. filtered solution of soda. The injections were well borne, though sometimes followed by slight fever. An hour after the injection the number of red cells and the percentage of hæmoglobin were reduced. This oligemia was transitory and proportional in degree to the quantity of fluid injected. At the end of from ten to twenty hours a decided increase in the number of blood-plaques and in the number and resistance of the red cells had taken place; the red corpuscles were, however, still pale; the hemometer detected little variation. In the course of four or five days the increase in the number of red cells became more conspicuous, the percentage of hæmoglobin remaining stationary. During this period the red corpuscles showed greater resistance to the serum than they did previously. At the end of from thirty to forty days the good effects of the injections had disappeared. In three cases the serum, which before injection had, on spectroscopic examination, contained a considerable quantity of hematin, became clear after injection. In a case of chronic malarial fever of quotidian type, the

injection was followed by a decline of 2° in temperature. Good results attended the injections in a case of intense chloremia and in one of purpura simplex. In both, the number of red corpuscles became doubled, the general condition improved, and there was an increase in body-weight.—*Wiener klinische Wochenschr.*, June 4, 1891.

MEDICINE.

NASAL REFLEXES.

Dr. F. C. Heath, in the *American Lancet*, says that the explanation of these reflexes is not altogether clear and satisfactory. There are several theories. Hack considers that hyperæmia is the essential condition of the nose causing reflexes. John Mackenzie attributes it all to certain sensitive areas—*i. e.*, the respiratory tract of the nose is the area of reflex action. Moure's theory is, that the reflexes arise from mechanical irritation in the nasal chambers. Bosworth adopts Hack's theory, but adds that "hyperæmia generally occurs in a patient of a decidedly neurotic temperament," and this temperament "is a prominent predisposing cause of a nasal reflex." Moldenhauer opposes Hack's theory, claiming that "nasal polypus and polypoid thickening, as well as atrophic rhinitis, are a source of reflex phenomena, in neither of which does hyperæmia exist." Bosworth denies this condition as far as polypi and polypoid thickening are concerned, holding that they are attended with vaso-motor paresis and distension of the vessels of the membrane; he also speaks of the rarity of reflexes in atrophic rhinitis. That they do sometimes occur in this condition, is evidenced by the fact that Frænkel and Schmaltz report facial neuralgia and vertigo in cases of atrophic rhinitis; Finne a case of neuralgia of the fifth nerve; and Gleason certain skin rashes. Rualt thinks they may be due to crust accumulations, but Bosworth attributes the reflex to impaired general nutrition.

This impairment of nutrition also takes place in obstructive lesions, and may account for many of the accompanying neuralgias.

Some of the diseases reported as reflexes are undoubtedly the direct results of nerve pressure or of the extension of inflammation from continuity of tissue. He is now treating a case of conjunctivitis, probable due to plugs retained in the nares too long, but whether the eye trouble is reflex or from extension of inflammation, is uncertain.

From this study of nasal reflexes, he thinks, we may safely draw these conclusions:

1. Nasal lesions often produce serious reflex diseases.

2. An examination of the nares should be made in all cases of obstinate neuralgias of the head and face.

3. An examination of the nares should be made in every case of asthma, and in all other spasmodic and paralytic nervous affections, before giving them up as hopeless.

4. An examination of the nares should be made in all ocular cases not yielding to ordinary treatment.

5. Proper nasal treatment should be instituted where lesions are found in the nose in connection with any of the neuralgias, spasmodic and paralytic nervous affections, and ocular diseases above reported, in the hope of relieving or curing the same.

INFLUENCE OF ACUTE FEBRILE DISEASE ON THE COURSE OF CHRONIC PHTHISIS.

Dr. A. Chelmouski reports a case (*Deutsche Medicinische Wochenschrift*, No. 14, 1891) from the wards of Professor Stolnikow, of Warsaw, in which an acute attack of erysipelas, occurring in a patient who was suffering from chronic phthisis, gave rise at first to exacerbation of the tuberculous affection, but subsequently to apparent recovery. The patient was a woman, aged 38, who had suffered for a long time from symptoms of chronic disease of apex of the right lung, bacilli being present in the sputum. Added to this there was very extended ulceration and tuberculous infiltration of the mouth and fauces. A sharp attack of erysipelas, presumably acquired from a patient in a neighboring bed, was followed by a decided increase in the symptoms of the pulmonary disease. With the subsidence of the erysipelas a marked improvement took place in the visible tuberculous disease in the mouth. The ulcerated patches became cleaner and smaller, and the points of infiltration gradually subsided and disappeared. Tubercle bacilli were no longer to be found, and by slow degrees the symptoms of the lung mischief passed away, until the patient in about six weeks was able to leave the hospital feeling perfectly well. Several observers have recorded the subsidence of syphilis and lupus after erysipelas, and a few instances of arrest of tubercle have been noted. An attack of typhoid fever may sometimes be followed by recovery from tubercle. An interesting example of this, in the person of a

professional colleague, is recorded. The patient not only lost all his previous tuberculous symptoms, but gained weight in a remarkable manner during the convalescence from the fever, the cough being reduced to a minimum. Without offering any special explanation of this striking improvement in the onward course of the tuberculous disease, the writer quotes the opinion of Gamaleia, von Fodor, and others, to prove that high temperature should not be regarded as a harmful thing in itself, but rather as an evidence of the destructive process that is going on in the blood to bring about the annihilation of the tuberculous virus. Presuming that a febrile state of blood is inimical to the spread of the tuberculous poison, the occurrence of an excessive febrile condition such as is produced during the course of erysipelas or typhoid might account for the cessation of the tuberculous process, and its rapid cure after the subsidence of the fever. In cases of long-standing disease, where the heart's action is enfeebled or its muscular structure degenerated, the result of the secondary fever may have no such salutary effect, but may simply increase the local disease and diminish the general recuperative power.—*Brit. Med. Jour.*

THE IMMEDIATE REPAIR OF LACERATIONS OF THE CERVIX UTERI.

After a study of this subject (*N. Y. Med. Jour.*) the conclusions reached by Dr. Barrows are that, under certain conditions, lacerations of the cervix uteri are unavoidable, that where they occur to any extent they should be repaired at once, and that this can be done easily without risk to the patient and with every prospect for a successful result. The objects aimed at by this procedure are—

1. To prevent hæmorrhage from the torn surfaces, but more particularly from the cavity of the uterus, by insuring complete and permanent contraction of the organ.

2. To prevent puerperal pelvic cellulitis, endometritis, metritis, salpingitis, oophoritis, and peritonitis, and their complications and sequelæ.

3. To restore the cervix to its normal condition and prevent the development of the conditions dependent on the formation of cicatrical tissue at the cite of the laceration.

4. To promote involution and prevent the evils dependent on subinvolution.

5. To remove at once a common source of septic infection.

NEW METHOD OF EXAMINATION OF THE DIGESTIVE ORGANS.

Dr. Sahli, of Berne, has adopted the following ingenious procedure for determining the condition of the digestive functions. A pill containing about three grains of iodide of potassium is enclosed in a round sheet of very thin gutta-percha paper, the free margins of which are twisted in form of a bag and then fastened by a firm moist cord of fibrine, about one-eighth inch thick. The ends of the cord are brought together by a thread. The rubber sheet should be well covered with talcum, so as to prevent adhesion of the opposed surface. To protect the bag during swallowing, it is enclosed in a gelatine capsule. The author's object was to determine the time required for the iodide of potassium reaction to manifest itself in the saliva under various physiological and pathological conditions, this depending upon the rapidity with which the fibrine cord was digested and the iodide set free from its envelope. It has been stated that the manifestation of the iodide of potassium reaction depended upon the qantity of free hydrochloric acid in the stomach, but Sahli's experiments tend to show that the quantity of contained acid exerts less influence than has been thought. Although in the majority of cases examined, patients whose stomachs contained free HCl. presented the iodide reaction in the saliva much more promptly than those having a deficiency of the acid, he met with several cases in which time of appearance of the reaction was about the same, independent of the presence or absence of acid. The administration of hydrochloric acid with pepsin in cases of deficient acid production had frequently little or no effect in hastening the manifestation of the reaction. In like manner the administration of soda and pancreatic ferments in these cases, for the purpose of initiating intestinal digestion in the stomach, had no effect in accelerating the appearance of the reaction, and sometimes even delayed it. The reason of this was found to be that the acid and pepsin, or the pancreatic ferments, remained for too short a time in the stomach to exert any digestive action, being partly absorbed and partly passed into the intestines.

The value of this method in demonstrating the condition of the digestive functions is shown by some experiments made by Dr. Henne regarding the influence of pepper on stomach digestion. He found by chemical examination of the gastric juice that pepper administered in doses of 2½ grammes before

meals had no essential effect upon the gastric functions, but that the iodide reaction appeared earlier if no pepper was given. Owing to the laxative effects of pepper, as demonstrated by these experiments, it is probable that it exerts a favorable influence upon intestinal digestion.—*Correspondenz-Blatt. f. Schweitzer Aerzte*, No. 3. 1891.

SIPHON DRAINAGE IN TUBERCULOUS EMPYEMA.

A paper and an illustrative case on the subject of rapid and successful healing of tuberculous empyema were brought forward by Dr. A. Fraenkel at the recent sitting of the Verein für Innere Medicin (*Deutsche med. Wochenschrift*, No. 17, 1891). The patient, a young man, aged 23, suffered from phthisis of the right apex, with slight signs at the left also. Effusion ensued in the right pleura, the fluid being somewhat blood-stained, and containing tubercle bacilli. No bacilli could at that time be found in the sputum. The pleuritic fluid became purulent, and was removed by Bülau's method (a long india rubber drainage tube passed through the cannula, after withdrawal of the trocar, the tube being made to act as a siphon, discharging into a vessel filled with antiseptic fluid). After subsidence of the fever, injections of Koch's tuberculin were begun and were well borne. In twenty days the secretion from the pleura ceased, and a few days later, after withdrawal of the tube, the wound was completely healed. The patient gained two stone in weight, and is at present doing well, although tubercle bacilli are now present in the sputum. Comparing the results of this case, and others similar to it, with such experience as that lately published by Professor König (see *Supplement*, March 21st, 1891), Dr. Fraenkel expresses astonishment at the strong evidence in favor of the siphon treatment. He believes that tuberculous empyema will soon come to be regarded from a new standpoint, and that the good results which have recently been obtained by operative treatment in the case of tuberculous peritonitis may, perhaps, be obtained in the similar affection of the pleura when the disease in the lung is not too far advanced. He commends the siphon method in all such cases except where the pus is offensive, and for these he regards free evacuation through a wide opening as the most satisfactory treatment.—*Brit. Med. Jour.*

SURGERY.

MESENTERY CYSTS.

Gazette Hebdomadaire of May 31st, 1891, reports the removal of many cysts of the mesentery by M. Terrillon. It is generally very difficult to differentiate between these and cysts of the pancreas; but patients having cysts of the mesentery do not generally suffer from renal disturbance; they are not emaciated, as those who have cysts of the pancreas. Having divided the epiploon, he emptied the cyst by puncture and aspiration, and then tried to remove the tumor, but without success. He has always found it necessary to fasten by suture the sides of the cyst to the abdominal walls and to have recourse to drainage in order to effect a cure.

Three cysts removed by Dr. Terrillon contained a lemon-colored fluid and their cavities were without epithelium.

More frequently the liquid found in cysts of the mesentery is of an undefined color, opalescent, and contains fat, but sometimes the liquid is yellow.

Jules Bœckel, in a work which he has recently published on cysts of the pancreas, gives, as a differential sign between them and those of the mesentery, the almost constant presence of an opaline, viscid liquid containing much fat.

The liquid in the cysts operated on by M. Terrillon seemed to be entirely serous. In these cases the large intestine was found to lie over the cyst so that direct puncture was contraindicated. M. Terrillon did not puncture until he had opened the abdomen in the median line.

These cysts are almost always extensively adherent to the surrounding parts, and, as a general rule, as in cysts of the pancreas, it is not possible to extirpate them entirely. After having opened them and fixed the sack with suture to the abdominal walls, it is necessary to await the gradual absorption of the abdominal cyst.—*Sanitarian.*

SURGICAL TREATMENT OF TYPHLITIS.

Dr. M. Kœrte, in an abstract in the *Medical Age*, says that surgical intervention is indicated in cases of peri-typhlitis. When we have an acute, diffuse peritonitis consecutive to a perforation. In cases of acute peritoneal abscess. When there is a retro-peritoneal abscess. In case of relapsing suppurative peri-typhlitis.

1. Mikuliez was the first to show that the

intervention of the surgeon may sometimes save patients affected with diffuse suppurative peritonitis consecutive to a perforation. I have three times operated on cases of this sort. One of the patients on whom I operated *in extremis*, succumbed. The autopsy showed a cure might have been obtained if there had not been a third abscess which could not be evacuated, seated between the stomach and diaphragm; this was the direct cause of death. Of the two other patients, one recovered with only a superficial wound remaining; the second, a young man of 18 years, is in the process of recovery.

In operating, I advise not to make antiseptic lavage of the abdominal cavity; it is better to mop out the abscess with dry tampons. I do not take a great deal of pains to find the appendix vermiformis to excise it, for it will not do greatly to prolong the operation, the patient being always very much exhausted; but if the appendix can be readily found, it is well to cut it off, after having ligated it at the base with catgut.

2. Encapsulated abscesses should be incised as soon as possible, if we would not have life compromised by perforation; there is always danger of fatal pyæmia, as happened to three of my patients who did not have surgical treatment. It is the rise of temperature on which we depend for knowledge as to whether the peri-typhlitic effusion be prevalent or not. We can have recourse to exploratory puncture with a hypodermatic needle to ascertain if we have to do with pus. I have operated on five abscesses of this kind. Four of the patients rapidly got well; the fifth has still a stercoral fistula; perhaps we have to do in this case with a tuberculous disease. I do not in operating adopt the method of two stages advised by Sonnenburg.

3. The perforation of paratyphlo-enteric abscesses is a relatively rare event, but these abscesses often occasion a phlegmon; the pus penetrates to the sub-diaphragmatic space, and may pass from thence, by perforation of the diaphragm, into the pleural cavity.

I have operated on five cases of this sort; and all got well. Many authorities say we ought to make an early diagnosis of these abscesses; the exploratory puncture with the Pravaz syringe will much facilitate diagnosis.

4. The well-known symptoms of perityphlitic relapse are often explained by the retention of pus, and this of itself gives a reason why surgical intervention is desirable. I have operated twice in cases of this kind. In one of the patients, the appendix was twisted around the colon and adhered firmly to it; it was full of pus. I carefully detached the appendix, tied, and cut it off, then sewed the stump into the wall of the colon. The sequelæ were very simple, and recovery rapidly ensued. In the second case after making a herniotomy I found the appendix in the hernial sac, and excised it after ligation. Eight days afterward the patient was well. The appendix contained fœtid pus.

There is no doubt as to the necessity of operating in these cases. I do not advise following the practice of certain American physicians, who resort to the operation as a prophylactic during the first twenty-four hours after making the diagnosis of appendicitis; in fact, the great majority of cases of perityphlitis get well by internal treatment.

GYNÆCOLOGY.

THE PEDICLE IN EXTRAPERITONEAL HYSTERECTOMY.

M. Doléris (*Revue Obstêt. et Gynêc.*, May, 1891) prefers the extraperitoneal operation in cases of fibroid tumors of the uterus. The chief objection to this procedure is the presence of a wide stump in the lower angle of the wound, which involves painful traction, free suppuration, and prolonged sloughing. He therefore modifies the operation in order to neutralize these evil results. The pedicle is trimmed away inside until it is reduced to a mere membranous collar, which can descend behind the wound just enough to avoid severe traction. This collar is then cauterized with a red hot iron till it becomes like a thick piece of parchment. Its edges are then united by silk sutures, like the stopper of a champagne bottle. Reduced to the size and hardness of a small chestnut, it cannot tear itself away from the pins. At the end of a week or ten days the pins are withdrawn and the pedicle is allowed to retract after its sutured extremity has been trimmed away. On the twelfth day the elastic ligature deep in the wound is cut away; this is not difficult if a thread of silk has been fixed to it, to allow of its being drawn up. Lastly, the sloughy fragments are left to come away; they are never abundant. Two or three deep sutures may be passed through the lower angle of the wound, leaving a small gap for drainage. Granulation proceeds with rapidity, and is complete within a month. From the tenth day the wound no longer appears as though extraperitoneal ovariotomy had been per-

formed, but looks more like the abdominal incision after ovariotomy, with a small opening at the inferior angle. As the cauterized stump is very dry, but a small amount of antiseptic powder need be used. M. Doléris has operated on nine cases after this manner, with good results.—*Brit. Med. Jour.*

OPERATION FOR VESICO-CERVICAL FISTULA THROUGH THE BLADDER.

In order to operate successfully upon a vesical fistula it is absolutely necessary to have a clear view of the field of operation. This is often extremely difficult in cases of vesico-uterine and vesico-cervical fistula, and in those cases of vesico-vaginal fistula in which there are cicatricial adhesions which prevent their being drawn down. Trendelenburg proposed a method of operating (*Volkmann' schen Sammlung klinischer Vortrage,* No. 355) which overcomes this difficulty, namely, performing a suprapubic operation, opening the bladder to freshen the edges, and to sew up the fistula, and then to close the bladder again, leaving an opening for drainage; the opening in the abdomen to be sewed up in part, and the prevesical space to be tamponed with iodoform gauze. Trendelenburg reports three cases operated upon in this manner. The first two were unsuccessful, and colpokleisis had to be performed later on. The third case made an excellent recovery.

Baum (*Arch. Gynakologie*) reports a case of vesico-cervical fistula in which he operated first per varginam, the fistula only healing in part. He then determined to operate according to the Tendelenburg method. The operation was only partly successful, as he was compelled to operate per vaginam again, and even then a fistulous opening remained in the abdominal wound. He then discusses the method, laying special emphasis on the following points: The technique of the operation is a simple one. It is absolutely necessary for the pelvis to be elevated, for only in this way it is possible to obtain a clear view of the field of operation. This is also facilitated if the bladder is pushed up from the vaginal side. The peritoneum is not injured, as the position of the patient causes it to fall up toward the diaphragm. In the care operated upon it lay three to four finger's breadth above the symphysis pubis. The amount of hæmorrhage is slight. It is essential to tie the sutures on the vaginal side, this being done by using two needles, one on each end of the thread, and passing them downward and allowing an assistant to tie them. This is not always easy, but it would scarcely be safe to have the knots in the bladder, lest it might produce a tendency to the formation of stone. It is advisable to use silkworm gut or wire in preference to silk or catgut, as the latter absorb the urine and thus may cause decomposition. A disadvantage in the operation consists in the fact that after its performance it becomes necessary to change the patient's position from one side to the other many times during the first day. This is quite painful. The knees have to be kept drawn up to relax the recti muscles. The urine must not become alkaline after the operation. If it does it becomes necessary to give acids to overcome this tendency.

OBSTETRICS.

THE KYPHOTIC PELVIS.

Among rather primitive people, like those of Hungary, in whom pelvic deformities are not so common as they are, for instance, among the Italians and the Austrians, there is some excuse for ignorance of pelvimetry; for the general practitioner, especially in the country, may not in many years be called upon to estimate the size of a pelvic canal. As civilization becomes more complex, however, developmental anomalies are more frequently seen.

This country, in its astonishing growth and development, has ceased to be an agricultural community, in which the people are well fed and well formed. The urban population has grown at the expense of the rural, and vast numbers of people live and work in conditions incompatible with normal physical growth and well-being. One result of this change in our civilization is seen in the increasing number of deformed pelves among child-bearing women, until at present the proportion of contracted pelves, in the Eastern cities at least, is almost as large as it is in Germany or England. It has become essential, therefore, that even the general practitioner should know the possibilities and limitations of pelvimetry before assuming the responsibilities of the obstetrician. In those parts of the world where pelvimetry is best understood and most assiduously practised, it is recognized that the exact measurement of a given pelvis is often difficult, especially if there is lateral or oblique contraction. The antero-posterior diameter, fortunately, is easily estimated with a won-

derful degree of accuracy if one takes into account the height of the symphysis and its angle with the conjugate. It is this measurement which is most frequently required, for the flat pelvis of various kinds constitutes the overwhelming majority of deformities which complicate labor. A practitioner of much experience, however, will surely encounter at some time a kyphotic pelvis with lateral contraction, if not oblique deformity as well. In such a case it is necessary, before labor, to estimate the degree of resistance which the fœtus will encounter during its expulsion. This is not always easy. Any one with a slight knowledge of pelvimetry can take the distance between the tuberosities of the ischia and so learn the transverse diameter of the outlet, which is usually the seat of greatest contraction; but this measurement does not always tell the whole story.

If there is scoliosis as well as kyphosis, the diameters of the inlet may be diminished more than appears by external measurements, and to a greater extent than can easily be estimated by an internal examination. There is also a possibility of exaggerated compensatory lordosis in the lumbar vertebræ, which may be a more serious obstruction to labor than the pelvic deformity itself. We have seen a case, for example, in which this condition necessitated Cæsarean section. The fœtal spine was bent at a right angle, from the fact that the projecting spine of the mother was firmly wedged in the child's abdomen, between the thorax and pelvis. It should be remembered, on the other hand, that, as a rule, labor in a kyphotic pelvis, if the deformity is not excessive, is easier than one would expect from the appearance of the woman and the size of the pelvis.

At the worst it is usually a simple matter, without much danger to the mother, to do craniotomy at the inferior strait. The late Dr. Taylor, of New York, delivered successfully in this way a woman whose transverse diameter at the outlet was less than two inches. If, however, there is marked scoliosis with oblique deformity of the inlet—if the whole pelvic canal is much narrowed laterally; if the outlet is so contracted that a living child cannot pass—it would be better, in view of the improved prognosis of the operation, to do a Sänger-Cæsarean section, if the consent of the family and patient can be secured. Unfortunately, the indication in these cases is usually relative and not absolute, so that the physician is bound to offer the choice between craniotomy and Cæsarean section, and, alas for human nature, the husband and wife will almost always demand the former if the case is put to them truthfully.—*Univ. Med. Mag.*

PÆDIATRICS.

CHEMICAL STUDY OF THE ETIOLOGY OF SUMMER DIARRHŒA IN CHILDREN.

The investigations of Vargas (*Anales de Obst., Gin., y Ped.*) are in accord with those which have been made by Booker and Escherich. He deduces the following conclusions, which condense the most acceptable and modern doctrine upon this intricate problem of the etiology of gastro-intestinal disorders in children.

1. In the intestines of children who suffer with summer diarrhœa numerous microbes have been found. There are three species of them which are capable of producing chemical poisons, which, when injected into animals, cause gastro-intestinal disorders identical with those experienced by children with summer diarrhœa.

2. The greater number of these germs are probably saprophytic. A microbe which lives in the intestine does not necessarily obtain its nourishment from living tissue. The alimentary substances in the duodenum before being absorbed have no more vitality than the fluids in culture-tubes. The same is true of the juices secreted by the intestine. A microbe which lives in a culture-fluid and develops a poison will also grow in the intestine and develop the same poison if it is not destroyed by the secretions of the body.

3. The only digestive secretion which has been demonstrated to be endowed with a germicide action is the gastric juice. There is no doubt that the acid gastric juice has a germicide action upon many micro-organisms. The author has demonstrated that a two-tenths-per-cent. solution of hydrochloric acid will destroy Eberth's bacillus in half an hour, and two other bacilli obtained from drinking water which were believed to have caused certain cases of typhoid fever. The principal reason why a child nourished at the breast stands a better chance of living than one who is fed from a bottle is that the first receives nourishment which is quite free from germs. In order to acidulate cow's milk the addition of hydrochloric acid is necessary. The gastric juice is the physiological safe-guard against microbic infection of the intestines. If one may speculate upon this matter, it is deemed credible that some of the secretions which are poured into the

intestines have germicidal properties, or that the cells, having absorbed poisonous albuminates, neutralize their effect in some unknown way, or that the liver, when in a state of functional activity, prevents these toxic elements from entering the circulation until they have undergone some kind of transformation.

4. Every germ which is capable of producing and developing an absorbable poison in the intestine is pathogenic. In order to demonstrate the pathogenic character of a microbe it is not sufficient that it be capable of causing disease and death when injected under the skin and into the blood, for the blood is a medium which is entirely distinct from the intestinal secretion in its action upon microbes, and it has been positively demonstrated that the blood holds germicidal properties.

5. The three microbes which have been described by the author differ enough from each other to be regarded as distinct species, and produce distinct poisons. Each of them will cause vomiting and diarrhœa, and will produce a fatal result if used in sufficient quantity.—*Archives Pœdiatrics.*

HYGIENE.

LEPRA AT HANOI (TONQUIN).

Boinet (*Revue de Médecine, Medical Chronicle,* 1890) finds that the disease exists along the watercourses, and that mud is a probable carrier of infection to the naked feet of the poor, the earth being impregnated by the sputa, crusts, and discharges from the lepers. The soil of the cemetery of Hanoi was found to be highly charged with the bacilli, the mode of burial being extremely careless. Native physicians scarcely acknowledge heredity. In the eighty cases examined, absence of heredity was found in sixty-one. The chiefs of the villages, forty years resident, deny having seen any case directly transmitted; nor are they themselves afflicted. Healthy young girls marry lepers and fail to contract the disease. A case is given in which grandfather and grandmother are lepers, while the father and five children, who have constantly lived in the community, have escaped. The eighty cases establish the *possibility* of direct contagion in fifty-one. Children of lepers removed soon after birth to an unaffected district remain free from the disease, while their brothers and sisters living in the leper community contract it. Such children, returning in adult life to the community from which they sprang presently develop symptoms. The theory of the infection by means of the mosquito is regarded as being by no means impossible. The bacillus can find entrance into the mosquito, and has been found in human blood.—*Amer. Jour. Med. Sci.*

THE ADULTERATION OF ALCOHOLIC BEVERAGES.

The Third Biennial Report of the Dairy Commissioners of Minnesota contains the following remarks, which are of importance to physicians: That there are extensive adulterations and sophistications of wines practised in the United States, no one will question. It must not be assumed, however, that all wines upon the American market are necessarily of this character, since there is not a particle of evidence to support such a claim. There are sections of this country that produce wines of excellent quality, and there is no evidence on record to show that these native wines are adulterated or sophisticated during their manufacture or before their sale. Chemical analysis of samples of California wines show them to agree closely to the accepted standards, and give no evidence of being other than pure and of good quality.

In the examination of beers, it was found that the principal sophistication consisted in the use of cheaper substitute for malt, either in the form of other grain: unmalted barley mixed with the malt, rice flour or glucose. The principal effect of these is the production of a beer which is poorer in albuminoids and phosphates, and is, consequently, less nutritious than it should be.

As substitutes for hop bitters, the report mentions picrotoxin and picric acid, but regards their use as rare.

Of preservatives, salicylic acid seemed to be the most popular, as nearly one-fourth of the samples examined contained it. No case of direct adulteration was discovered, all variations from the normal article being some fault of curing or clearing, and the above-mentioned substitutes in the manufacture.

The report deals harshly with foreign brandy. Most of the brandy imported to this country from France is of inferior quality, frequently by reason of absolute sophistication. The term "brandy" seems to be no longer applied to a spirit produced by fermentation of grapes, but to a complex mixture of alcohol derived from grain,

potato or beet-root refuse. Potato and beet-root spirit is shipped into France from Germany and the United States. These are the most objectionable of all spirits, and hence brandy made from them is objectionable. They are flavored and colored, branded and labeled, and shipped to America in large quantities. Physicians frequently order brandy, while when they do so they can confidently expect that one of these mixtures will be supplied to the patient.

The report calls attention to the fact, further, that not one of the samples examined by the Dairy Commissioners of New Jersey in 1888 came up to the pharmacopœial standard. Most of the native brandies are genuine, although they have not been aged enough to make them bland and palatable, and many of them contain fusel oil.

The most of the samples of whiskey examined were deficient in alcoholic strength, and contained too much solid matter in the form of burnt sugar, glycerine, etc. Two out of fifteen samples examined were not whiskey, but artificial mixtures. Those that were genuine were not properly mellowed by age, and were, therefore, harsh, irritating, and consequently disturb the digestion of drinkers, and make them unfit for medicinal use.

MEDICAL CHEMISTRY.

PERMANGANATE OF POTASSIUM AS A URINARY TEST.

At the meeting of the Hunterian Society, held February 25, 1891, Mr. F. R. Humphries read a paper on the reduction of permanganate of potassium by the urine, in which he stated (*British Medical Journal*, March 14, 1891) that, after testing the known organic and inorganic constituents normally present, he came to the conclusion that a phenol was the only one which could produce this effect. The phenol might be present in such form as to admit of ready oxidation. Baumann had proved that phenol, besides being made in the intestine, was also formed during the decomposition of albumen. The reducing body corresponded in its diurnal variations with urea and the uncombined sulphates; it was, therefore, certain that it was, like them, a product of the metabolism of the tissues. If the reducing body was a phenol compound, it ought, when retained, to produce cerebral and nerve effects. It was remarkable that the forms, degrees, and symptoms of carbolic acid poisoning bore the very closest resemblance to those of uræmia, and that several of the most useful drugs in the latter condition were antidotes in the former. It was found that when the excretion of the reducing body was much diminished or increased, symptoms of uræmia were generally present. One cubic centimetre of a five per cent. solution of permanganate was diluted with 4 or 5 parts of water in a test-tube, and the urine rapidly run in from a pipette marked in cubic centimetres. The normal amount of the reducing body excreted in the twenty-four hours was found to be from seventeen to thirty-four grains, reckoned as permanganate, being highest in the first urine of the morning, in that passed four or five hours after a meal, and in fine warm weather. It was much increased in all febrile cases, except when marked cerebral symptoms were present; much diminished during a sick headache, but increased rapidly as it passed off. The author claimed to have discovered the presence of a powerful reducing body in the urine, whose daily history showed it to be a product of the metabolism of the tissues, whose reactions corresponded to a certain extent with those of a phenol, and whose suppression or excess corresponded closely with febrile cerebral symptoms, and with those of uræmia.

Dr. W. Hunter said the views of Proust and Thudichum on urine pigments were foremost down to 1870; since then Jaffé had opened a new era. The coloring-matter was no longer looked on as an independent body, but as a variety of pigments whose genetic relation to those of the bile and blood was established. Bilirubin was, without doubt, of the same nature as hæmatoidin; the relation was illustrated in old blood extravasations where blood was found in the centre; then an area of hæmatoidin crystals, and outside the green color of biliverdin. The modifications of urobilin found in urine (MacMunn) were almost precisely the same as those found in the bile. Urinary pigments were extremely unstable, and readily passed from one body to another when exposed to the air to a few drops of acid. He viewed, then, with suspicion the results of such heroic methods as the use of phosphomolybdic acid, and relied more on the spectroscope and simple extraction with ether, etc. These methods led to the belief that all the pigment was derived from the blood, and was hence an index of the changes in the body.

Dr. Lewis Jones had found a red body in febrile urine, giving a band at F, the junc-

tion of green and blue; this was urobilin, the uropittin, he supposed, of Dr. Thudichum. The color of normal urine was due to a yellow body, which gave no characteristic spectrum, and was unknown.—*Ther. Gaz.*

NEWS AND MISCELLANY.

DOCTOR AND PREACHER.

Parson and doctor joined in one
Most suitably we find;
The one the suffering body treats,
The other soothes the mind.
The parson shows the way to heaven;
And then, with tender care,
The doctor consummates the work,
And gets the patient there.

—*Medical Age.*

MEDICAL DIPLOMAS CONFERRED AND REFUSED IN 1889–1890 IN FRANCE AND GERMANY.

In the German Empire (45,000,000 inhabitants) the German Universities conferred in 1889 and 1890, 1,125 diplomas of doctors of medicine, distributed as follows: Berlin, 163; Bonn, 110; Breslau, 42; Erlangen, 69; Frebourg, 44; Giessen, 12; Goettingen, 25; Griefswald, 80; Halle, 36; Heidelburg, 22; Jena, 42; Kiel, 48; Kœnigsburg, 26; Leipsig, 2; Marburg, 23; Munich, 114; Rostock 6; Strassburg, 63; Tubingen, 22; Wurtzburg, 166. The number of doctors rejected in 1888–89 was 1,030; in 1887–8, 935; in 1886–87, 847; in 1885–86, 685.

In France (38,000,000 inhabitants not reckoning the colonies) the number of doctors rejected in 1889–90 by the six French faculties was 597, a decrease of 28 on the year preceding. Bordeaux rejected 60; Lille, 16; Lyons, 63; Montpellier, 46; Nancy, 26; Paris, 386.

FROM THE DIARY OF A NURSLING.

A Dr. Guster gave a German newspaper the brief but pathetic journal of a baby who. after thirteen days in this world, departed, leaving these reflections for our instruction:

First Day—Wonderful, heavenly! At last I am in this beautiful world! who would have thought it, that one could breathe, freely breathe, and cry out what one thinks? I rejoice particularly in the sunlight and blue sky, in the fresh, pure air with its cool ness. If I could only see and feel all this splendor!

Second Day—O, this horrible heat! I have been deceived. This air, this water, this light; how entirely different have I imagined it would be. But patience, all will come right by and by. The old woman who cares for me does not seem to understand me.

Fifth Day—Still no solution! If it goes on this way I cannot hold out long. The whole livelong day must I lie buried in feather cushions so that I can scarcely gasp down a bit of air. Two linen and one flannel binders, a little shirt, a flannel slip, a long cushion filled with feathers in which I am wrapped from head to foot, over this a coverlet filled with feathers, the curtains of my crib drawn to, the room darkened with double curtains, the windows closed, so must I, poor worm lie from morning till evening. My burning skin is worse off than the hot stove near me, which can at least, as I feel, give off its heat. O, that I did know what I shall do! If I cry it brings the old woman with her milk, which increases my misery; if my hands are cold while my brain and skin are burning she brings a few more wraps. I turn my half closed eyes from side to side seeking help, and my tormentor says "the baby shivers," and really heats the horrible things at the stove. Will no one come to my relief?

Tenth Day.—Again a fearful night! I cry but I am not understood. I must drink, drink, and again drink, until the stomach overflows. A half hour later they give me something with a horrible taste from a teaspoon. Air, air, pure, cool air, light, water! Shall I then have no help from this world?

Twelfth Day.—Yesterday there was a great council of my aunts and cousins. Each one advised a different remedy for my sickness, but all agreed that its cause is a cold. Warmth was urgently recommended, and I received a new kind of infant food just discovered, and some strengthening wine which heated my brain yet a little more, so that I was deathly still. My body is wrapped so tightly with the roller that my stomach overflows every time a teaspoonful of anything is given. My feet are forcibly extended and enveloped, so I cannot bring them up to relieve the pain, but my feeling is gradually going. Would that all were soon over.

Thirteenth Day.—Farewell thou beautiful world! Thy light and thine air have been denied me, but thither, where I go, there are no fetters.—*Schweiz Blätter für Gesundheit spflege.—Sanitary Inspector.*

No. 1808. PHILADELPHIA, OCTOBER 24, 1891. Vol. LXV.—No. 17.

Clinical Lecture.

THE NATURE AND TREATMENT OF ORGANIC STRICTURE OF THE URETHRA IN THE MALE.*

BY JOHN H. BRINTON, M. D.,

PROFESSOR OF THE PRACTICE OF SURGERY AND OF CLINICAL SURGERY, AT THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

Continuing my remarks from the first lecture, let us suppose that you have been called to treat a stricture near the bulbo-membranous urethra, the result of an old gonorrhœa, in a man who is still able to be about. His symptoms have in time, become troublesome, and he wishes to be cured. You have already, by examination on a previous day, demonstrated the existence and locality of a tight stricture. The patient has had a full night's rest, has remained in bed the morning of operation, his bowels have been fully moved by a laxative and injection, and he has taken five or six grains of quinine and half an ounce of whiskey, an hour before your arrival.

In very many cases I operate without anæsthesia, using instead, ordinarily, an injection of half a drachm of a two per cent. solution of cocaine, thrown into the urethra fifteen minutes before I begin. If the stricture be irritable, or the patient nervous, I employ a stronger solution, or, preferably, etherize the patient.

We will suppose an operation without ether. Let the patient be placed on a narrow table—a bed is too low and inconvenient—and let each leg be wrapped separately in a blanket, let the shoulders be slightly elevated, and let him be directed to keep his mouth open during the manipulation, so as to prevent abdominal straining and tension.

If you are not using ether, watch your patient's face and encourage and quiet him. By all means, be gentle with him, and try thus to win his confidence. Above all things, have confidence in yourself; work with the idea that you will pass that stricture, if not to-day, yet in a day or two—sooner or later—and that your success is only a question of time; believing this, your success will be certain.

To begin, with a small syringe, throw into the urethra half a fluid drachm of carbolized olive oil, then, with one hand grasping the penis behind the head, pass a filiform along the inferior floor of the urethra until it is arrested, as it most probably will be at the point of stricture. Then rotate it slightly, and if the point advances, well and good; if not, stop with this whalebone, and do not push it. Take another and repeat the process; if this fails, another, and so on until five or six are *in situ*. Then take each one in turn, and rotate it slightly between thumb and finger; use no force, but let every motion be gentle, the more so the better the chance of immediate success. Remember that there must be an opening through the stricture—it may be small and out of the centre, but tact will surely find it; force or impatience, never.

Perhaps you may not at first succeed with your filiforms. If so, desist for a moment, leaving them in place; then begin again, essaying each one in turn, and the chances are that, at last, one will find the opening, traverse the stricture, and enter the bladder. When it does pass the stricture you will be surprised to find how easily it travels, and you will then recognize that the hindrance was not the tightness of the stricture or its tortuosity or crookedness, but simply a difficulty in finding and entering its mouth or opening. This once accomplished, its passage is the affair of a second.

Occasionally it happens, even after fair efforts, that the stricture opening is not de-

*Second Lecture.—The first Lecture was published in the preceding number of the Reporter.

tected. I then withdraw two or three filiforms from the urethra, and reinsert them, working from the *opposite side* of the patient. Sometimes I take all out, and begin anew from the changed side, and often, very often, I have found that a whalebone carried down under these new conditions will pass without check into the bladder. The explanation of this probably is, that the hand instinctively works towards itself, and so directs the filiforms. Thus it happens that if the stricture opening be excentric, or towards the opposite side of the urethra, the filiform end may travel away from rather than towards the opening sought. Should you fail in your first attempt, it may be necessary to have more than one sitting (to use an artist's expression), and it is better to repeat than to prolong the effort. As to their duration and continuance, you must use your judgment and common sense. If the patient becomes tired or irritated, and especially if there is steady slight bleeding, I advise you to stop for a time. You are probably doing mischief with the whalebone points, using, perhaps unconsciously, a harmful force. The clots of blood, too, form sticky masses, which mask the passage.

By these manipulations—carefully, gently, patiently repeated—you will, I am sure, in the course of one or two trials, pass the stricture, and the first and often the hardest part of the operation is accomplished. The rest is a matter of adroitness and good judgment, and, in the exercise of the latter, it is often well, when the stricture is very tight, to defer the dilatation twenty-four or forty-eight hours, in the mean-while *leaving the whalebone* in the urethra. It can easily be retained, by tying it to the pubic hair. In allowing it to remain in the urethra, it is well, however, to withdraw the extremity from the bladder, so as to avoid irritating the sensitive vesical neck. The filiform thus left produces a degree of continuous dilatation of the stricture and facilitates the more ready introduction of the metallic dilators. For distension of the stricture, I advise the consecutive use first of Sir Henry Thompson's dilator, and next that of the late Professor S. W. Gross. The circumference of the point of the former is seven, and of its thickest part eleven millimeters. By screwing apart its blades, the urethra can readily be dilated to twenty-one or twenty-two, a calibre large enough to permit the introduction of the powerful Gross dilator. This latter instrument with a point of 14, and a shank of 17 or 18, is very efficient, and if properly used, safe.

To return to our procedure; we will suppose that the filiform has passed the stricture, and that its point is in the bladder. It is the guide for the Thompson dilator, and you may think that the latter can readily be pushed over the former, and through the stricture. This is only in part true, and it is just here that mistakes are often made, which have resulted in the failure of the surgeon, and have brought the whole procedure into disfavor. To avoid accidents, proceed in this way: Thread the filiform end through the tunnel of Thompson's dilator, and carefully carry the point of the latter down to the stricture, not by forcibly thrusting the dilator, but rather by drawing upon the whalebone, and gently sliding the metallic instrument downwards and onwards. When the stricture is reached, which will be at once recognized by its resistance, cease absolutely to push or slide the dilator, on the filiform through the stricture. If you persist in the previous sliding motion, you will run the risk of cutting the whalebone, with the perforated end of the instrumen, especially if the opening of the stricture be excentric, and the whalebone be consequently bent at an angle. To avoid this not infrequent accident, when the end of the dilator has reached the stricture, desist entirely from attempting to push or slide it along the whalebone, but slightly withdrawing the latter, grasp both it and the dilator, so that their lengths shall be closely applied, and move them forward by the same motion of the hand. You will find that guided by the lower extremity of the filiform, the dilator will readily advance and as its handle is lowered, its beak will enter the bladder. The presence of the instrument in the bladder will be made manifest by its freedom of motion, and the escape of urine by its side and through its channel, if the stylet be withdrawn. Now slowly turn the screw of the dilator, and separate the blades, alternately increasing and lessening the screw power, until a dilatation equal to 23 or 24 of the French scale is reached. Then lessening the tension three or four millimetres, slowly withdraw the blades and the whalebone from the urethra and meatus. There will generally be some bleeding, slight, and of no importance.

The Thompson instrument having been removed, next introduce the Gross dilator, which will readily pass through the now dilated urethra, and as before, separate the blades and over-distend the stricture. I generally push this dilatation up to 30 or 35, according to the resistance of the stricture, and the thickness of the penis. The greater

the diameter of the latter, as shown by Otis, the larger is the normal urethra; thus a penis three-and-a-half inches in circumference possesses usually a urethra 28 to 30 calibre. In withdrawing the instrument, reverse the screw and bring the blades to a calibre of 26 or 30, and avoid enlarging the meatus unless it has been morbidly contracted. It is well, then, to pass a series of Thompson's sounds, 26 to 30, in order to be certain that the stricture is well dilated, and that easy instrumentation is feasible. Then draw off the urine and tie a soft catheter of 24 or 25 calibre in the urethra to prevent the contact of the urine with the urethral walls. After the operation, the patient should be well wrapped up, and a hypodermic of one-sixth of a grain of morphia given, to be repeated if necessary. Severe symptoms rarely follow, if the after insertion of the soft catheter be made to prevent urethral fever and the septic effect of urine contact. On the third or fourth day, I remove the soft catheter and pass 26, 27 or 28 Thompson's sound, which is generally painless if gently done. The use of the sound is continued every other day, and by the expiration of eight or ten days, the patient is usually dismissed from treatment, having been first instructed and practised in the use of the sound, and furnished with 25, 26 and 27 for self-introduction.

The diet of the patient in the early days after operation should be from one-and-a-half to three quarts of milk, with a free use of lemonade for the thirst. This contraction seems incongruous, but it is satisfactory, sufficient and grateful to the patient.

Such, gentlemen, would be the treatment I prefer for a deep seated, tight, organic, idiopathic urethral stricture, when the circumstances of the case admit the time required for the procedure.

Again, urethral stricture, as you know, often gives rise to retention of urine, more or less prolonged, a condition demanding immediate relief. It is not then a question of dilating or curing the stricture at that time, but rather of passing a catheter into the bladder, drawing off the urine and thus relieving the man from torture. To do this, etherize your patient, pass the whalebone, as above directed, and over this carry into the bladder a small-sized tunneled silver catheter, such as were devised some years ago, by Professor Gouley, of New York. Of late I have somewhat varied this process, and use a whalebone filiform twenty-six inches in length. Over this I pass an ordinary flexible gum catheter, perforated at the point, which can easily be threaded on the whalebone, and passed into the bladder. If it should happen, that the stricture binds so tightly as to prevent its immediate passage, I am content to leave the filiform in position, the point of which has entered the bladder. Experience has repeatedly shown me that the urine will pass along it by capillary attraction, and that in a few hours the bladder will be entirely relieved. By its presence also, continuous dilatation is established, and in twenty-four, or forty-eight hours it becomes loose, however tight was the stricture when first introduced, and thus, the immediate symptoms of irritation and retention having passed, dilating processes may safely be resorted to.

In all cases of urethral instrumentation, even in so simple a matter as passing a sound or catheter in my office, I observe certain precautions: *first*, I always place the patient in the recumbent posture, to prevent faintness, or should that happen, to prevent him from falling and injuring himself; *secondly*, to prevent shock and irritation, I give him at the time a teaspoonful of paregoric; *thirdly*, to allay the burning sensation in the urethra, and to ward off vesical irritation, consequent upon the presence of a foreign body, for an instrument is a foreign body, I direct a cold douche to the head of the penis to be thus applied; let the patient guard his clothes with a napkin, and then retracting the prepuce, play a small stream of water, less than the thickness of a quill on the glans penis behind the corona, especially on its under surface. The effect of this on the terminal branches of the pudic nerves is magical. Urethral soreness, and vesical irritation disappear on the instant, and the patient departs in a condition of physical comfort, and mental satisfaction. Over the water basin in my office, I have a small faucet, and flexible pipe for this purpose, but a fountain syringe or a funnel affixed to the wall, with a small rubber pipe and a quill or catheter nozzle will answer equally as well.

Comparative dangers of urethral operations. No manipulation with the urethra, is entirely free from danger. I have known the insertion of a flexible acorn bougie No. 11 F. though painless at the time, to be followed in an hour by terrible shock, and eventually by an obstinate *epidydimitis*. Many years ago in a middle aged man, I divided at his clamorous request, a stricture of the meatus, which obstructed urination, and had months previously, been cut with

impunity. Sudden collapse, and death took place in seven or eight hours, possibly after urination. The most searching post-mortem examination failed to detect any cause of death. Incision of stricture of the anterior urethra is ordinarily harmless, and yet I have seen violent hæmorrhage follow, and death from septic poisoning. Gradual dilatation of soft and tractable strictures of the same part is usually well borne, but if the stricture be tight, it may prove tedious, and if resilient the result is apt to be temporary and ineffectual. Excessive irritability frequently forbids further dilating and repeated operation and demands incision of the stricture; and when this is done, it often happens that the previous irritability passes away.

As we have seen, the most frequent seat of annoying stricture, is at the bulbo-membranous region; how shall they be dealt with? shall they be cut by internal urethrotomy, or can they be dilated or over distended? I have endeavored to show you, and at all events have expressed my earnest conviction, that all deep non-traumatic strictures are permeable, that they can be traversed by a filiform, and by its guidance, they can be fully dilated and so kept, and that their method is applicable to every stricture, however firm its structure, however small and devious its calibre may be. In many years of private practice, and of public clinical demonstration, I have never met with a failure, nor with a death. Difficult cases I have had, and cases demanding great patience, but all ultimately yielded to the procedure I have described, a result which in great part I attribute to the blessed influences of antiseptic precautions. Under these circumstances I therefore contend that the processes we have studied together are as approximately safe as any urethral manipulations can be.

Now how is it with internal urethrotomy? Many, indeed almost all of the latest workers in genito-urinary diseases, admit a mortality for internal urethrotomy of certainly one or two per cent., and some as high as five per cent., a death rate which I think must be over estimated. But in any event, it appears that internal urethrotomy is a much more dangerous operation than it was at first considered, and this mortality rate is becoming greater as the voices of operators are being heard. As a consequence, there is a growing disposition, even among its ardent partisans to restrict and limit the applicability of the operation. I have myself seen death follow the blades of skilful and renowned urethrotomists, one of whom, and I have it from his own lips, was disposed to greatly limit if not entirely renounce the operation, of which he had been a most ardent advocate, on the very eve of his being sadly taken from us.

One fact in regard to this operation must always be borne in mind, and that is, that internal urethrotomy from behind forward, the most popular and safest form of division, demands a previous dilatation of the stricture, equal to the diameter of the cutting instrument.

It has been asserted and truly, that full dilatation cuts or lacerates a urethral induration, in nearly the same manner as internal urethrotomy, and that this is demonstrated by the endoscope. True, but with this important difference. If the dilatation be gently and slowly done, the stricturing tissues give way first and the traumatism is limited to the bands at fault. With the cutting blade, on the contrary the incision is not self limited; the tissues, diseased and healthy alike, are apt to be largely divided, the bleeding is often considerable, and as the admitted evil consequences show, septic poisoning follows in an appreciable percentage of cases.

Of the operation of *divulsion* introduced some years since by Mr. Holt I need say little. Here are the instruments. By sliding this tube over a central rod, two blades were forcibly separated, and the stricture, instantaneously burst. It was a rude process, mechanically successful, but often, very often followed by disastrous shock, and death. I remember, at one society meeting, the exhibition, in which I took my share, of seven or eight specimens of ruptured urethra, since which time I have refrained from the operation. I believe that it is deservedly a thing of the past.

I have not in these remarks referred to external urethrotomy or perineal section. You have seen me perform it in deep seated traumatic stricture, and in old iodiopathic strictures, attended with fistulæ, burrowing sinuses, and loss of perineal substance. Under these circumstances the external section, has been demanded by the attending complications rather than by the tightness of the stricture. But, of these I shall speak hereafter.

In advocating the dilatation of stricture, I am aware that it is often said that the process is incomplete, and not abreast with the latest procedures. Yet I maintain that with suitable care, this operation when properly performed, will accomplish as great, if not greater results, than the methods of internal

division. The secret of the procedure, is the intelligent use of rightly constructed fine capillary whalebones, which possess qualities not to be found in the gum or soft instruments, however minute. The dilating or distending process, is, I am convinced far more safe than the cutting operation, the death rate of which is steadily augmenting.

I have thus expressed to you my preferences in the treatment of stricture. At the same time I must add that within reasonable limits, every surgeon ought to practice those methods, in which he individually is most skilled, and which therefore presumably offer the best chances to his patient. The Japanese carpenter planes backwards, the American forwards; neither can adopt the method of the other, yet the handicraft of both is good.

The general rules which govern me in the treatment of organic stricture of the urethra, may be thus formularized:

First—Strictures of the meatus, and its immediate neighborhood, should be incised.

Second—Strictures of the pendulous urethra, not markedly annular, not resilient, and not irritable, may be gradually dilated by solid bougies. If annular, resilient, and irritable they should be treated by internal urethrotomy.

Third—Idiopathic strictures of large calibre, at or near the bulbo-membranous junction, should if possible be treated by gradual dilatation.

Fourth—At the same locality, tight strictures of small calibre, will still be found permeable to filiforms, and can be treated by whalebones, and dilators with greater safety than by internal urethrotomy.

Fifth—In traumatic strictures, wherever situated, those which follow violence or surgical cutting, internal or external, the continuity of the urethra is disturbed, and the apertures of its channel often do not correspond. These constitute the true impermeable stricture, and may require external urethrotomy, and perineal section.

Benzin for Boils.—Dr. F. W. Langdon uses benzin as an abortive agent in furunculosis, employing it in the following manner (*Lancet-Clinic*): At the first appearance of the little hard, painful papule, saturate a pledget of absorbent cotton with the remedy, and press it firmly, but not forcibly, over the swelling for about half a minute. Repeat this every hour or two for the first day; after that, two or three times a day, as the swelling and pain subside.

Communications.

COCAINE POISONING.*

BY J. B. MATTISON, M. D.,

MEDICAL DIRECTOR, BROOKLYN HOME FOR HABITUES—MEMBER AMERICAN MEDICAL ASSOCIATION—AMERICAN ASSOCIATION FOR THE CURE OF INEBRIETY, N. Y. ACADEMY OF MEDICINE, MEDICO-LEGAL SOCIETY, N. Y. NEUROLOGICAL SOCIETY, MEDICAL SOCIETY OF THE COUNTY OF KINGS.

At a meeting of the New York Neurological Society, November 5, 1886, Dr. Wm. A. Hammond, speaking of cocaine said, "He did not believe any dose that could be taken was dangerous."

In a paper by the writer, read before the Kings County Medical Society, February 13, 1887, on "Cocaine Dosage and Cocaine Addiction"—published in the *Lancet*, London, May 23, 1887—four deaths from single or repeated doses, and 46 less toxic cases were cited; and in a second paper, on "Cocaine Toxæmia", read before the American Association for the Cure of Inebriety, November 8, 1887—published in *La Tribune Medicale*, Paris, January 1, 1888—3 more deaths and 73 less lethal cases were noted—more than 125 in all—making the most extensive resumé, to that date, and impelling an editorial assertion from the *British Medical Journal*, that "if it were needful to produce more proof of the unsoundness of Dr. Hammond's statement, Dr. Mattison has effectually done this."

In discussing a paper on "Cocainism", read by myself before the D. C. Medical Society in Washington, December 24, 1890, Dr. Hammond confessed that he was *wrong* in his original statement, and said *he* had noted nearly fatal results from cocaine.

This paper will add proof upon proof as to its poisonous power, by citing more fatal, several nearly so, and many less toxic cases; it will place a proper estimate on the lethal strength of this—in some respects—peerless drug; and it will make pertinent the preamble and resolutions presented this Society.

In an extensive brochure, brought out last year, by Dumont of Berne, reference is made to the more than six score cases cited in my papers, and others are noted.

*Read before the N. Y. Medico-Legal Society, March 11, 1891.

We shall first detail the fatal cases instanced from June 1888, to March 1891, and then those less toxic.

Simes—Male, age 29, one drachm of a 20 per cent. solution injected in urethra, prior to urethrotomy. Instrument was scarcely removed, when patient made a foolish remark, facial muscles twitched, eyes staring, frothed at mouth, and face was congested, breathing embarrassed and a violent epileptiform convulsion, lasting several seconds, ensued. This, increasingly severe, continued several times a minute; the whole muscular system was involved, requiring force to keep him on table. Lung action first failed, then the heart irregular and slow, breathing more and more disturbed, face and entire body deeply congested, and twenty minutes from the first convulsion, patient was dead.

Abadie—Three-quarters of a syringe full of a 5 per cent. solution, was injected prior to operation on eye-lid. In ten minutes patient became unconscious, face cyanosed, and respiration ceased. After great effort with hypodermic ether injections, and artificial breathing, there was partial resuscitation, but patient died.

Zambianchi—Female, 4 grains, 225 millegram. injected near mammary cancer, as local anæsthetic; immediately epileptiform convulsions ensued, lasting fifteen minutes; transient rally under artificial respiration, then renewed convulsions, and in 5 minutes, death.

Montalti—Female, phthisical, one lung; 22 grains taken per mouth, by mistake. In 15 minutes, mental wandering, general coldness, increasing delirium, lips cyanotic, pallid and pulseless; became unconscious and "in short time" died.

University College Hospital, London—Male, 20 grains, in solution, intended for bladder injection, swallowed through mistake. Patient's condition not noted for nearly an hour; then found with opisthotonos and limb spasms. Soon after, died.

J. fur Z.—Female, 29 years, healthy, but very nervous, three injections, one-third gr. each, in gum, prior to teeth extraction. Operator withdrew from patient's chair to get water for rinsing mouth, and on return, found her motionless. Artificial respiration employed, but woman died.

Stewart—Male, 32 years, one and one-half drachms of four per cent. solution, injected prior to dilating urethra. Almost at once patient said, "I feel sick", pupils widely dilated, pulse weak and quick, became rigid and unconscious. After one minute partial recovery, but two minutes later fell back on table, rigid, unconscious and began to have violent general convulsions, almost throwing him to floor. Spasms were clonic, commencing in face and extending over whole body; deep cyanosis, quick, weak heart, and partial suspension of breathing; convulsions lasted three minutes, then gradual return to consciousness and able to leave in an hour.

Chetwood—Male, 25 years, one drachm, four per cent. solution injected, before cutting stricture. In three minutes patient nervous and excited, wildly violent, needing several men to restrain him; fought and shouted like a madman; had tetanic spasms, arm, leg and thorax muscles rigid and drawn; stiff-legged walk, would have tumbled without aid; under whiskey and hypodermic morphia, became quiet.

Finlay—Female, six teeth extracted, prior to each, one grain injected in gum. It caused extreme general pallor, coldness and insensibility; pulse 38, weak and intermittent; "heart almost exhausted"; respiration fell to 5 per minute, shallow, irregular and extremely dyspnœac; arm spasms; great pains in back of head and heart. Despite free stimulation, breathing almost ceased, then artificial respiration and external stimulating for forty-five minutes; heart and lung action improved, but spasms continued. Relapse; pulseless and seemingly dead; renewed forced breathing, and hypodermic injection, ether 30 min. in arm; treatment continued three hours; gradual recovery. Patient was five months pregnant; no untoward effect on child.

Golookoff—Female, 15 min. 2 per cent. solution injected. In five minutes, patient restless, pallid, shivering, quick pulse, "respiration soon ran up to 200 per minute" (?), and was labored; heart sounds heard two paces from patient; limb spasms, and great pain in heart and back.

Monat.—Male, 29. 7 min. of a 20 per cent. solution for local anæsthesia. In 3 minutes patient faint, gasping, cold, rigid extremities, face blue and pinched, pulse 120 and weak, speechless, and had repeated clonic spasms.

Booth.—Male. Ten grains injected in urethra, patient became excited and demented for 45 minutes.

Gooding.—Female. One-half grain injected in gum before tooth taking. Immediately wild staring look, very restless, quick gasping breath; in two minutes condition alarming, wildly delirious, tossing arms and legs, extremities cold to elbows and knees, breathing fast and irregular, pulse 120 and weak. Despite ether, ammonia, and brandy

by mouth and ether hypodermically, the collapse became profound, R. 60, P. 150, irregular and almost lost; rallies under continued stimulating, but after 3 hours was still delirious; mental disorder continued 7 hours and ended in sleep.

Neilson.—Male 29. 45 min. of 4 per cent. solution in prepuce as anæsthetic; patient became restless and excited, incoherent talk, pale, profuse sweat, feet cramps, pinched, ashen face, pulse 44 and small, breathing shallow.

Neilson.—Male, 33. 50 min. of 5 per cent. solution injected in scrotum. In one minute eyes fixed, pallid, sweat bath, running pulse and violent vomiting.

Randall.—Male, 6. Pledget, 5 min. of 4 per cent. solution, ½ grain in nose, caused inability to walk, wild delirium, with hallucinations, tremors, unconsciousness. Subsultus and convulsive movements lasting several hours.

Roux.—Female. 2½ centigrammes injected caused opisthotonos.

Roux.—Female. 3½ centigrammes, toxic symptoms, pallor, and cardiac distress.

Roux.—Female. 5½ centigrammes injected in temporal region for headache caused violent tetanoid spasms.

Earle.—Male, 65. Three-quarters of a grain injected as local anæsthetic caused great depression and other toxic symptoms, so that, despite nitro-glycerine injections with amyl inhalations and whiskey, *ad. lib.*, it was nearly an hour before patient was safe.

Wissinger.—Ten min. 15 per cent solution injected, caused pallor, profuse sweating, small, wiry, 140 pulse, respiration 40, great dyspnœa, and spasms of arms and legs.

River.—Male. Six drops 4 per cent. solution in each eye caused nausea, faintness, clammy sweat, and pulse of 40.

Schadle.—Male, 35. Repeated application of 4 per cent. solution on cotton to nostrils caused peculiar feeling about genitalia; cold and sensation as of penis absent; this effect repeated several times; remarkable action on genitalia; "cold and relaxed;" "gone feeling," noted towards end of treatment; this increased to semen loss and impotence, which lasted till cocaine ended, when virile power gradually returned.

Settier.—Male. 25 grammes of 4 per cent. solution in bladder: patient had daily injected for 7 months; this time caused vertigo, nausea, vomiting, "rocky" gait, cold sweat, thready, 103 pulse, indistinct speech, voice thick and shaky. Two relapses, 1½ minutes each, but quite recovered in eight hours.

B. M. J.—One and one-quarter grains injected for sciatica; soon restless and excited; pulse and breathing rapid; choreic movements; symptoms lasted 4 days; even then, patient restless and giddy.

B. M. J.—Boy, 13. 1½ grains injected as local anæsthetic. In 5 minutes patient pale, restless, and dyspnœac; pulse almost uncountable; nausea and epigastric pain. Patient recovered in 4 hours.

Garcin.—One-half drachm of 3 per cent. solution by bowel, caused hurried breathing, quick, weak pulse, and cold extremities. Recovered under stimulants.

Myrtle.—Female, 45. 3 drops of 3 per cent. solution in each eye. Immediate numbness of tongue and throat, faintness, intense palpitation and irregular heart action, extreme nausea and great flatulent distension of stomach and bowels, lasting one hour. Not $\frac{1}{1\frac{1}{1}}$ grain in each eye.

Myrtle.—Eight minims, same solution as nasal injection, caused like, but less severe symptoms.

Stedman.—Twenty min. 5 per cent. solution—1 grain—as local anæsthetic in labial cancer. Soon became excited, pulse 160 and scarcely felt; respiration quick, short, irregular, panting; cold feet and clammy sweat; marked cyanosis. Recovered under hypodermic ether, 20 minims, every 7 minutes, 4 times. Symptoms ended in one and a half hours, except that pulse continued at 112.

Ficano.—Woman, 45. "Few drops" of a 5 per cent. solution in cavity of middle ear. Caused vertigo, nausea, vomiting and cramps, lasting several hours.

Brinton noted a case in which cocaine was injected after applying a tourniquet, but "as soon as it was loosened, the patient gave a gasp, face became livid, he struggled for breath, pulse was feeble and his condition quite alarming for some time."

Mitchell reported 5 cases. Both sexes, age from 20 to 50, in which a 4 to 10 per cent. solution used under skin, by spray and nasal pledget, caused vertigo, heart pain, dyspnœa, quick, weak pulse, syncope, general numbness and tremor, rigid limbs, and in one case complete paralysis, except tongue.

Hœnel.—Female, 19. One and one-half grs. injected in gum, two injections, prior to tooth extraction. Immediately after second injection patient became pallid and fell in convulsions. Nitrite of amyl, useless. Was cyanosed. Unconscious and in severe convulsions 5 hours. After convulsions unconsciousness continued 2 hours, pulse at first uncountable, then 176, resp. 44, axillary temperature 101; mouth, throat and nose

numb; suppression of urine 24 hours; sleepless 40 hours. Symptoms persisted 2 days.

Lobker observed five cases in which severe collapse followed the injection of small doses of a fresh 5 per cent. solution in gums prior to tooth drawing.

Judkin observed two cases with dangerous symptoms.

Buscarlet reported a case with toxic symptoms, after injecting in a hydrocele.

Witzel noted hallucinations of sight, hearing and taste after injection of one-half grain.

Meyer reported a child with headache and difficult speech from injection of two decigrammes.

Schilling.—Male. Age 20. Prior to lithotrity, one grain in bladder caused general rigidity and pulse of 180.

Ricci.—Male. Injected in thigh for sciatica, 22 grains by mistake. Caused restless excitement, facial spasms, choreic movements, quick action of heart and lungs, symptoms persistent 3 days. On 4th day symptoms recurred with increased intensity; patient unable to lie down on account of dyspnœa several nights; vertigo persisted for days.

Manley.—Male. 1½ oz. 4 per cent. solution, 4 grs. nearly, as anæsthetic before amputation; "He reeled over in a faint, became nearly pulseless, cold and deathly pale. After perhaps 20 minutes, reaction set in. * * * I felt earnestly thankful that a life was not lost through our experiment, for I was thoroughly frightened."

Wyeth has seen convulsive movements followed by opisthotonos. In another case decided convulsions after gradual injection of 30 min. of a 4 per cent solution in urethra.

Hallopeau noted a case in which an injection of 8 centi-grammes in the gum caused grave toxic symptoms.

Brush reported two cases of poisonous results.

Bissell.—Male. Age 29. 40 min. of a 6 per cent. solution injected before circumcision: "Serious constitutional symptoms;" nausea, vertigo, blindness and unable to walk for several hours.

Spivak.—Girl. Age 2 years. 1 gr. by suppository. One hour later child became restless, very excited, quick pulse and choreic movements.

Douthwaite.— Female. Accustomed to using injections to relieve sciatica. Took repeated doses, aggregating 16 grains; was found unconscious and in convulsions.

Slayter noted a case in which 15 min. of a 10 per cent. solution injected in toe, caused cyanosis and epileptiform convulsion.

Réclus and Wahl observed, in 4 cases, serious symptoms; pallor, nausea, cold sweats, quick pulse, dyspnœa, vertigo and syncope.

Johnston.—Female. Aged 20. After half gr. injection in toe for anæsthesia in ingrowing nail, patient was cyanotic, pulseless and collapsed.

Moizard.—Child. Aged 4. Given by mistake, four grains, caused extreme nervousness, severe chest cramps, muscular twitching, lasting 31 hours. Hallucinations and convulsions.

Wood cites a case in which 5 grains by mouth caused nausea, great sweating, incoherent speech, blindness, rapid intermittent pulse, cyanosis and suffocation.

Von Ploss.—Male. Would-be-suicide took 22 grains in beer, causing great belly pain, intense dyspnœa and vertigo, and urine suppression for 24 hours.

Cauldwell noted a case where 15 minutes after injection of 5 grains, there was unconsciousness and general convulsions.

In another case, headache, great vertigo, partial blindness, and temperature fell to 96.7.

Ingalls reported alarming symptoms from ½ grain applied to nasal membrane.

De Beck reported two cases, female. 4 per cent. solution to eye, caused clammy sweat, quick weak pulse, with gasping respiration, 6 per minute. Third case. 8 drops of a 5 per cent. solution caused such alarming symptoms, cataract operation had to be abandoned.

Chalmers Da Costa reported to me case of woman, age 22, in whose forehead he injected 10 min. of a 6 per cent. solution, causing shallow, rapid breathing, quick, weak pulse, great tremor, temperature 102, with delirium for several hours, and complete analgesia.

Here are more than 200 recorded cases. What of the unrecorded? Here is evidence too weighty to be rejected. Here is an oft-told lethal tale. What is the moral?

Before reaching conclusions, let us note the views of various observers touching the toxic power of cocaine, with such counsel as they have given to lessen the risk of untoward results that have robbed this peerless drug of much favor in the minds of many surgeons, and so deprived them of a most valued ally.

Réclus and Dumont lay large stress on three points—the quality of the drug, the quantity of the drug, and the site of injection. The former's brochure—brought out last year—is the most extensive yet presented on the action of cocaine as a local

surgical anæsthetic—his experience covering 700 operations. He thinks many ill results, near and remote, due to stale or spurious solutions. Dosage, too, is important; ½ to 2 grains he thinks the maximum, and that not less than 20 centigrammes would poison. In this last opinion he is wrong.

Réclus has a special method of dosing. He quadrangles the operative field, and plunges a long, fine needle in its entire length along each lateral outline. Then—and on this he much depends—as the piston is pushed down the needle is withdrawn, timing the combined movement so that when the needle tip emerges, the syringe is empty. This is done four times, quickly, and, by so doing, he thinks a large area is anæsthetized and the chance of a blood vessel injection brought to a minimum. He also thinks it of "priceless value" in weak heart and renal disorders.

Réclus is clearly an enthusiast on cocaine, and we think, although his experience has been such a happy one, it would be courting a large risk to place full reliance on his assertions. Judging by scores of well attested, he is wrong as to non-toxic effects from less than 12 to 20 centigrammes. His care as to slowness of injecting and gradual withdrawal is commendable.

Dujardin Beaumetz takes issue with him on one point—claiming it extra-hazardous in cardiac weakness; and, just here it may be well to recall a case noted by Knabe of Berlin—cited in my first paper—girl, aged eleven, who was given 4 to 12 drops of a 4 per cent. solution, by injection over the deltoid to remedy frequent fainting fits, she having cardiac debility sequeling scarlatina. In less than 40 seconds she took a deep breath, became deadly pale and dropped unconscious. One minute later she was dead.

As to its effect in renal disease, more than one writer has laid stress on the fact that as it is largely excreted by that organ, a crippled kidney would enhance the toxic risk.

As an opposite extreme to Réclus regarding dosage, Lauderer says, a maximum injection should be 12 to 15 millegrammes!

Dumont thinks a surgical subcutaneous injection should not exceed ⅓ to ⅚ of a grain. Litten, Wölfer, Decker, Hænel, Orloff and Szumann share in this opinion.

Wölfer says injections about the head are more dangerous than on body or limbs, and that more than ⅓ gr. should not be injected. Dumont thinks there is less danger from cocaine in eye, nose and throat diseases.

Koller advises weaker solutions on body than on limbs, and says that nothing stronger than a 5 per cent. solution should be used in the nose; the effects being the same as from a 20 per cent. solution, only more time is needed to secure it.

Wyeth advises against cocaine under 10 or 12 years; and it is worth noting that the smallest fatal dose recorded was in a girl of twelve.

Regarding a danger from impure cocaine I believe this feature as a toxic factor is small. It has a killing power, *per se*, and the purer the product, the more decided this may be. Let no one think the pure drug harmless.

Dumont, Wyeth and J. M. Barton specially advise the use of Esmarch's bandage whenever cocaine is injected in the limbs for local anæsthesia. Barton says that when the operation is ended he loosens the bandage and immediately tightens it. This is repeated several times, every few minutes. In this way a small quantity enters the circulation at a time, and a large amount can be disposed of without harm. He states that prior to using this plan he often found toxic symptoms when bandage was loosened after fifteen minutes, whereas before no ill effects at all were noted. Leonard Corning adopts a similar device.

Of the fatal cases, 4 were by hypodermic injection, 2 by urethra, one each by gums, larynx, stomach, bowels and bladder, 2 unknown.

In 9 cases death followed collapse; 3 convulsions; 1 unknown.

The largest fatal dose, not injected, was 23 grains, by bowel. The next highest, 22 grains, by mouth. The largest non-fatal dose, not injected, was 22 grains, by mouth. The largest non-fatal dose injected was 19 grains, in leg. The smallest fatal dose, hypodermically, was 8 drops of a 4 per cent. solution, in arm.

COCAINE HAS KILLED IN SMALLER DOSE THAN MORPHINE.

Autopsies were held in cases of Simes, Montalti, and University College Hospital. In each there was marked congestion of brain, lungs, liver, and kidneys. Montalti thinks the drug kills by causing vaso-motor paralysis and consequent congestion.

CONCLUSIONS.

1. Cocaine may be toxic.
2. This effect is not rare.

3. There is a lethal dose of cocaine.
4. The lethal dose is uncertain.
5. Dangerous or deadly results may follow doses usually deemed safe.
6. Toxic effects may be sequence of doses large or small, in patients young or old, the feeble or the strong.
7. The danger, near and remote, is greatest when given under the skin.
8. Cardiac or renal weakness increase this risk.
9. Purity of drug will not exempt from ill-result.
10. Caution is needful under all conditions.
11. Réclus' method, Corning's device, or Esmarch's bandage should be used when injecting.
12. Nitrate of amyl, hypodermic morphia, hypodermic ether, alcohol, ammonia, and caffeine should be at command.

Brooklyn Avenue, Brooklyn.

POLYURIA IN EARLY INFANCY. *

BY GEORGE W. RACHEL, M. D.,

INSTRUCTOR IN DISEASES OF CHILDREN AT THE NEW YORK POLYCLINIC, SUPERVISING PHYSICIAN OF ST. MARK'S HOSPITAL AND PHYSICIAN TO THE GERMAN POLIKLINIK.

Diabetes insipidus, or Polyuria during the first year of life, has, I think, not been observed before this—certain it is that I have not been able to find the record of a case while scanning the literature pretty carefully. It seems, therefore, quite appropriate to publish the few cases which I have had the opportunity to see. They are four in number, but in two only have I been able to see the patients through to recovery.

I—*Francis M.*, born November 22d, 1888, the first child of his mother, had been healthy during the first months of his life. He had been nursed until about two months old; but the secretion of milk gave out gradually, so that at last he had to be fed artificially entirely. His food consisted alternately of milk and barley-water, Soluble food and Nestle's and the child seemed to thrive well on this diet.

On April 18th, 1889, I was called to see him for an attack of purging and vomiting. I prescribed calomel and bismuth and ordered barley-water only to be given.

I was told the next day that the child seemed to feel better; towards evening of the 19th, he became very restless and this lasted till noon the following day (April 20th.) Slight convulsive twitchings were observed during the forenoon of that day and no urine was passed from 6 A. M. till 12.30 P. M. Some cough had set in and respiration had been growing very rapid. The mother had also noticed that the child looked somewhat puffed up in the face.

On examining the child that afternoon, I found some œdema of the face, hands and feet; his stomach was quite distended, partly tympanitic, partly dull on percussion; he had had no passage for about 18 hours. T. 101½° F., R. 35, P. 120, pretty weak.

On percussion there was some dulness below the left scapula, some rough breathing, almost bronchial in character and a little crepitation was heard on auscultation. On both sides posteriorly rough respiration and numerous râles were heard all over, especially over the lower portion of the chest; the heart did not show anything abnormal.

Taking all the symptoms in consideration I concluded that I had to deal with a congestion of the kidneys. The convulsive attack and the œdemata justified me in attributing the bronchial symptoms to the same cause: beginning uræmia. I ordered a laxative to be given and some urine to be collected and sent to me as soon as possible. It was not until noon of the following day (21st) that the mother succeeded in doing so; the child passed urine only four or five times from 6 A. M. on the 20th to 12 M. on the 21st. The first time at 12.30 P. M. on the 20th, as before stated.

To my great surprise the urine sent to me was as colorless as water; its specific gravity was between 1,000 and 1,001. Of course, it did not contain either albumen or sugar.

Dr. P. Guenster and Dr. J. H. Mennen were kind enough to examine the urine microscopically, the former at the laboratory of the "Post Graduate Medical School," the latter at Dr. Heitzmann's laboratory. Both gentlemen reported that they had found numerous micrococci, epidermal scales and mucous corpuscles, but no other abnormal elements.

Next morning's report was perfectly in accord with this unexpected result. The amount of urine passed by the child had increased considerably. He had to be changed very often and every time all his clothes and sheets were thoroughly soaked. The boy appeared to be unusually thirsty, too; while previously he had been a very

* Read before the Pædiatric Section of the New York Academy of Medicine on May 14, 1891.

good child, he now was very restless and wanted to drink constantly, although there was no fever.

As is well known, the treatment of diabetes insipidus or polyuria is a very unsatisfactory chapter of our therapeutics; a glance at the great number of drugs recommended for it is one of the best proofs of this fact. Külz† mentions more than thirty, of which I shall refer only to those best recommended. These are: belladonna, valerian, ergot, salicyl, phenol, arsenic, antipyrin, and nitric acid. One of the latest agents‡, recommended by Dr. Gaiffe, an assistant of Prof. Dujardin-Beaumetz, is phenacetine. This gentlemen has had encouraging results with it in two cases.

Both were patients having suffered for some length of time from nervous polyuria. Dr. Gaiffe succeeded in reducing the amount of urine passed daily from 6,500 grammes (216 ounces) to 4,225 grammes (140 ounces) in one case, and from 4,000 grammes (133 ounces) to 1,500 grammes (50 ounces) in the other. In the beginning he gave 0.5 grammes (8¼ grains) in 24 hours, a dose which he gradually increased to 2.8 grammes (℥ss). He observed in both cases a partial return of the polyuria as soon as he discontinued the phenacetine. (The latter observation I have not been able to corroborate.)

All the various drugs enumerated above having proved unreliable, I did not hesitate to follow Dr. Gaiffe's recommendation. I prescribed 0.25 grammes (4 grains) of phenacetine, to be given four times a day. I was agreeably surprised to hear that gradually the amount of urine passed by the little one diminished, the polydipsia became very much less marked, and the specific gravity of the urine increased in proportion. On April 26th, it was 1,005; on April 29th, 1,007; on May 1st, 1,008, and on May 4th, 1,012; I discontinued the phenacetine and the child appeared to be well. On May 19th the specific gravity of the child's urine was 1,015.

The boy had regained what he had lost in the meanwhile and looked well; his health remained good up to the end of June. Then he had a very severe attack of gastro-intestinal catarrh, from which he recovered only gradually. On July 20th, pneumonia on the right side supervened, which carried him off within four days. There never was anything abnormal observed in regard to his urine during his last illness. No autopsy.

† Gerhardt's *H. d. Kinderkr.* 3, Vol. I, pp. 285 to 298.

‡ *Bull. gen. de Therapeutique*, 1888, p. 71.

The second case came under my observation last summer while I was substituting for Prof. Dr. A. Seibert, in the New York Polyclinic.

II.—*Louise G.*, 10 months old, had an obstinate gastro-intestinal catarrh during June last; while this was slowly improving, numerous furuncles appeared about the head, trunk, and lower extremities. While these were breaking and healing, others formed on the arms, etc. This extensive furunculosis led me to suspect sugar in the urine, since I have been led to diagnosticate diabetes mellitus three times by examining the urine of adults, suffering from general furunculosis.

On questioning the child's mother, I obtained the information that the little patient wanted to drink almost continuously, that she passed water very frequently, and that every time she was "wet through and through." I gave her instructions how to collect some urine which she was to bring with her the next time.

On July 25th, I received the first sample and examined it before the class. The urine was almost colorless; instead of a yellowish, it had a slightly greenish hue, however. To my great surprise I found the specific gravity to be extremely low; its surface was just sufficiently below the mark to show that it was somewhat more than 1,000, but it did not reach the next line of division. It will be readily understood that it did not contain either sugar or albumen.

The child now received the phenacetine treatment for its polyuria, 0.25 grammes (4 grains), being given three times daily. On July 30th, the specific gravity of the urine had risen to 1,004, its color was of a light yellow, and the child had not wetted itself as frequently. Under continued treatment the specific gravity gradually rose and the urine assumed its natural color.

The formation of furuncles also ceased and by the middle of August only two of them remained, one over the right temple and the other on the left arm, about the wrist. The specific gravity when last examined on the 15th day of August, was 1010. It is to be regretted that I was not able to follow the case up any further since the mother did not show up after this at the clinic.

The history of my third case is less satisfactory still.

III.—*Fred. I.*, 4 months old, was treated for gastro-intestinal catarrh like the former patient at the N. Y. Polyclinic, and about the same time, *i.e.* during June of last year. This lasted a few weeks. While the child was recovering from it, furunculosis also set

in, although it was not as severe as in the other case. The child's urine which was brought to me on July 25th, had hardly any color, and its specific gravity was found to be 1002. The child was given phenacetine, but unhappily we had no further opportunity to examine his urine. Diarrhœa soon set in again and the mother reported that she was unable to collect any of the urine, since it was always passed at the same time with the fæces. She stayed away about a week afterward and the case was lost to us.

The peculiar coincidence of two rare cases presenting at the same time, is not unusual, nor is their causeless staying away from a clinic.

IV.—*John W.*, 11 months old, was brought to my office on October 12th last. The mother reported that since several days the child, whose history contained nothing but a protracted icterus during the first five weeks of his life, had become very restless, crying almost incessantly, and that he wanted to drink almost continually. He had become considerably emaciated during the last month or so, since which time his illness seemed to have developed.

A physical examination of the child failed to elicit anything to account for the boy's condition. His liver was somewhat enlarged and seemed to be painful on slight pressure, but otherwise everything seemed to be normal. No fever.

I, therefore, instructed the mother to procure some of his urine, although she did not think that the child passed it oftener than usual. But that much she admitted that the quantity of urine passed every time seemed to be larger than formerly.

In order to appease the child without giving him too much to drink, she had given him a piece of sugar in a rag to suckle. This I forbid her to do and allowed her to give the child a teaspoonful of brandy and water or cold tea occasionally between the nursings. The latter she was to do every two hours. Placebo.

She did not appear until the 16th with a sample of the child's urine, which was almost colorless and had a specific gravity ranging between 1002 and 1003. No sugar and no albumen was present. I gave the child 0.25 grammes (4 grains) of phenacetine four times a day. On October 20th the specific gravity of the urine was still 1003 only, although it seemed to have somewhat more color. On October 26th the mother stated that the child was better, cried less and did not wet its clothes as thoroughly as before. But it drank just as eagerly as before. This urine weighed 1006 and had a well-pronounced amber color. Both, the bismuth and the indigo test failed to show any sugar; no albumen. On October 29th the specific gravity was 1010. On November 2d it was again down to 1005. I now increased the dose of phenacetine to 0.35 grammes (6 grains) four times daily. The specific gravity went up steadily after this; it was 1010 on November 5th, and 1012 on November 10th. There it remained and on the 15th of November when I examined it last, it was still at that figure. I now stopped the drug and the child has been well ever since.

On December 2d the specific gravity was 1013, a figure which may be considered almost normal in children who live exclusively on liquid diet.

The most interesting point in connection with polyuria is its *etiology*. In connection with this I may be permitted to refer to the well established fact of its heredity.

It was first shown conclusively by Weil that heredity must be considered a potent etiological factor in diabetes insipidus.

Weil reported the history of a certain family in which a hereditary liability to polyuria was to be traced through four generations. Among 93 members of this family as many as 23 (of which 12 were males and 11 females) suffered from diabetes insipidus.

In connection with the first case I was able to elicit the following facts in regard to heredity.

The mother of the first mentioned infant had passed urine very frequently and in large quantities up to the tenth year of her life and this constantly night and day. She was not sent to school for this reason until after she had completed her tenth year. At that time the polyuria ceased without treatment and without any visible cause. Since then she has been well, except a vaginal discharge which ceased after her confinement. She was at that time 24 years old. No other member of her family has been subject to polyuria as far as she knows—which does, of course, not at all preclude the possibility that such may have been the case.

In the other cases, I was unable to learn anything in regard to a possible hereditary taint.

The feature common to the first three cases is that in every one of them polyuria appeared after prolonged gastro-intestinal trouble. While in one œdematous effusions existed for a short time, the other two were subject to quite extensive furunculosis for many weeks; it was this condition which

led me to examine the urine, as I have stated. Nothing of the kind existed in the last case.

To consider the furunculosis as a manifestation of the tendency to necrotic and gangrenous inflammations, such as seen frequently in diabetes mellitus would, I think, be too rash, for it is, to my knowledge, not supposed to be a feature of diabetes insipidus.

It is not improbable that it was due to the absorption of some septic material from the diseased intestinal mucous membrane. In this regard, it is in place to state that in my experience as well as in that of others, infantile diarrhœa was followed in an exceptional manner by cutaneous affections during that summer.

As to the action and efficacy of the phenacetine, I have nothing to suggest. It can only be explained through its well-known influence on nerves and nerve-centers, polyuria being considered by most authors a nervous affection.

THE TOXIC EFFECT OF TOBACCO VAPOR, WITH A REPORT OF CASES.*

BY W. CARROLL CHAPMAN, M. D.,
LOUISVILLE, KY.

As the grand aim of medicine is to alleviate distress, the careful recording and description of rare diseases as well as the unusual manifestations of ordinary disease, would seem to be two of the most important features of professional literature. Another factor, and probably of no less importance than the first two, is the accuracy in diagnosis. The three cases I desire to report have been recorded at length and with care, and will be described with as much brevity as is consistent with the facts and my ability to outline the symptoms clearly. As to the diagnosis, while I feel that further and deeper research is necessary to make it positive, it is well supported by the physical and functional signs, associated with the fact that each patient had been daily subjected to the inhalation and absorption of fumes emanating from tobacco, and further, that these symptoms, when not so severe, would appear or disappear, according as the patient received the exhalation from tobacco into the system or not. Then I have been unable to find the record of any disease to which this train of symptoms can be applied with precision. On the other hand a grave defect, bearing on the diagnosis, is readily admitted; namely, the failure to make a chemical examination of the excretions. This error is due, principally, to having allowed myself to become so thoroughly convinced of the correctness of my diagnosis, which was concurred in by the consulting physician, as to fail to realize at that time the value of a chemical examination in confirming it, especially to the medical profession.

In treating of the toxic effect of tobacco vapor it is the intention of the writer to confine himself closely to the graver and more dangerous cases due to its inhalation or absorption, or both. The obscure effects of tobacco-smoking and the inhalations from cigarettes will not be considered.

Tobacco stemmeries have a process by which they get dry tobacco in a proper condition for stemming. This is done by means of a number of reservoirs containing steam generated from pure water, which is turned on the tobacco previously arranged, so as to receive and retain the necessary amount of moisture. When ready, this is carried to the men who do the stemming. The carriers are usually children from nine to fifteen years of age. Knowning then that the vapor of tobacco contains numerous basic substances of the picoline series, and several fatty acids, and probably nicotine and nicotianine, it can be readily seen how the systems of these children become saturated with these poisons.

Usually their presence is manifested during the first day or two by violent vomiting, retching, purging, and often a state of collapse, after which the system may become inured to them. Occasionally we find one whose constitution even by contact and time, although there is a certain amount of tolerence, refuses to receive them kindly, and emaciation begins, attended sooner or later by the following symptoms:

Case I.—I was called to see Willie C., aged ten years, April 3, 1889. Found him suffering extreme pain in the abdominal region, with the intensity centering at the umbilicus. Temperature, under the tongue, 100°; pulse 108, small, wiry and irregular; respiration 20 to 22, but irregular—several short, shallow respirations followed by one deep and gasping. Tongue glairy, red appearance and pointed. Patient constipated for the last several days; abdomen flat or rather depressed; urine scanty and slightly colored; skin dry, as were the hands and feet—the latter being a little cold. When

*Read before the Mississippi Valley Medical Association in October, 1891.

near the patient the odor of tobacco was so pronounced that I made inquiry regarding it, and learned that he worked in a tobacco stemmery, and further, that he had slight attacks of similar pains at several different times, except of milder form. Though the working clothes had been displaced by his night apparel, the odor was strong and led me to suspect tobacco as a cause. Not being able to make a satisfactory diagnosis at the time, I decided to use palliative treatment and study the disease further. Gave a hypodermic injection of morphia and atropia; ordered a large dose of castor oil to be followed by bismuth and quinia. After the patient had been given some relief I instructed the nurse to use turpentine stupes freely should the pain return.

The next morning (April 4th) I found the patient suffering pretty much in the same way as on the evening previous—more nervous and tossing from side to side. The morphia and atropia gave relief for several hours, when the use of turpentine stupes was begun and continued until the patient became so restless they could not be applied. The oil had failed to move the bowels. Immediately gave morphia and atropia hypodermically. Temperature 100°; pulse 112; respiration 22, and of the same character as on the evening previous; pupils contracted, expression marked for anxiety. He described the pains as sickening. Previous to the time he started to work in tobacco, he was plump, robust and healthy, but for the last several weeks had been decreasing in flesh and weight. Ordered another dose of oil and told the nurse to apply a sinapism of mustard to the abdomen, should the pains return before I saw him in the evening.

5 P. M.—Patient had just begun to suffer intensely when I arrived. Had been quiet through the day but slept none. Oil still refused to cause the bowels to act. Ordered it by the rectum with a pint of tepid water. Gave morphia and atropia and ordered the enema repeated in case it failed to act in one hour.

April 5th.—Patient had rested better the night before, but slept comparatively none. Pulse, temperature and respiration about the same as on the day previous. The enema had caused a scanty action upon the bowels —very dark, with greenish tinge to the liquid. No tenderness of the abdomen on pressure, except at umbilicus; pain still intense. Repeated the morpia and atropia. Although catharsis and diaphoresis were absent, I felt convinced that tobacco was the cause, and decided to push cathartic remedies to thorough effect and stimulate the skin to action. Believing there was no intussusception, I prescribed a full dose of calomel, podophyllin, extract belladonna and soda. Ordered the clothing and bedclothing changed, and the patient sponged with tepid water and a little ammonia, followed by mild rubbing; this to be repeated in the evening, at which time I administered morphia and atropia again.

April 6th.—Patient rested better through the night than at any time previous. Bowels acted two or three times; fæces black, with green tinge. Pain dull, sickening character; no material change in temperature, pulse or respiration. Liquid food with whiskey. Continued baths; prescribed morphia, belladonna, quinia and nux vomica.

April 7th, 8th, 9th, 10th, 11th, 12th and 13th.—Patient continued pretty much the same, temperature going to 101°, with a slight advance in pulse-rate on one day. No change in treatment, except to add pepsin and hydrochloric acid. Kept the bowels open by enema.

April 14th.—Abdomen tympanitic, with tenderness; nausea and vomiting. Patient complained that the capsules made him vomit; discontinued them. Pain intense, same character as before.

April 15th.—Was sent for to relieve the pain. Administered morphia and atropia hypodermically; prescribed deodorized tincture of opium, and ordered turpentine stupes over the abdomen.

April 16th.—No change.

April 17th, A. M.—Temperature 101,5°; pulse 120; respiration labored. Digitalis, whiskey, atropia. P. M., temperature 102°, pulse 130. Continued same.

April 18th, A. M.—Temperature 100°; pulse 108; respiration improved. Slept after 1 A. M. P. M., same as morning. Rested pretty well. Continued whiskey and digitalis.

April 19th.—Temperature 99°; pulse 100; respiration 18, more regular. Other symptoms improved.

Improvement was gradual from this on.

April 22d.—Facial neuralgia manifested itself and lasted several days. Gave morphia and atropia and prescribed iron, quinia and strychnia. Dismissed the case on April 29th, after three-and-a-half weeks of illness, with instructions for him never to work in tobacco again. He has obeyed, and now (two-and-a-half years later) the boy is inclined to be fleshy.

Case II.—Lizzie M——, aged twelve years. Worked in tobacco stemmery. Called

in on July 19, 1889. Patient was taken sick three days before with pains in the abdomen. The mother had treated her with castor oil, laudanum and hot applications, with very little relief. These remedies had answered the purpose on two or three other occasions within the last several weeks, but the pains had never been so violent. On the evening of the above date I found her condition as follows: Anæmic; violent pain in the abdomen with intensity centering at umbilicus; abdomen flat with only slight tenderness on pressure; constipated; urine, scanty and slightly colored; tongue, red and pointed; temperature in axilla, 100.5°; pulse 120, small and wiry and irregular; skin, dry; pupils, contracted; respiration, 24; four or five short and shallow followed by one deep and gasping. The odor of tobacco was present. Gave morphia and atropia hypodermically. Prescribed a cathartic, also digitalis, and ordered teaspoonful of whiskey every two hours.

July 20th, A. M.—Patient had rested the early part of the night; small action from the bowels, dark, greenish appearance. Pains have been severe for last hour or two; pulse, temperature and respiration same as evening before. Continued same treatment; gave morphia and atropia and ordered an enema. P. M.—Bowels had moved twice; fæces dark, greenish appearance. Repeated morphia and atropia and ordered patient sponged with tepid water and ammonia and rubbed dry. Liquid food.

July 21st, A. M.—Pulse, 130; temperature, 101.5°; respiration, 22 and more labored; abdomen, slightly tympanitic. Prescribed aromatic spirits of ammonia with the digitalis. Gave morphia, quinia and strychnia in capsules, increased the whiskey. P. M.—Condition same.

July 22d and 23d.—No change except abdomen little more tympanitic, and vomiting at times.

July 24th, A. M.—Vomiting, cannot retain the medicine in the stomach; pulse, 140; temperature, 100°; respiration so irregular can't be estimated positively. Whiskey, hypodermically. P. M.—No perceptible change unless for worse.

July 25th.—Patient sinking; pulse, fluttering; respiration, 10 and gasping. Died in the afternoon by asphyxia, after an illness of nine days.

I requested the privilege of making a *post-mortem* but was refused.

Case 3. Johnnie C——, nine years old. Called in on July 14, 1890. Patient suffering intense pain in abdomen, especially at umbilicus. Had a few slight pains a few days before, but stopped his work in tobacco stemmery and came home. The pains ceased without treatment. A day or two later resumed his work until the above date. Emaciated; abdomen, flat; very slight pain on pressure; temperature, 100°; pulse, 100, small, wiry; respiration, 22 and shallow; pupils somewhat contracted; tongue, bright red; constipated. Gave morphia and atropia hypodermically; castor-oil by mouth; prescribed tincture of opium deodorized to be given when the effects of the morphia began to wear off, provided the oil acted.

July 15th.—Patient rested very well through the night. Oil moved the bowels two or three times; dark, greenish actions; temperature, 99°; pulse, 90; respiration, 20 and easier. Diminished the opium with instructions to leave it off if pain ceased. Prescribed pepsin, pancreatin, bismuth and hydrochloric acid.

July 16th.—Left opium off and pains returned. Temperature, 99.5°; pulse, 96; respiration, 22. Began opium immediately. Ordered him sponged with tepid water and ammonia.

July 17th.—Patient improved; pulse, 84; temperature, 98.4°; respiration, easy. Prescribed iron, quinia and strychinia; improvement continued. Facial neuralgia developed on 19th instant and lasted two or three days.

I desire to state just here that, during the interval between cases 2 and 3, reported above, I saw two patients, who worked in tobacco, with symptoms similar to those reported, but greatly modified. To the first of these I gave castor oil, followed by pepsin, pancreatin, bismuth and muriatic acid, with instructions to stop work in tobacco. He followed my advice and has not suffered in that way since. To the second I merely gave castor oil with same instructions as to the first. He followed them for a few months, then returned to work in tobacco, which he kept up for six weeks when he came to me with the same symptoms as at first. Yielded to simple treatment, but slowly. Since case 3, I have had several mild cases. I invariably warn them to stop work in tobacco, especially where it is steamed. I believe all would have been well with the three cases reported had they stopped work in tobacco at the first warning pains.

Attention is called to two factors noticeable in all the cases, namely: The emaciation and the time each one had followed the occupation, that is, from six weeks to three

months. The three cases reported had not suffered from the vomiting and retching usually attendant upon young tobacco workers the first day or two. In the other or milder cases, I neglected to inquire regarding that point.

This paper would be incomplete without a review of these cases for the purpose of considering the relation between this cause and result.

Emaciation is one of the symptoms noticeable in persons suffering from the presence of tobacco vapor in their systems. Dr. Ydan Pouchkine, of Russia, has recently reported an interesting series of experiments relative to the influence of tobacco upon the digestive functions of the stomach. He concludes that the free hydrochloric acid of the gastric juice is diminished under the influence of tobacco and the motility of the stomach is increased. This would interfere with the digestion of the food not only by lessening the power of the gastric fluid, but by hastening the matter to be digested into the duodenum before it has been subjected to the influence of the gastric juice for a sufficient length of time. Consequently and in proportion as digestion is imperfect, would secretion and assimilation be deficient and emaciation result.

As to the particular ingredient or ingredients causing the symptoms reported, chemical examination would furnish the most weighty evidence. Having neglected that in these cases, I can only console myself by awaiting an opportunity to make that test at some future period. Our knowledge, though, of the substances entering into the composition of tobacco, and their separate and collective properties and actions upon the body furnish us material worthy of consideration.

In regard to nicotine, which has been suggested as a cause, I must say that I do not believe it for a number of reasons. In the first place, nicotine is not readily separated from tobacco unless treated by a fluid or vapor containing alkaline properties, potassa for instance. The vapor used at the stemmeries, I learned upon inquiry, was from water only.

Again, had nicotine been the cause, the effect would likely not have been so delayed and vomiting and purging have been present.

As to nicotianine, indications point strongly to its being a cause. According to Landerer it occurs only in dried tobacco-leaves, and has the odor of that plant, a point strongly in its favor, and that odor was so distinct in every case I have seen. It would seem, further, that the basic substances and fatty acids were causative agents, because authors have proved by physiological experiments that these cause contraction of the pupil, dyspnœa, abdominal pains, convulsions and death.

Why these symptoms have been so delayed in these cases, instead of the poisons manifesting themselves the first day or two, by retching, vomiting, etc., as is most generally the case, I am at a loss to say, and would suggest, by way of excuse, a cumulative effect.

The toxic effect of tobacco vapor and its treatment is a subject worthy of more consideration than the profession has accorded to it in the past, and I hope that the next few years, aided by diligent and careful investigation, will place the matter in a more intelligent light.

Society Reports.

SURGICAL ASSOCIATION.

THURSDAY.—EXECUTIVE SESSION.

The officers for ensuing year are as follows:

PRESIDENT.—Dr. Phineas S. Conner, Cincinnati.

1st VICE-PRESIDENT.—Dr. L. McLane Tiffany, Baltimore.

2d VICE-PRESIDENT.—Dr. Levi C. Lane, San Francisco, Cal.

SECRETARY.—Dr. J. R. Weist, Richmond, Ind.

RECORDER.—Dr. J. Ewing Mears, Philadelphia.

TREASURER.—Dr. John B. Roberts, Philadelphia.

MEMBER OF COUNCIL.—Dr. Claudius H. Martin, Mobile.

The committee recommended the following resolution, which was adopted:

Resolved, That the Association hereafter hold each triennial meeting at Washington, and that other annual meetings be held at such time and place as the Association may name.

It was decided to hold the next meeting at Boston, in June, 1892.

The following were elected to membership:

Dr. J. S. Wright, Brooklyn, N. Y.

Dr. E. W. Walker, Cincinnati, Ohio.

Dr. George R. Fowler, Brooklyn, N. Y.

The following honorary members were elected:

Mr. John Chiene, Edinburgh.
Mr. Reginald Harrison, London.
Mrs. Thomas Bryant, London.
Mr. Arthur Edward Durham, London.

THURSDAY SESSION.

RECURRENCE OF CANCER OF THE BREAST, BY DR. FREDERICK S. DENNIS, M. D., OF NEW YORK.

Only those cases were included in which a microscopical examination of the tumor has been made. The necessity of an investigation of carcinoma of the breast is shown by the fact that in England alone 7000 deaths occur annually from carcinoma, and a large proportion of these are cases of the breast. It has been demonstrated that cancer is a disease which is slowly increasing in civilized nations. A study of the subject shows us that there are 75 per cent. of recurrences. These include cases of incomplete operations, *i. e.* when axillas have not been opened. In the primary growth at the beginning, the neoplasm is of local origin. Early and complete removal of the growth relieves the local disease, but the operation does not relieve the predisposition, or susceptibility, or capability for the recurrence of the disease. It is possible that the capability is limited to certain extents.

First, the recurrence of carcinoma of the breast is influenced by the period of time from the appearance of the growth to the date of the operation. In the cases of the author in which the cure had continued for three years or more the tumors were removed on an average, six months from the date of their first recognition in the breast. In all the cases of permanent cure, the axillary glands were not invaded.

Second, recurrence is influenced, by the extent to which infiltration has taken place by any one or all of the three well recognized ways of dissemination. If, when the tumor has existed long enough to show extension in these directions, the growth has been of long duration.

Third, recurrence is influenced by the radical character of the operation itself. Complete removal of the breast is essential. The method of Mr. Stiles, of Edinburgh, by which the tumor after removal is treated with dilute nitric acid in order to show whether or not the incisions have been made in healthy structures and all the diseased structure has been removed, was described. The reported mortality of the operation is high, but in the author's 71 cases there had been but one death and that was from continued bleeding in hæmophilia. In operation not only the breast but the axillary glands were removed in most cases.

Fourth. Recurrence is influenced by the histological character of the carinoma itself. Where the structure differs slightly from the normal, the clinical history is favorable. In none of these cases was there recurrence. Where there is great departure from the normal type, the clinical history is unfavorable. The more embryonic the structure, the greater the chance of recurrence.

Fifth. The recurrence is influenced by the simultaneousness in both breasts. This occurs in five per cent of the cases. These patients are very liable to these recurrences.

Sixth. Recurrence is influenced by the personal factor of the individual, such as age, sex, marriage, fecundity, sterility, pregnancy, traumatism, heredity, menstruation, metasosis, mental condition, locality, etc.

Seventy-one cases of carcinoma of the breast, which had been operated on, were referred to. In one there had been death from hæmophilia. In nearly all the axilla was opened. The operation consisted of excision of the entire breast, with all contiguous skin, the para and peri mammary, fatty areolin tissue, the pectoral glands, the pectoral fascia and also removal of the axillary glands and fatty axillary tissue. In some cases the supra clavicular glands were removed, and in one case excision of the ribs was done. The per centage of permanent cures amounted to 30 per cent. The author held that with early and radical operation, recurrence of carcinoma of the breast will be comparatively scarce.

DISCUSSION.

Mr. Thomas Bryant, London, believed firmly in the local origin of carcinoma although we must admit that there may be a predisposition on the part of the patient to the development of the disease. The disease should be treated at an early period, and this brings in the question of diagnosis. Many cases do not come under observation until the disease is well advanced, because the patient imagines that a disease unassociated with pain cannot be cancer. Where induration appears in a breast during the period of functional activity there may be some hesitation in the diagnosis, but in some thirty cases of this kind he had recommended an immediate operation, and in all the cases the disease was shown to be malignant. In none has recurrence taken place. When

the disease has advanced somewhat further with dimpling and puckering of the skin and some immobility we may get a good result by making a thorough operation. He had had some cases without recurrence for from five to twenty years. In the more advanced cases the surgeon should limit his operations to those in which there was a reasonable prospect of removing all the diseased structure. He does not remove the axillary glands in every case. If the glands be enlarged or the disease extend upward in that direction he removes the glands thoroughly. When the disease is quite local and there is no evidence of axillary involvement, the axilla is not opened. In the atrophic form of cancer he thought it better not to interfere unless the tumor was giving rise to great inconvenience. Operation in these cases is often followed by a more rapid form of growth. Again in the form of cancer where the lymphatics can be traced distinctly, and the breast has a brawny feel—the lymphatic form of cancer—the surgeon does no good by interference.

Sir William McCormac, London, thought that the axilla should be opened in operations for carcinoma of the breast, for two reasons, viz: An examination of 117 cases of cancer of the breast showed that in all but two there was axillary involvement, and second, in ninety per cent of the recurrences the disease appears in the axilla.

Dr. Lewis S. Pilcher, Brooklyn, thought that the term "recurrence" was not applicable to many of these cases, and that in many the disease was simply a continuance of the former growth. If the case goes one year without the appearance of return of the disease, it may be considered that the disease has been removed, and if it appear later it can be regarded as a recurrence, a renewed or new attack of cancer. In every case of cancer there is a predisposition to the disease, and we should search for some agent to counteract this constitutional predisposition which we can use in addition to operative measures. Arsenic has for many years been used for this purpose. Dr. Wright, of Brooklyn, has suggested the use of carbonate of lime for the same purpose.

Dr. L. McLane Tiffany, Baltimore, did not think we could set any limit to the time of which recurrence might take place. He had had the disease return eight years after the operation. He was a firm believer in the local origin of cancer. The date at which this disease is recognized varies much. In some the disease comes before the surgeon shortly after its commencement, while in others the tumor has reached considerable size. The time at which the disease is discovered by the patient bears no relation to the time of its commencement. Too much stress had not been laid on the necessity of thorough operation. In only two cases out 80 operations for cancer of the breast had he found the axillary glands not enlarged. The pectoral fascia should be removed, and at times the portions of the muscles should be cut away.

Dr. Kingston, Montreal, believed that cancer was essentially a local disease. If we believe this, operation should be done at as early a date as possible. The glands should be removed not only from the axilla, but from its neighborhood if they are enlarged, but this should not form a necessary part of the first operation. Such a procedure adds greatly to the discomfort and to the danger. Where there is the slightest suspicion of involvement of the glands, they should be removed. If there should be recurrence the operation should be repeated as often as circumstances seem to warrant.

Dr. Joseph Ransohoff, Cincinnati, reported thirty cases of removal of the breast for cancer, without a death. He thought that the danger of the operation was not materially increased by opening the axilla.

Dr. C. B. Nancrede, Ann Arbor, said with reference to the three year limit that this had been proven to exclude 98 per cent. of the recurrences. It is impossible to tell whether or not, the axillary glands are involved without opening the axilla. Unless this is done the majority of the cases will be left unbenefited. He advised that the axilla be opened first, and if the glands could not be removed, to close the wound and not remove the breast.

Dr. J. R. Weist, Richmond, Ind., had operated 55 times for cancer of the breast and makes it a rule to open the axilla in every case.

Dr. Geo. W. Gay, Boston, felt that there was no such thing as a local origin of cancer as we have the local origin of a fatty tumor. When it can be shown that a cancer taken out, will not return just as a fatty tumor when removed does not return, then we can prove the local origin of carcinoma.

Dr. Edward M. Moore, Rochester, always operates in as thorough a manner as possible. He always opens the axilla and did not think that it added to the risks of the operation. He did not agree with Mr. Bryant in regard to the atrophic cases in old individuals. In these, he recommended

operations considering recurrence very improbable. He reported one case living 17 years after operation, and now 79 years of age.

A CASE OF DIFFUSE FIBROMA, WITH A TENDENCY TO INTRA-CANILICULAR GROWTH OF BOTH BREASTS, BY DR. C. B. PORTER, OF BOSTON, MASS.

Mrs. M., age 37 years, resident of Nova Scotia, was admitted to the Massachusetts General Hospital. Has had two children, the youngest ten years old. Three years ago she discovered a hard lump in the right breast which gradually increased in size. Three months later the right breast commenced to enlarge. The breasts continued to slowly enlarge until three months ago, when a rapid increase took place, and the breasts soon became burdensome by their size and weight. On examination she was found to be pale, emaciated, and with ovarian fæces. Right breast, largest circumference 38 inches; length from chest wall to nipple, 17 inches; circumference of base, 23 inches. Left breast, largest circumference 28 inches; length from chest wall to nipple, 14 inches; circumference at base, 23 inches. Throughout both breasts were felt movable, hardened masses of irregular outline varying in size from an orange to a closed fist.

It was decided to remove the left breast first. The breast was transfixed at the base with two skewers, and constricted below this with a tightly drawn rubber tourniquet. The breast was then removed, and but little blood lost. Three weeks later the right breast was removed. Twenty days after the second operation the patient was permitted to leave the hospital to visit friends, but instead she returned to her home, requiring a long sea journey. A week later she developed erysipelas. This had much improved in four days when she suddenly aborted a month fœtus.

The weight of the right breast after removal was 43 pounds, and that of the left 17 pounds, a total of 60 pounds.

A resumé of three reported cases was added.

Dr. J. M. Barton, of Philadelphia, reported a similar case, on which he had operated, and in which one breast was involved. Adjourned Thursday.

FRIDAY MORNING.

The committee to which was referred the suggestion in the President's address offered the following resolution, which was adopted:

Resolved, That the President appoint a committee with authority to confer with the friends and admirers of Professor S. D. Gross, and with the profession at large, for the initiation of a movement on the part of the Association, having for its object the erection of a monument to Dr. Gross in the city of Washington.

As the matter is an important one, the President stated that he would announce the committee in a few days.

TREATMENT OF FRACTURES INVOLVING THE ELBOW JOINT, BY DR. LEWIS A. STIMSON, NEW YORK.

The special interest of the subject arises from the frequency with which fractures of the lower end of the humerus are followed by more or less diminution of the functions of the elbow joint and by deformity of the region or of the limb. The paper was devoted mainly to a consideration of the causes of these unfavorable results.

Causes of limitation of motion. Permanent stiffness after simple fracture is commonly due to change in the shape of the articular surfaces or in their relations to one another, that destroys the coincidence of the axis of curvature with that of motion; or to an overgrowth of bone upon the surface of the humerus, arresting the movement of the olecranon or coronoid process; or to more or less extensive ossification of the ligaments and capsule.

Overgrowth of bone from traumatism is more frequent in the young than in the adult, as limitation of motion may be caused by bony outgrowth from the humerus, itself the result of a persistent displacement of a fragment or of separation of the periosteum. The most efficient way to prevent it, lies in an exact diagnosis and reduction of displacement and in the avoidance of any subsequent irritation of the periosteum.

Limitation of motion from thickening of the capsule and peri-articular tissues by the process of inflammation is as a rule a temporary condition. In the more permanent form the lesions are more extensive. The soft tissues are torn and a true cicatrix results. The thickened tissue may become ossified in whole or in part. This cause of limitation has been attributed, but improperly so to prolonged immobilization and has led to the practice of passive motion in the early stages with the object of preventing its occurrence. Observation and experiment has, however, shown that immobilization is not itself a cause of ankylosis, but that it is an efficient agent against

inflammation, and that passive motion is powerless to prevent ankylosis when conditions contributory thereto are present. Passive motion therefore is either harmful or useless. The primary cause of the exudation and of the proliferation of connective tissues that are the anatomical obstacles to motion, is of course the original traumatism. The secondary cause is the following reaction. The only factor that can be increased or diminished by treatment is the second, that is the inflammatory reaction. Rest is universally admitted to be the best antiphlogistic measure that can be applied to an inflamed joint. An important disadvantage of rest at once suggests itself namely, that the torn tissues may unite with shortening. Both clinical observation and theoretical considerations indicate that passive motion in the early stage does not avoid this disadvantage, but actually increases it. In the present state of our knowledge it seems that a certain amount of limitation is unavoidable. Massage, however, hastens the absorption of exudation and the restoration of mobility, as does also permanent elevation or suspension of the limb. Reunion with shortening may be opposed by change in the attitude of the limb every few days. At a later period passive motion has its value, but in the early stages it is to be avoided.

In regard to deformity reference was made to one only, that commonly known as the "gun stock" deformity due to unreduced displacement of the internal or external condyle. In order to avoid this deformity the displacement should be reduced by pressure upon the fragment or by abduction of the extended forearm until its outward deviation is equal to that of its fellow and immobilization, by dressings that will not reproduce the displacement.

Treatment.—The first element in the treatment is the reduction of the displacement. If necessary an anæsthetic should be employed. In supra-condyloid fractures permanent traction is usually necessary to overcome the displacing action of the flexors and extensors. This can be effected by vertical suspension of the limb, the patient being kept in bed or by a weight suspended from the upper part of the flexed forearm while the patient is erect. The former method was recommended for the first fortnight of treatment, especially in compound fractures. Suspension is made by strips of adhesive plaster placed along the front and back of the forearm and attacked to the support by India-rubber cords or a weight and pulley. In simple fractures the other method may be employed. The limb is encased in plaster-of-Paris with the elbow at the right angle. The wrist being placed in a sling and a weight not exceeding five pounds suspended from the elbow.

In inter-condyloid fractures with marked separation, there is no practicable means of surely maintaining reduction and considerable limitation is to be expected. In these cases a broad heavy posterior splint covering about two-thirds of the circumference of the limbs, the elbow being at a right angle, was recommended.

In fractures of either condyle the treatment is by a posterior rectangular splint, either of metal or plaster. The forearm has been supported across the chest by a sling at the wrist. In some cases treatment in full extension has been employed. After this method has been employed for the first ten days or fortnight, recourse is had to the position with the elbow at a right angle.

Gentle massage will hasten convalescence. It may be advisable to change the position of the limb during treatment and if great limitation is to be expected, that attitude should be given to the joint in which, if stiff, the usefulness of the limb will be greatest. In supra-condyloid and inter-condyloid fractures, the splint should be worn six weeks and in fractures of the condyles, for about four weeks. After removal of the splint, the arm should for a few days be supported in a sling if necessary. Passive motions may at this time be resorted to increase the range of motion.

DISCUSSION.

Dr. N. P. Dandridge, of Cincinnati, agreed with what had been said by the reader of the paper and referred to two cases occurring under his observation. In one case of simple fracture from great violence in which nonunion had occurred, the arm was treated in a position of almost complete extension. The second case was one in which after fracture at the elbow joint a projection of bone pressed upon the median nerve causing severe pain and atrophy of the muscles in the distribution of the nerve. The case was seen three months after the accident. Removal of the bone was followed by relief of the pain and a gradual restoration of the function of the muscles.

Dr. R. A. Kinloch, of Charleston, thought that in simple fracture about the elbow, if seen early and the ordinary principles in regard to the treatment of fractures be applied, the result would be good. Probably in a

large number of cases we must expect some restriction of movement. The most important element in the treatment is the proper reduction of the fragments. This should be done at once, an anæsthetic being employed if necessary. The proper reduction of the fragments is determined by testing the functions of the joint. The second indication is to retain the fragments in the proper position. If the case is treated with intelligence it makes little difference what way the splint is applied or whether it is treated in flexion. The position is to be determined largely by the peculiarities of the individual case. He was himself inclined to favor the extended position.

In regard to passive motion used early, he thought that it did more harm than good. If the parts have been properly reduced and held in position and there is danger of subsequent trouble, passive motion may begin in three or four weeks.

Dr. E. M. Moore, Rochester.—In a fracture of the internal condyle the cause of the displacement is the flexor muscles and to relax these muscles the arm is to be placed in the flexed position. In fractures of the external condyle he had also found this position the preferable one, for when the forearm is flexed thedense fascia on the front of the arm is rendered tense and acts as an efficient splint. He objected to the extended position entirely. He treats all fractures about the elbow joint with the exception of fractures of the olecranon in the rectangular position for the first ten days or two weeks. Latural splints are used with the object of pressing the fragments together after the tenth day. The fracture is dressed every other day. The angle of the splint being changed a little each time so that the arm passes from almost complete flexion to almost complete extension. He had never had the slightest difficulty in any case since adopting this mode of treatment.

Dr. James M. Cann, Pittsburgh, said that it was not always easy to determine the exact nature of these fractures about the elbow-joint even with the patient under the influence of an anæsthetic. While the patient is under the anæsthetic the preliminary dressing should be applied. He recommended the use of the internal angula splint preferably that suggested by Dr. Packard. He did not favor the use of passive motion at an early stage. Passive motion should not be resorted to prior to the twentieth day.

Dr. John B. Roberts, Philadelphia, thought that the teaching advocated by some of the speakers was to a large extent dangerous and incorrect, that is that injury about the elbow joint should be treated in the flexed position. He believed that except in unusual cases these fractures should be treated in the extended position according to the doctrine advocated by Dr. Allis. In this way the gun-stock deformity is avoided. He now approached fractures of the elbow with the same certainty of getting a good result as he did fractures of the lower end of the radius.

Dr. S. H. Weeks, Portland, dwelt upon the fact that all authorities, with few exceptions, advised the flexed position in the treatment for fractures about the elbow joint. Until there was more positive evidence of the value of the extended position he thought it better to continue to treat these fractures in the flexed position. He employed passive motion in a modified way. After two weeks' treatment the splints are removed and the joint moved gently about, but not sufficiently to cause pain. This simply alters the relations of the parts without doing any damage.

Dr. L. McLane Tiffany, Baltimore, thought that as good results were reported from various dissimilar methods of treatment we must conclude that the prognosis of elbow injuries depended more upon the patient than upon the surgeon. Fracture of the elbow is rare in adults and common in children, and in children with reasonably good treatment there should be a good result and by the time adult age was reached the motion would be almost perfect. In the adult the prognosis is more grave. He had had good results both with the flexed and with the extended position. In compound fractures the secret lies in the relief of tension irrespective of the apparatus employed. Incision up and down the arm through the strong fascia should be made as freely as may be required.

RETRO-PERITONEAL TUMORS—THEIR ANATOMICAL RELATION—PATHOLOGY, DIAGNOSIS AND TREATMENT, WITH REPORT OF CASES, BY ALBERT VANDERVEER, M. D., OF ALBANY.

As our experience in abdominal surgery increases, we find that there are yet many problems that confront us, and of these problems there are none which require more careful research and are capable of greater improvement, both in operative management and in prognosis, than the new growths arising from the retro-peritoneal space. In order to bring this subject more fully to the attention of the Association, the following cases are reported:

Case 1.—Miss S., aged 42 years, consulted the author in March 1882, on account of a tumor located in the back. This was first noticed fifteen years previously. Examination showed a large tumor attached to the right side of the spine at the level of the first lumbar vertebræ. It seemed attached to surrounding tissues of a smooth contour and hard to the touch. Operation was advised but declined. The tumor continued to increase in size until November 1888, when she died from other causes. The autopsy showed the origin of the growth to be the connective tissue about the right kidney. It was encapsulated and could have been easily removed. It weighed eight pounds. The microscope revealed the presence of fat and myxomatous tissue with an abundant small round cell infiltration.

Case 2.—Mr. V., aged 42 years, married. Was first seen May 28, 1889. Five years ago strained his back. The pain following this has not been relieved by any treatment. Three months ago he became worse; the abdomen began to enlarge. The pain was more severe. He lost appetite and flesh. The ankles became œdematous and a distressing cough developed. The urine was scanty and high colored but free from albumen and casts. The abdomen was more prominent on the right side. Fluctuation could not be elicited but palpation gave an impression similar to that of a lipomatous tumor. On the right side there was flatness from the nipple to the crest of the ileum with the exception of a narrow space along the border of the ribs where there was a zone of resonance. The probability of the growth arising from the kidney was strong and an exploratory abdominal section advised.

This was done June 1, 1889. An incision five inches long being made over the external border of the right rectus muscle. The growth was reached and the capsule divided, but from its attachments it seemed futile to attempt its removal. The patient recovered from the operation and for a considerable period was relieved of pain. The growth continued to increase in size, and the patient died October 21, 1889.

The tumor which weighed fifty-six pounds originated behind the peritoneum and was attached to the right kidney. The microscope showed it to be an adipose tumor presenting a condition of myxosarcoma with sarcomatous infiltration.

Case 3.—Mr. N., aged 39, a brass worker by occupation, began to have vague abdominal symptoms late in the year 1888, with failure of flesh and strength. In June, 1889, he developed jaundice and a tumor was found in the left hypochondriac region and lumbar region. This was as large as a child's head. An exploratory operation was advised but refused. It was believed that the growth was connected with the left kidney. The tumor continued to grow and in November 1889, the patient died. The tumor was found to have sprung from the region of the left suprarenal capsule and involved it. It also surrounded the kidney. It weighed six and one-eighth pounds. The microscope showed an appearance similar to that in case two, but with greater preponderance of sarcomatous and myxomatous elements.

A careful study of the reported cases and of the literature of the subject impresses one with the belief that the most frequent origin of these growths is in the connective tissue of the capsule of the kidney, and that the next most frequent seat is the supra-henal capsule. None of these tumors can be said to be absolutely benign, even those which are made up entirely of histological elements, such as lipoma, fibroma, or myoma. While they show no great tendency to recurrence after complete removal, yet, from the great size to which they develop and their tendency to undergo degenerative changes they can not be classed as innocent growths.

In many of the reported cases the origin is not stated and indeed it would, from the subsequent changes in anatomical relations, seem quite impossible to determine the exact origin of many of the large retro-peritoneal growths. They almost always present themselves in the line of least resistance, that is anteriorly. Careful study of these tumors shows them to be of a mixed variety, containing both the elements of the lipoma and myxoma tissues which are histologically very closely associated. Fat is developed from embryonal mucin and in post-fœtal life occupies those spaces in the economy which later, in the fœtus is of myxomatous elements. Doubtless many of these growth arise, under suitable conditions, from congenital neoplasms. These growths often become cystic and reach immense proportions. They often present a numerous round-celled infiltration pointing to a sarcomatous element. Sarcoma either in its typical form or in combination with other tissues often occurs.

Diagnosis.—There is not a single symptom that is pathogenic and the diagnosis is more dependent upon the process of exclusion. Tumors of the other abdominal and pelvic organs as well as aneurisms and tumors of the abdominal wall must be excluded. As already stated many of these tumors have

their origin in the capsule of the kidney or the connective tissue surrounding it, these present, in their earlier stages at least, physical signs differing in no respect from tumors of the nephritic parenchyma. In none of the cases reported has renal hæmorrhage or albuminuria, with or without casts, occurred, conditions which are the rule with tumors of the parenchyma of the kidney a valuable adjunct in the diagnosis consists in noting the relation of the tumor to the intestinal tube as shown by the insufflation of hydrogen gas.

Prognosis.—Without operative interference there is but one termination. The rapidity with which the fatal result is reached varies with the character of the growth. The mean duration of life after the discovery of the tumor is about nine months. Operative treatment offers much promise. The immediate mortality of the operation is great, yet from the hopelessness of the condition, it is to be urged with great earnestness.

In operations for the removal of retro-peritoneal growths, the choice of incision, will usually fall in the line of the linea semilunaris. By the separation of the peritoneum from the internal border of the tumor, it may be attached to the internal border of the abdominal wound, making the whole field of operation extra-peritoneal. The incision of the posterior fold of the peritoneum should be external to the attachment of the mesentery of the colon, although not absolutely necessary. In the removal of the growth by enucleation, care should be taken to determine the source of the blood supply and the relation of the great vessels. There are likely to be large thin-walled veins deep in the wound, requiring ligature. At times it will be found necessary to remove the kidney with the tumor, as in all abdominal work, the operator should be prepared for any and every complication. After enucleation, the cavity must be thoroughly drained. The after treatment is the same as all other severe abdominal sections.

Like all other conditions in surgery, there is certainly a better understanding of these cases going on. A more correct and early diagnosis, as is the case in all that pertains to medicine and surgery, will surely bring a larger percentage of recoveries.

These are purely surgical cases, no medicines, no mineral waters or baths, electricity or other lines of therapeutics having, as yet, been of any service.

The paper was appended by a complete bibliography of retro-peritoneal new growths.

INTRA-THORACIC SURGERY—BRONCHOTOMY THROUGH THE CHEST WALLS FOR FOREIGN BODIES IMPACTED IN THE BRONCHUS, BY DE FOREST WILLARD, M. D., PHILADELPHIA.

Dr. Willard gave the results of a number of experiments on dogs in which an opening was made in the chest walls, one or more ribs excised and the bronchus thus reached either anteriorly or posteriorly. The operations were all fatal.

The following conclusions were presented:

1. In dogs, the bronchus can be reached either anteriorly or posteriorly through the chest walls, but the anatomical position is in such close proximity to large and important structures that safe incision is a matter of extreme difficulty and danger.

2. Bronchotomy through the walls of the thorax is an operation attended with great shock from collapse of the lungs and until the technique is further advanced is liable to result in immediate death.

3. Collapse of the lung is more serious in a healthy organ than in one previously crippled by disease.

4. The serious inherent difficulties are shock, suffocation from lung collapse, enormous risks of hæmorrhage from pulmonary vessels, injury of or interference with the pneumogastric nerve, great and fatal delays owing to the exaggerated movement of the root of the lung caused by the excessive dyspnœa.

5. Closure of the bronchial slit is slow and dangerous; to leave it open causes increasing pneumothorax by its valve action and also permits the entrance of septic air into the pleural cavity.

6. Although a foreign body can be reached by this route, yet removal is hazardous. To secure a subsequent complete cure seems in the present state of knowledge very problematical.

7. When the presence of a foreign body in the bronchus is definitely determined, and primary voluntary expulsion has not been accomplished, there is great danger in permitting it to remain, even though it may but partially obstruct the tube, the risks both of immediate and of subsequent inflammation are serious.

8. Low tracheotomy is then advisable when the presence of a foreign body is certain, it adds but little to the risks and affords easier escape for the object even when extraction is not feasible.

9. *Subsequent dangers arise from severe and prolonged instrumentation, not from tracheotomy.*

10. Voluntary expulsion is more probable after than before tracheotomy.

11. Tracheotomy is permissible even after an object has been long in position unless serious lung changes have resulted.

12. The question of tracheotomy will depend largely upon the form, size and character of the foreign body.

13. The term bronchotomy should be limited to an opening of the bronchus, and should not be employed to designate higher operations.

14. The risks from thoracotomy and bronchotomy following unsuccessful tracheotomy, are much greater than the dangers incurred by permitting the foreign body to remain.

Discussion.—Dr. J. R. Weist, of Richmond said that from a study of one thousand cases in which a foreign body was impacted into a bronchus, he reached the conclusion that the chances of the patient were better if left alone than if an operation of what was formerly called bronchotomy was done.

Dr. S. H. Weeks, of Portland, thought that in these cases tracheotomy should be performed as this offers a chance of reaching the foreign body and also offers a chance for the spontaneous expulsion of the body. It occasionally happens that the body is forced up against the vocal cords and then falls back or else suffocates the patient before relief could be afforded. He reported the case of a child ten years old, who had so gotten into the trachea a screw cap that was used to close a pocket flask. It had been there several days before the patient came under observation. It was decided to open the trachea, this was done and the patient suspended but the foreign body did not escape. The patient was then placed in the horizontal position and the attempt made to remove the cap with forceps. It could be felt but not grasped. After working unsuccessfully for some time, the patient was again suspended and the attempt with the forceps renewed and at once the body was grasped and removed. The patient made a perfect recovery.

Dr. Kingston, of Montreal, reported a case in which he had removed an artificial incisor tooth with its attachments from the trachea where it had remained for three months. The operation necessitated prolonged manipulation but was followed by no bad results.

Dr. Howard Marsh, England, thought that on account of the danger of leaving the foreign body in the bronchus, the uncertainty in regard to the possibility of removal until the attempt is made and the safety of tracheotomy, the operation should be performed. The operation should be performed in all these cases as it gives the patient a chance where otherwise he perhaps has none.

Mr. Arthur Edward Durham, of London, agreed with the author of the paper that the operation through the chest wall was a dangerous and doubtful procedure. The more he saw of these cases the more satisfied was he that the proper thing to do where there is clear evidence that a foreign body is impacted in the bronchus, is to open the trachea low down and endeavor to remove the foreign body or to facilitate its spontaneous expulsion. This opinion was the result of considerable experience.

Dr. Lewis A. Stimson read a paper on "Old Unreduced Dislocations of the Elbow."

The following papers were read by title:

"Fractures Involving the Upper Third of the Femur, Exclusive of the Neck;" by Dr. O. H. Allis, Philadelphia.

"Fractures of the Bones Which Form the Elbow Joint, and Their Treatment;" by Dr. Levi C. Lane, San Francisco.

"Hæmiplegia With Aphasia, Following Ligature of the Common Carotid Artery;" by Dr. J. Ewing Mears, Philadelphia.

"Investigation of Pistol Shot Wounds of the Skull and Their Treatment;" by Dr. E. H. Bradford, Boston.

"The Results of Experiments in the Filling of Cavities of Bones Following Operations for Caries;" by Dr. E. H. Bradford, Boston.

After extending a vote of thanks to the retiring president the Association adjourned to meet in Boston, Mass., in June 1892.

Selected Formulæ.

SOLVENT FOR DIPHTHERITIC MEMBRANE.

℞
Pepsini..... ....ʒiss.
Ac. hydrochlor. dil.....ℳj.
Aq. dest.
Glycerini, aa.....ʒss.
M. Sig. Paint.

—*Canada Lancet.*

PILL FOR TUBERCULOSIS.

According to *L'Union Médical* Chauvin uses the following pill:

℞
Iodoform.....¾ grain.
Dover's powder.....1½ grains.
Extract of gentian enough to make a pill.

Give one pill three times a day immediately after meals.—*Med. News.*

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO, (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

CERTAIN CAUSES OF FAILURE IN THE USE OF PESSARIES.

The reason why the use of pessaries is condemned by some, is because they fail to appreciate the real status of the instrument. In order to accomplish definite results it must be used under definite conditions. Perhaps the most frequent cause of disappointment to the inexperienced physician in the use of the pessary, and of discomfort or even injury to the patient, is the failure to realize that pelvic inflammation—salpingo-oöphoritis—is either a relative or an absolute contra-indication to its employment. Malposition of the uterus is a matter of secondary and minor importance, in the presence of advanced tubo-ovarian inflammation. As well may we treat a uterine lesion when a large ovarian cystoma is present. Again malpositions of the uterus are frequently of a purely secondary or symptomatic nature. For example we have "anteflexion, and retroflexion with adhesions." This term simply illustrates the persistence of an old nomenclature. The real disease is almost always a chronic peritonitis, or the remnants of a peritonitis—the uterine malposition being simply an accident in the course of the disease. Whether it is best to attempt the reposition of the organ in such cases depends entirely on the nature of the peritonitis and the state of the tubes and ovaries. In some of these cases in which the tubo-ovarian condition does not require operation, an Emmetts pessary of suitable size will afford relief by taking off the strain from adhesions, but broadly speaking pessaries are contra-indicated in the entire class. Again retroversion or flexion and prolapse of the uterus growing out of laceration of the levator ani muscle is an illustration of malposition which is secondary or symptomatic. The lesion is the laceration. Other factors may enter into the case, as the tonicity of the tissues in general, the habits of the patient, etc., but the primary fact is the tear in the muscle, or, as it is generally stated, in the perineum. In this broad group of cases the utility of pessa-

ries is undoubted, but the results to be gotten in the individual case depends strictly upon the conditions present. The greater the muscular lesion, and the more the patient must do manual labor, the less can be accomplished by pessaries. When the supporting action of the pelvic floor is markedly deficient by reason of the laceration, a suitable plastic operation is indispensable to a cure. When this has been done the pessary may prove very useful in the cure of the uterine malposition which remains. But when the laceration is slight and the loss of support is but little, if the patient does not need to do manual labor, she can be made comfortable and relatively well by maintaining the uterus in its normal position by a suitable pessary.

The field in which the pessary is most useful, and its employment most logical, is in the treatment of simple retroversion and flexion, and prolapse. The rationale of its use is that it keeps the uterus in proper position, while the cause of the displacement is removed, and thus the secondary consequesces of the displacement are cured. For example, the retroversion due to subinvolution of the uterus following labor is curable by maintaining the uterus in proper position while the subinvolution is combated by local depletion, with glycerin or the artificial leech, by the use of ergot, the regulation of the bowels, attention to the general health, and the avoidance of undue exercise—lactation being maintained when possible.

Finally, the practitioner will experience the least disappointment in the use of the pessary, who will regard it as a mechanical agent capable of producing certain results only in a line of treatment, and who will consider the faithful employment of the other measures or agents indicated as being of equal importance in effecting a cure. Not only that, but he must have due regard for the contra-indications present. The pessary has done harm enough as a "cure all" for the manifold ailments of women, and the day should be past when it can be used as the "routine treatment."

SYPHILIS AND GASTRIC ULCER.

An interesting case is reported in the September number of the *British Medical Journal*, from the service of Dr. J. Keser, at the French Hospital, London. The point of interest is that it indicates that syphilis may greatly influence the course and treatment of gastric ulcer.

Dr. Keser's patient was an unmarried female aged 19 years, who presented on admission the classical symptoms of ulcer of the stomach. Careful treatment with various drugs failed to relieve her, and after about three months, with no improvement in her condition, it was discovered that she had condylomata on the labia majora and mucous patches on the tonsils. Antisyphilitic remedies were substituted for all other treatment, and a strikingly rapid improvement began and proceeded to an uninterrupted convalescence.

From the published account of this case, it would appear that the presence of the syphilitic virus in the blood can delay or even prevent the healing of a gastric ulcer, and therefore the presence or absence of syphilis becomes a proper subject for investigation in all cases of ulcer of the stomach, particularly in those resisting ordinary treatment.

CORRESPONDENCE.

A WORD FOR SURGERY OF THE PAST.

To the Editor of The Medical and Surgical Reporter:

In your journal of the 4th of July, in Dr. Rickett's excellent article on Nephrectomy, page 10, vol. LXV, he refers to Pean as having first in modern surgery performed Splenectomy. With your permission I would draw his attention to letter LXV, article 10, of Morgani's great work, where he will find recorded a case of successful Splenectomy performed by "the very excellent Fontana," and reported by him in his medical and anatomical observations. The patient, a woman, survived the operation for

five years "and having conceived and brought forth in the mean time; least any one should doubt of the extraction of this viscus, no spleen was found in any part of the body on dissection; only cicatraces appeared in the neighbouring parts; to which it is wont naturally to adhere." By this post I send you a copy of the *Medical Press and Circular* which contains some articles of medieval surgery of the kidney and abdomen.

Yours truly,

GEORGE FOY.

7 Cavendish Row, Rutland Square, Dublin.

BOOK REVIEWS.

THE SURGICAL TREATMENT OF WOUNDS AND OBSTRUCTIONS OF THE INTESTINES. By EDWARD MARTIN, M. D., and H. A. HARE, M. D., Philadelphia: W. B. Saunders, 1891.

This work was awarded the "Fiske Fund Prize" for 1890, as being the best essay presented upon the subject of which it treats. It is composed of an introductory and twelve other chapters, besides tables of cases of cœliotomy for gun-shot wounds of the abdomen, and a summary of the tables of these injuries. The subjects considered include the following: Congenital malformations, intussusception, internal strangulation, valvulus, obstruction from foreign bodies, intestinal paralysis, and chronic obstruction. A chapter on peritonitis is added, for the reason that it is such a frequent complication of intestinal obstruction. The relative merits of the opium and the saline treatment of peritonitis are discussed and the indications for each method of medication is pointed out. The chapter on peritonitis is followed by others on diagnosis, general, special and surgical treatment of obstruction of the intestines, etc.

The chapter on wounds of the intestine is very complete. Much of the material for this essay, is based upon considerable experimental work done in the laboratory, references to which appear throughout the book.

Taken in its entirety, the volume is a thorough treatise upon the subjects considered; the conclusion reached by the authors in every case being based upon clinical and experimental studies rather than upon personal prejudice or preference—which so often mars and lessens the scientific value of a work,—essentially one of reference.

We consider the present work an important addition to medical literature, and one which will amply repay the reader for time spent in its perusal.

A MANUAL OF DISEASES OF THE NOSE AND THROAT INCLUDING THE NOSE, NASO-PHARYNX, PHARYNX AND LARYNX. By PROCTER S. HUTCHINSON, M. R. C. S., London. P. Blakiston, Son & Co., Philadelphia, 1891.

This brochure, of nearly one hundred and thirty pages, amply fulfils the author's intention of supplying to the post-graduate student a concise and practical work upon this especial branch of medicine.

Hay fever, the author states is most prevalent in Europe during June and July, and in America during August and September. Nothing new is suggested in the treatment of this distressing complaint. The author advises, change of climate; when this is impossible, and the patient has to reside in the country during the hay season, a pair of spectacles with broad, closely fitting brims, and some form of nasal respirator should be worn. A veil sufficiently impervious to keep out the pollen is too hot for summer.

Locally, chromic acid (gr. 1–8, 1–16 to $\bar{3}$j water) is advised as a spray for the nose in some cases. Perchloride of mercury (1–3000) is also suggested; the author disapproves of the use of cocaine, as he thinks it is injurious if used over long periods. Nerve tonics are recommended, such as, quinine, nux vomica, and valerianate of zinc.

The book should certainly be considered as the *vade mecum* to the student of diseases of the nose and throat; and to all interested in acquiring a practical working knowledge of this branch of medicine, the work can be conscientiously recommended.

PERISCOPE.

THERAPEUTICS.

TREATMENT OF GALL-STONES.

According to Naunyn, *Centralblatt für klin. Medicin.*, about every tenth adult suffers from gall-stones. The disease is extremely chronic and painful. Latterly surgical interference has been resorted to, but there still remains much for the physician to do. It is necessary first to understand the mode of origin. Gall-stones are formed if the bile is laden with the ingredients that form them, and which are very insoluble, namely, cholesterin and billirubin-chalk.

The cause of the increase of this in the bile is disputed. One view states that the excretion of cholesterin and of chalk is too great —cholesterin because of anomalous metabolism, chalk because of two much chalk being in the food. The other view is that the bile has lost its power of dissolving these bodies. Cholesterin forms two per cent. of the solid ingredients of the bile, and this proportion is fairly constant, independent of disease or food, and also of the amount present in the blood. There is an increase, however, where there is catarrh of the bile passages. Chalk also is formed from the diseased mucous membrane, the amount otherwise being independent of the quantity taken with the food. Naunyn holds that it is untenable to look for the formation of gall-stones in decomposition of the bile. Physiological considerations have afforded no help in accounting for the formation of gall-stones. The frequency of the occurrence can only be safely based upon post-mortem examination. The per centage found after death varies from five to twelve per cent. with different competent observers. The differences of these observations are probably due to the fact that the gall-stones are easily overlooked. From all statistics three very important deductions can be made: (1) Gall-stones are four and a half times more frequent in women than in men. (4) Before thirty they are infrequent (two to three per cent. Schrœder), after that age they become much more frequent—ten per cent. In old age their frequency becomes strikingly increased—twenty-five per cent. over sixty years of age. (3) Women that have borne children are most frequently affected of all. Thus Schrœder found that among women with gall-stones ninety per cent. had borne children. It must therefore be concluded that the most distinct cause is the stagnation of the bile in its passages. In women this is favored by clothing and pregnancy, both of which retard those movements of the diaphragm that assist in the expulsion of the bile. The frequency of gall-stones in old age is due to retardation of the bile flow, through atrophy of the smooth muscles in the bile passages (Charcot). The stagnation produces disease of the mucous membranes of the passages, and the cholesterin and bilirubin-chalk arise in consequence of destruction of the epithelium. At first an amorphous deposit is formed, which by absorption of the fluid becomes granular. These granules increase by deposition of bilirubin-chalk, and the infiltration of cholesterin. The latter supplanting the bilirubin-chalk forms ultimately the beautiful pure white cholesterin-solitaire. A further secondary formation occurs in the deposition of carbonate of lime, of importance because the stone is then no longer soluble. The cause of the stone forming desquamative angio-cholitis is the retarded discharge of the bile, through which an infection of the bile passage is favored. It is also possible that the bacillus growth in the bile favors the formation of gall-stones. Probably it is in this manner that the intrahepatic stones are formed. In regard to symptoms there should be distinguished a regular form and an irregular form of the disease. The former occurs when there is simply lodgment of the calculus in the gall-bladder or passage of the stone along the duct. The irregular form is seen when there is infectious angio-cholitis with abscesses in the liver, fistula, and all other consequences. As a final issue of the regular gall-stone disease may be the formation of carcinoma in the biliary passages and the liver. In regard to the symptoms, it should be remembered that the stone is most often lodged in the cystic duct, giving rise to colic, and less often in the common bile duct; therefore the occurrence of jaundice is not so common. Further, it should be borne in mind the ease with which infection can arise, giving rise to biliary fever. The connection between gall-stone and food is not proven, so that it is not possible to recommend a prophylactic diet. For the removal of gall-stones, cholagogues are not to be depended on. After an abundant varied diet the bile flows more freely than after cholagogues. In practice, errors of diet should be avoided, and alkaline saline waters (particularly the hot Karlsbad) act beneficially. These act by increasing the peristaltic activity of the digestive tract, and increasing the flow of blood to the abdominal organs. In the peristalsis the bile passages participate, and the movement of the bowels act as a form of massage, while the diseased mucous membrane benefits by the increased flow of blood. The injection into the rectum of large quantities of hot water serves the same purpose.

. Fürbinger based his remarks on 64 cases he had carefully observed, so that there was no doubt of the diagnoses. Of these, 13 were men and 51 women. The chief site of pain did not lie in most of the cases in the right hypochondrium, but in the epigastrium, radiating from thence upwards and downwards. With jaundice there was enlargement of the liver, and the dilated gall-

bladder was not infrequently to be felt. In 24 out of 41 there was slight fever; considable slowing of the pulse can accompany the fever. In 30 out of 41 there was jaundice. Duration of attack showed a variation from transient to several days' duration, with intervals of weeks and years. The *corpus delicti* should always be looked for, and its absence does not vitiate the diagnosis. Very seldom was the stone perceived through a peculiar grating noise in the gall bladder. When there is fever, it is irregular and accompanied by other symptoms pointing to the liver. When protracted for weeks and months the victim declines with severe cachexia (liver phthisis). The local pain may not be excessive till there is inflammation and ulceration of the peritoneum, on account of the latency of the catarrh of the gall bladder and biliary passages. In suppurative inflammation of the liver, pain in the right hypochondrium and jaundice are frequently wanting. When perforation takes place into the peritoneal cavity a fatal peritonitis is set up by the decomposed bile. When a fistula is formed it is often very distant, and daily discharges quantities of bile and rarely gall-stones. Most frequently the perforation takes place into the small intestine. The gall-stone can here cause grave mischief (ileus, perityphlitis, etc). Finally there may be set up interstitial hepatitis (too frequently doubted) as well as adhesions between the liver and neighboring organs. The latter may be a source of great discomfort. In regard to the diagnosis, gall-stone disease was often mistaken for gastric ulcer, cramp of the bowel and stomach, renal colic, and hepatic neuralgia. Further, the pain may lie in any region of the abdomen save that of the liver. Slight jaundice is not easy to recognize, but is valuable when it does occur. Surgical interference should not be delayed too long in order to aid the diagnosis. The puncture of the gall bladder is dangerous. Care should be taken not to confuse the intermittent fever with malaria or typhus. In regard to prognosis of the attack it is favorable, but of the after condition rather grave, although the surgical methods have improved it. It is consoling to know that serious cases can obtain ultimate recovery by internal treatment. Of Fürbinger's cases thirty-four per cent. were cured, forty-two per cent. were improved, ten per cent. were unsuccessful, and fourteen per cent. died. Of the six treated by surgical means four recovered. In regard to treatment, it is necessary to prevent the formation, to remove the concrements, and to combat the tendency to the formation of gall-stones. Morphia and opium are the best agents for subduing the attacks of colic. It is folly to try to dissolve the stone. The endeavor must be made to increase the mechanical driving force of the bile and swell out the stone. Health resorts and springs have much success and not a few failures. The salicylate of soda and the oil cure has been useful in Fürbinger's hands. With the latter the liver becomes permeated with fat, and a saponified fat is formed which can be found in the stools as pseudo-gall-stone. While this treatment can often be borne, it sometimes gives rise to distressing dyspepsia. In regard to diet, more depends on temperance than on the choice or denial of certain foods. There is no value in theoretic or empiric reasoning, and there should only be excluded excessive fatty and sugary foods, alcohol of bad quality, and notoriously indigestible matters. Of high value are warm baths, rational clothing, dwelling in fresh air, and avoidance of over exertion. Fürbinger cannot praise the attempts to express the stone by kneading the gall bladder and pressing the liver. Notwithstanding the brilliant results of surgical practice, he thinks that the operative procedure should not be lightly undertaken. Still when all other means fail, and the patient is threatened with cholæmia and pyæmia, then he would advise surgical interference. The operative removal of cicatricial bands is often valuable.

Reidel gave his experience of thirty-two cases. Sixteen of these had not jaundice, on whom he operated. All recovered, and no fistula was left behind. Sixteen had jaundice and the result was not so satisfactory. Ten completely recovered, two were under treatment, and four died. Of these four, one died after complete extirpation of the gall-bladder, two were in an exhausted condition when they came under treatment, and one died in consequence of escape of bile into the peritoneal cavity.

ON THE LOCAL TREATMENT OF STRANGULATED HERNIA BY ETHER.

Dr. Finkelstein gave in 1882, from his own practice, 63 cases of strangulated hernia. Of these, five yielded to taxis. In 58 he employed "local etherization," taxis having failed, and of these 58 cases 54 proved successful. Of the four unsuccessful cases two underwent surgical operations and two died refusing operative treatment. Since then he has had numerous successful cases re-

ported from others and six in his own practice. (*Berlin Klin. Woch.*) As he remarks himself, the number of cases is sufficiently great, and the successful results speak plainly enough to give his method a status in the practice of medicine—or, at all events, a more extended trial.

The method is simplicity itself. The patient is placed on his back, with the hips slightly raised and legs flexed, and then every ten minutes or a quarter of an hour a table-spoonful of sulphuric ether is poured on the hernia-ring and tumor. The application of ether is carried on for, as a rule, from three-quarters to three hours (or even four hours) until the tense tumor relaxes and lessens a little. As soon as this occurs, and if the strangulated bowel does not reduce itself, several slight efforts are made to reduce it, and almost "always" it slips with a gurgle and amazing ease into the belly cavity.

If the omentum alone be strangulated, the ether method is absolutely useless. As the ether causes an after feeling of heat and burning on the penis, labia, etc., Dr. Koch (America) protects these and other sensitive parts by previously smearing them with olive oil, and in addition covering them with pledgets of cotton wadding.

The ether seems to act thus. Richter, Velpean, and others, hold that strangulation may in some cases be caused by spasm of the abdominal orifice. In these cases the ether may act by relaxing the spasm and thus reducing the bowel movable. That may be so, our author remarks, but he himself lays most stress on the property ether has of producing intense cold by rapid evaporation. The intense cold condenses the gas in the bowel, and by so doing diminishes its calibre. Possibly, also, the cold stimulates the peripheric nerves in the bowel sheath, and excites it to natural peristaltic action, which is more likely to empty it of gas, fluid and semifluid contents than the rude manipulations in taxis.

Hence it follows the less the vitality of the bowel is impaired by taxis, the more successful will be the etherization process. The method certainly deserves a trial.

MEDICINE.

RESPIRATION AND THE CARDIAC IMPULSE.

It is a well known fact, which is stated in all text-books, that the cardiac impulse changes its position with expiration and inspiration. By most authors this is considered to be due to the movement of the diaphragm. Eichhorst says, in his text-book of clinical examination, that if by any means the movement of the diaphragm is paralyzed, the changes in position of the heart's apex no longer occur. Riegel and Tuczek observed some cases in which during inspiration the apex beat became stronger and more perceptible, whilst the reverse took place with expiration. After death, adhesions were found between the pleuro and pericardium. Eichhorst has also recorded a case in which the same symptoms were noticed when a diffused bronchial catarrh was present, being especially severe in the anterior and lower part of the left lung. In accordance with the theory generally accepted, these phenomena are difficult to explain, but Dr. P. E. Livierato brings forward some observations which seem to show that the explanation of the variations in the position of the cardiac impulse with respiration is not, after all, the correct one. After describing the apparatus employed in his investigations, he gives the following conclusions at which he has arrived: (1) The heart may undergo under normal circumstances, considerable changes in its position, which are due to extraordinary movements of the lungs in respiration; (2) in ordinary respiration these changes are not appreciable; (3) the alterations in position of the heart are brought about chiefly by the increase in size of the lungs with inspiration, especially the left; (4) the influence of the diaphragm is only secondary; (5) the same changes of position of the heart can be produced in the dead body by artificial respiration when the diaphragm has no action; (6) in forced inspiration the heart moves to the right, downwards, and forwards; (7) the greatest changes are noticed when the subject is in a sitting position; (8) the movement of the heart to the right is more marked when the expansion of the right lung is prevented by some pathological condition; (9) the movement towards the right is always the one most easily observed, next the downward, the anterior movement being the least; (10) Dr. Livierato claims that such cases as were quoted above—namely, those of Riegel, Tuczek, and Eichhorst, add additional support to his theory; for in these cases the forward movement becomes very marked, since, owing either to the pleuro-pericardial adhesions or to the infiltration of the lower part of the lung, when a deep inspiration is taken the lung tends to push the heart apex more to the

front, and consequently accentuate the anterior movement. It is to be concluded from this that this phenomenon is not diagnostic of pleuro-pericardial adhesions as Riegel and Tuczek maintained.—*Lancet.*

COMPLICATIONS IN TWO THOUSAND FATAL CASES OF TYPHOID FEVER.

Holscher (*Munchener Med. Wochenschrift*, January, 1891,) reports 2,000 deaths from typhoid fever in which post mortems were held. Twenty-four per cent., or 480 cases, died from the immediate effects of the typhoid poison. Twenty-four cases are reported as sudden deaths, the cause of death in the majority of these being degeneration of the heart muscle. Tracheotomy was performed in fifteen cases, usually for perichondritis of larynx. Pregnancy is considered a serious complication. Out of 800 women in the series twenty-seven were pregnant. Five cases of "walking" typhoid are reported; two of these died from an error in diet, two of degeneration of the heart, and one of high grade anemia.

Relapse took place in 103 cases. This number—five per cent. of all the cases—is above the average usually given, but the author considers eight per cent. of fatal cases to have suffered relapse.

The proportion of males to females was as three to two; the average age was 27½ years. Of the males, one was over 75 years, and one a nursing infant. Of the females, one was 72 years, one 9 months.

Death took place in the third and fourth week in fifty per cent. of the cases; twenty-five per cent. occurred in the second and fifth weeks; two-and-a-half per cent. in the first week. Over fifty per cent. of those who died in the first week were free from complications.

The causes of death which reached five per cent. or over were the following: Edema of the lungs, fifteen per cent.; parenchymatous and fatty degeneration of the heart, thirteen per cent.; parenchymatous and fatty degeneration of the liver, ten per cent.; bronchitis, ten per cent,; lobular pneumonia, eight per cent.; croupous pneumonia, seven per cent.; hæmorrhagic lung infarct, six per cent.; perforation of the intestine, with peritonitis, six per cent.; intestinal hæmorrhage and edema of the brain, each five per cent. —*Univ. Med. Mag.*

HEMIOPIA, HEMIANOPIA, HEMIANOPSIA.

The correct use of these words is not well understood and much confusion often results. *Hemiopia* is an old word and signifies literally "half vision," and has always been used to designate that condition in which a person sees only one-half of objects. *Hemianopia* and *Hemianopsia* are synonimous and are new words, recently introduced for the purpose of more correctly expressing the visual changes that follow certain pathological conditions of the brain and signify absence of vision (blindness), in one-half of the field. The little particle, *an*, gives both words a negative signfication, the opposite of vision, blindness. These words are not found in the medical dictionaries, having only recently come into use. They are good words and are much to be preferred to hemiopia, since it is much more important to use a word that will express the absence of the function of vision in certain parts of the field of vision, rather than its presence in certain other parts, not designated, are blind. To illustrate: When I say there is "left lateral hemianopia or hemianopsia," I mean to say (and these words express my meaning exactly), that the left half of the field of vision is blind (absence of vision in that part of the field). If I use the old word, and say there is "left lateral hemiopia," I mean that the vision is still present in the left half of the field of vision, leaving it to be inferred that the right half of the field is blind. It must always be understood that the part of the retina involved is the opposite part to that of the field designated.

This subject is the more important because it plays such an important part in most cases of cerebral localization.—*St. Louis Med. and Surg. Jour.*

THE ÆTIOLOGY OF CHEYNE-STOKES RESPIRATION.

At a meeting of the Section in Medicine of the Royal Academy of Medicine in Ireland, held on May 22d, Dr. M. A. Boyd read a paper in which he reviewed all the physiological explanations of this phenomenon offered by writers on the subject since Stoke's time to the present day. He particularly pointed out the very rational explanations offered by Traube and Filehene, who regarded the respiratory derangement from the altered nutrition of the respiratory-center point of view; and of those of the Dublin school, including Hayden and Little, who regarded it primarily from the cardiac point of view, and complimented the Dublin School as offering by far the best evidence, both clinically and

pathologically, in explanation of the phenomenon. Dr. Boyd, having alluded to the marked rythmical irregularities between the heart pulse and respirations in this affection, drew attention to a point which heretofore in the literature of the subject, so far as he was aware, had not been alluded to—namely, that the latter portion of the forced respiratory phase of the Cheyne-Stokes cycle was chiefly an expiratory one, in contrast to the first portion of it, which was an inspiratory one; and that this forced expiration had a most important bearing on the weak ventricles of the heart, by helping them to squeeze the blood, on the one side into the pulmonary artery, and on the other into the dilated and inelastic aorta. In proof of this, he exhibited sphygmographic tracings showing that it was only during this expiratory portion of the respiration that arterial tension was raised in the arteries, and that this tension continued through the apnœal period following, during which time the respiratory center was fully supplied with arterial blood and the weak and degenerated left ventricle resting. He regarded the apnœal period, during which time respiration was suspended, as only an effort on the part of the higher automatic centers to rest a heart the ventricle of which was too feeble to charge an arterial system the aorta of which might be dilated and inelastic, or the vaso-motor control of which might be defective, and whose own blood supply might be rendered insufficient in consequence, and its nutrition enfeebled. After the intrinsic muscle of the heart had been fed by this increased arterial tension of the expiratory and apnœal periods, forced inspirations began again, and the heart contractions were stronger, but they failed to fill the dilated aorta until the forced expirations, by making pressure on the ventricles, came to their aid again.

The most typical and pronounced forms of Cheyne-Stokes respiration were to be met with in alterations of the heart and aorta produced by degeneration and disease. The forms of it met with in cerebral disease, or injury, and in apoplexy and uræmic coma, without any primary engagement of the heart, he regarded as due to direct interference with the respiratory center in the medulla, either by pressure or by poisoned blood, and the phases of it were never so well marked as in those cases of the affection depending primarily on alterations in the heart.

Owing to its dual origin in this way came the differences of opinion as regarded its pathology. As regarded its treatment, Dr. Boyd found so much improvement following the inhalation of oxygen in all the cases where disease or degeneration of the heart produced it, that he urged a trial of this remedy in all such cases, and ventured to suggest, from his experience of the remedy, that it should be tried not alone in this affection but in all cases where degeneration of the heart existed from any other cause.—*N. Y. Med. Jour.*

SURGERY.

THE OPERATIVE TREATMENT OF SQUINT.

The careful investigations by numerous observers, beginning with Donders, of the conditions which give rise to non-paralytic strabismus, have, as might naturally have been anticipated, led to considerable modifications in the treatment of this deformity. The very noticeable result of the increased knowledge of the pathogenesis of squint has been a great diminution in the number of cases subjected to operation. Not very many years ago cases of squint in children were treated by tenotomy with little or no attempt to correct the ametropia almost constantly present. The results of these indiscriminate tenotomies were often disastrous; the deformity for which the operation was undertaken being followed by one even more noticeable. It was for the correction of this latter condition that the operation of advancement or readjustment of the recti muscles of the eye was introduced. In recent years, however, this procedure, in one of its numerous modifications, has come into use as the primary operation in the treatment of many cases of strabismus and, as indicated by a recent discussion at the Ophthalmological Society, finds favor with many surgeons. The greater confidence with which a definite result can be foretold, and the much greater effect which can be produced by this method of operating than by simple tenotomy, seem good reasons for advocating its adoption in high degrees of squint, especially in those cases, probably a large majority of the total number, in which the deviating eye is amblyopic.—*Brit. Med. Jour.*

THE RADICAL CURE OF LARYNGEAL PHTHISIS BY ENDOLARYNGEAL SURGICAL TREATMENT.

A number of interesting cases are narrated by Dr. Th. Heryng, and the following indications for the use of the curette are enumerated:

1. In limited infiltrations or ulcerations of the posterior wall of the larynx and in recent unilateral infiltrations of the epiglottis, which are sometimes the beginning of laryngeal phthisis. Here the double curette of Krause is indicated.

2. In the infiltrations and deep ulcerations of the ventricular bands where one may use the author's curette, or the instrument of Krause or Landgraf.

3. In the hypertrophic ulcerations covered with granulations which spring from the surface or the borders of the vocal bands and sometimes induce dangerous stenosis; for a similar reason in polypoid formations, in tubercular tumors, etc.—*Annales des mal. de l'oreille, du larynx,* etc.—*Epitome.*

MEDICATED INTRAOCULAR INJECTIONS.

M. Abadie injected 1 drop doses of a 1:1000 sublimate solution into an eye affected with rebellious syphilis with most gratifying results. We know how helpless we are in cases of hæmorrhagic glaucoma in which neither sclerotomy nor iridectomy give relief, and where the pain is so intense as to threaten the necessity of enucleation. M. Abadie has succeeded several times in calming the pain and saving the eye by injecting a drop of ergotine into the vitreous. He also obtained good results from the injection of the same remedy in an eye affected by hydrophthalmia, in which there was evidence of intraocular hæmorrhage. He mentions the favorable results obtained from sublimate injections in certain cases of septic infection of the cornea, and in severe forms of macular retino-choroiditis. He thinks the intraocular injections should be followed for some time with subcutaneous ocular injections of sublimate with a view of preventing recurrence of the trouble. M. Darier employs subconjunctival sublimate injections in various ocular troubles supposed to be infectious. Grave forms of specific iritis and cases of the gumma of the iris recover much more quickly with this method than under the usual treatment. This is also true of corneal affections of similar origin, as well as certain acute forms of iritis, in which it is impossible to be certain of the specific nature. Subconjunctival injections are indicated in all cases where it is necessary to reach the trouble in the shortest possible time. No other plan of medication gives such prompt result. A perfectly aseptic solution and syringe must be used. A dose of $\frac{1}{20}$ milligramme at each injection every three days should be given four or five times. It is well to combine the subconjunctival injections with subcutaneous treatment when mercury is indicated. De Wecker opposes the practice of injecting into the vitreous. In a severe case of syphilitic retino-choroiditis one drop of 1:1000 of sublimate solution resulted very unfavorably. —*Union Médical.*

OPERATIVE TREATMENT OF PERITONITIS.

Dr. J. F. W. Ross (*Canada Lancet*) concludes:

(1) That in typhoid-perforation, operation is useless.

(2) That in traumatic general peritonitis, and in all cases of general peritonitis, the abdomen should be opened, washed out and drained, and the cause of the peritonitis found and removed.

(3) That in cases of localized peritonitis, and in obscure cases of injury not followed by general peritonitis, it is better to follow an expectant plan of treatment, unless abscess formation can be made out.

(4) That in all cases of abscess formation, opening and draining will give the most rapid convalescence, and will prevent unfavorable rupture into other parts.

(5) That in view of the complications that may be found after opening the abdomen, the best interests of the patient will be consulted by having the operation done by some one accustomed to do abdominal surgery.

EXCISION OF THE SCAPULA.

At a meeting of the Medico-Chirurgical Society of Bologna on April 19th, the President, Professor Putti (*Riforma Medica,* May 1st, 1891) related two cases in which he had completely extirpated the scapula, leaving the other elements of the shoulder and the arm intact. In both cases the greater part of the muscles covering the bone and portions of those attached to it were removed at the same time. In one of the cases (a man, aged 45, with osteosarcoma of the scapula) the operation had been performed two years previously, the patient dying fourteen months after it of acute enterocolitis; the other (a woman with a myxomatous osteochondrosarcoma of the scapula, who was shown to the Society) had been operated on recently. In both cases, after removal of the bone, an attempt had been made to form a new joint by placing the articular head of the humerus under the acromial end of the clavicle, and suturing the remains of the capsule to the portions of the excised muscles which were

left behind. The deltoid was made to cover the new joint as closely as possible, and fixed in position with sutures. The new joint proved a success in each case, there being a fair amount of mobility and considerable muscular power. The man, indeed, had been able to resume the lighter part of his work as a farm laborer. Professor Putti pointed out that the published statistics of excision of the scapula were for the most part misleading, inasmuch as they included cases of resection of larger or smaller portions of the bone as well as cases of complete removal.—*Brit. Med. Jour.*

PALLIATIVE OPERATIONS IN CASES OF ENLARGED PROSTATE.

Vignard (*Annal des Malad. des Org. Génito-urinê.*, vol. x, 1891; *Centralbl.f. Chir.*, No. 10, 1891) believes that in the very great majority of cases of hypertrophy of the prostate, bloodless therapeutic measures are sufficient. He would recommend surgical intervention—that is, puncture of the bladder or supra-pubic cystotomy, or the boutonniére operation—only in cases of retention where catheterization is impossible, and where septic urine absolutely requires evacuation; in cases where great difficulty in passing the catheter is not relieved by permanent catheterization; and in cases of cystitis not relieved by careful and long-continued medication. In the first two instances the boutonniére operation is indicated, whilst where cystitis is present supra-pubic cystotomy should be practised.—*Amer. Jour. Med. Sci.*

GYNÆCOLOGY.

JAUNDICE IN CHILDBED.

M. Labusquière (*Revue. Obstét. et Gynéc.*, February, 1891) attended in December the confinement of a married woman of emotional temperament. The catamenia were always painful, and associated at their commencement with sharp hypogastric pains and marked anæmia. Attacks of urticaria were frequent. She burst into tears on one occasion because the doctor called and saw her before she had time to adorn herself like a fashionable convalescent. Labor was lingering, and the forceps were applied under chloroform. She manifested extreme alarm when informed that the use of instruments and chloroform was necessary. The child was saved. On the second day the patient was observed to be jaundiced. There was no pain in the hepatic region, but the gall-bladder was very tender on pressure. The milk, as well as the urine, contained biliary pigments. The jaundice subsided within a few days; as it disappeared the patient was troubled with severe itching of the skin and a mild attack of urticaria. The patient made a good recovery, and was able, after the cessation of jaundice, to suckle her child. M. Labusquiére refers to the icterus of menstruation noted by Senator and others. Pilliet has recently written on the liver in eclamptic cases, and jaundice occurring in puerperal eclampsia is an extremely grave symptom. In M. Labusquiére's case the jaundice was simple. The lingering labor might have involved much disturbance of the circulation of the liver. The chloroform might have played some part in causing the complication, though not quite two ounces were used for a long forceps delivery. It appears most probable, however, in M. Labusquiére's opinion, that mental agitation was the cause of the jaundice. Emotion may set up vasomotor disturbance in the liver and consequent excessive secretion of bile. On the other hand, it may act, as Potain believes, by causing spasm of the muscular elements of the bile ducts. The patient had been a spoilt child, and her health was permanently enfeebled by severe attacks of several febrile disorders in infancy.—*Brit. Med. Jour.*

TREATMENT OF PUERPERAL ECLAMPSIA.

Lohlein has collected 325 cases of eclampsia observed in 52,325 puerperal women; *i. e.*, 1 case in 161 labors. The mortality was 19 per 100, and has not been reduced in later years. In a few cases Lohlein performed Cæsarean section, which offers the last chance of saving the life of the mother, although the convulsions do not always cease after extraction of the fœtus. It also affords sufficient hope to warrant recourse to it when the life of the fœtus is endangered. Véit advises morphine in large doses, which gives fairly good results, reducing the mortality to 13.8 per 100. Chrobak prefers chloroform to morphine. Schmorl announces the existence of hæmorrhagic foci either about the portal veins or about the capillaries. The walls of the vessels are frequently ruptured. Emboli are produced by special cells which originate, according to Klebs, in the liver, and according to Schmorl, in the placenta.—*Union Médicale*, June 2, 1891.

OBSTETRICS.

TREATMENT OF PLACENTA PRAEVIA.

Wyder (address at the thirty-ninth meeting of the "Aerztliche Centralverin" in Zurich) rejects the method much in use by practitioners, of tamponade of the vagina with following internal version and extraction of the child, and recommends in its place the method of Braxton Hicks, which has been for a few years in vogue at the principal German clinics, under the lead of Schröder and Gusserow.

The principal disadvantages of the former method Wyder sets forth as:

1. Hæmorrhage from the patulent uterine sinus is not certainly checked by the tamponade. Moreover, in case the waters have broken away, this procedure is absolutely contra-indicated on account of possible internal hæmorrhage.

2. In the manipulations of this method there is always great danger of infection which even the most rigid observance of antiseptic precautions cannot always prevent.

3. In the effort to extract the child immediately after version injuries are often inflicted upon the lower uterine segment.

4. A farther difficulty is encountered in the profuse hæmorrhage of the third stage of labor, and the manual extraction of the placenta with its attending results, rendered necessary by the bleeding.

5. An additional disadvantage of the tamponade is the enormous loss of time to the busy practitioner unavoidable on account of the extremely close attention necessary throughout the whole procedure.

Braxton Hicks' method overcomes all these disadvantages in that at the same time the farther separation of the placenta is hindered by the early discharge of the water; the hæmorrhage attendant upon the manœuvre is completely checked by the natural tamponade,—the breech of the child filling the whole pelvis and in an aseptic fashion.

In Schröder's words the procedure is "rupture the membranes and pull down the foot." Where the case is one of breech presentation this is very simple, but where we have a head or cross presentation it is necessary to turn for the sake of bringing down the foot and should the cervix be undilated, version must be accomplished by Braxton Hicks' method.

After turning and pulling down the foot, the expulsion of the child must be left as far as possible to natural forces. Only immediately impending danger to mother or child affords indication for extraction. Digital separation of the placenta must also be avoided as far as possible.

For carrying out the version in case the mouth of the womb be fully occupied by the placenta, Wyder recommends thrusting the finger through the placentar tissue while with the other hand the presenting part is pressed against the finger. The hæmorrhage following the injury to the placenta—though it comes principally from the placental circulation of the child—is insignificant. The principal objection made hitherto to this method is the great mortality to the child. Wyder justly offsets this by the relatively greater mortality to the mother under the older procedure. By the latter the mortality of mothers was 30–40 per cent. while by combined version in Schröder's and Gusserow's clinics it was 6–7 per cent.

The mortality of children under the older method amounted to 50–70 per cent. and of those who were born alive 30–40 per cent. perished from inanition. The statistics of the clinics mentioned show for the other method a mortality of 70–80 per cent. of the children.—*Therapeutic Monatshefte.*

FIVE CASES OF ECTOPIC PREGNANCY.

Foerster (*Med. Monatsschrift,* November, 1890) remarks that, notwithstanding the many contributions to this subject in recent times, there are still many things regarding it that are obscure. Especially is this true in regard to its ætiology. Even those who have had most experience with this condition are still in the dark in regard to important particulars. There are many cases that are so complicated by peritoneal adhesions that they present the greatest difficulties or are quite unsuitable for operation. The author agrees with those who believe that prior to rupture this condition is almost impossible of diagnosis. His experience includes five cases which have been seen within the past two years. Four of the patients were operated upon—two with a successful and two with a fatal result. The fifth patient died of hæmorrhage, no operation having been attempted. The pains, which resemble labor pains in these cases, are regarded as an important factor in establishing the diagnosis. The atypical hæmorrhages from the uterus should also excite suspicion of this condition, as has been observed by many authors. Other important diagnostic factors are the enlargement

of the uterus, its mobility, the sense of its emptiness when the sound is passed, and the activity of the mammary glands; also the anæmic condition of the patient, which is usually present. As to the operation in such cases, it should be performed as rapidly as possible, and it is doubtless well to leave a large quantity of hot water in the abdominal cavity to be absorbed, and thus take the place of the blood which has been lost.

PÆDIATRICS.

IRRIGATION OF THE STOMACH OF SMALL CHILDREN FOR THERAPEUTIC PURPOSES.

The following are the conclusions of Troitzky (*Arch. f. Kinderh.*, Bd. xii. 5, 6):

1. Irrigation of the stomach is a valuable agent for the treatment of beginning disorders of the stomach and intestines, if used at the proper time. It may prevent their transformation into severe or dangerous conditions. The favorable results to be obtained are the more evident the earlier in the history of the disease this treatment is undertaken.

2. The most favorable cases for cure by this means of treatment alone are the dyspepsias which are unattended by fever, the gastric form will yield most readily, the mixed gastric and intestinal form less readily, and the intestinal form least readily. The chronic forms of dyspepsia yield to this treatment less readily than the acute, and the different varieties yield in the same order as mentioned for the acute forms.

3. Irrigation is also useful for the quickly-developing disorders of the stomach and bowels, for example, the specific form of diarrhœa. But it should be used in conjunction with other therapeutic means.

4. The subacute and chronic disorders of the stomach and bowels may gradually be overcome if, with the irrigation of the stomach and the internal medication, careful efforts are observed to strengthen the system at large.—*Archives Pœdiatrics.*

ANTIPYRETICS IN INFANTILE THERAPEUTICS.

Investigations by Demme (*La Cronica Med.*) were made at the hospital at Bern. From these it was deduced that in temperatures from 38.5° C. to 39.5° C. of brief duration there is no indication for the use of antipyretics. For such conditions cold packs are preferable, and if there is insomnia and restlessness, baths at 25° C. to 28° C. for five or ten minutes should be given twice daily. The elevated temperatures are those which call for particular attention, though one must also take into consideration their cause, and the resisting power of the patient. In typhoid fever, acute rheumatism, and broncho-pneumonia they fill an important indication, but not in diphtheria, the exanthemata, or fibrinous pneumonia. It is not advisable to combine the use of antipyretics and cold baths; with the former warm baths should be used. In cases in which there is cyanosis the warm bath may be used and cold affusions to the head and nucha. If the digestive tract is tolerant, one may use salicylate of soda internally, but salol should be used if there is a tendency to vomiting and diarrhœa. Of the former, half a gramme to a gramme may be given to children two to four years of age, one to two grammes to those of five to ten years, two to three grammes from eleven to fifteen years. Of salol, twenty-five to thirty centigrammes may be given three times daily to children of two to four years, fifty to seventy-five centigrammes three or four times daily to those of five to ten years, seventy-five to one hundred centrigrammes three to four times daily to those of eleven to fifteen years. Thalline has been used by the author with good results, but it will sometimes produce collapse. In broncho-pneumonia the use of antipyrin in an aromatic solution with a small quantity of alcohol is recommended, provided it does not produce digestive disturbance. The dosage is twenty to forty centigrammes every hour for the ages two to four, fifty to seventy-five centigrammes from five to ten, seventy-five to one hundred centigrammes from eleven to fifteen. Should hectic fever supervene in the course of a broncho-pneumonia, quinine should be substitued for antipyrin.—*Archives Pœdiatrics.*

THE USE OF PURE BENZOLE IN WHOOPING COUGH.

Dr. W. Robertson, writes in the *Lancet* that after some years' experience of the use of benzole in whooping-cough he can safely say that it effects better results than all the other remedies recognized as useful in this affection. In the adult and child it is of equal benefit. In an infant just now under treatment the attacks have been reduced from twenty or thirty in the night to two or three, and whereas when the treatment was

begun evidences of bronchitis were present, now the chest is clear and the child able to be taken out of doors daily. All this improvement was brought about in less than ten days. He has administered benzole in whooping cough, where convulsions and other complications were fast reducing all chances of recovery, with perfect success in a few days. In adults, where pertussis assumes often serious aspects, benzole has proved equally efficacious. Two minims in mucilage are sufficient for a child six months old, and five minims in mucilage on sugar or in capsule for adults. Whenever the benzole odor is observed in the breath of the patient, then all anxiety as to the result may be allayed.

HYGIENE.

CARBOLIC ACID, CREOLIN AND LYSOL.

From *Revue D'Hygiene* we extract the following notes on the work of Drs. Remonchemps and Sugg, relative to the comparative disinfecting values of carbolic acid, creolin and lysol. The last is a comparatively new addition to the list of disinfectants. The result of various studies of creolin were given in the Fifth Annual Report.

The authors used the bacilli and spores of anthrax, of typhoid fever, and of cholera in their provings. On the free spores the agents all act slowly; creolin and lysol act a little more promptly than carbolic acid on cultures in bouillon, but the difference would not amount to much in practice. There is, however, an important element of safety, due to the difference in the poisonous properties of these agents. While it took only 0.30 gramme of carbolic acid to kill a given weight of rabbit, it required 1.10 of creolin or 2.30 of lysol.

One interesting point brought out is that spots on clothing soiled with fœcal discharges of typhoid fever and cholera patients may be completely sterilized in two hours in a one per cent. solution of any one of these agents cold, but if warmed to 122° F. the sterilization is complete in thirty minutes.

With lysol, disinfection of the hands and instruments was accomplished with a five per cent. solution in five seconds, especially when warm; with a two and one-half per cent. solution, ulcers and cavities were disinfected in five minutes.

Lysol is a thick, light brown liquid with a specific gravity of 1.042. It is perfectly soluble in water, and forms a clear solution in contradistinction to creolin which forms a milky opaque emulsion. In washing in a solution of lysol it forms a lather, and thus, while exerting the action of a disinfectant, it plays the part of a soap. It, therefore, has the advantage of easily and rapidly permeating tissues with which it is brought into contact.—*Sanitary Inspector.*

STERILITY OF FAT PEOPLE.

Obesity is an obstacle to fecundation in all animals; and this law obtains also in the vegetable kingdom. Hippocrates enrolled this among his aphorisms. As proof, he cited the frequent sterility of the Scythian women, often fat, in comparison with the remarkable fecundity of their slaves, who become pregnant upon the least provocation.

Without seeking for demonstrative instances in Eastern countries, M. H. Kisch (*Le Bull. Med.*) has ascertained that while sterility exists on an average in one household in ten, or at least in more than one in eight—six among the aristocracy—this proportion is increased to one in five when the wife or both parties are fat; if we reckon families which have only one child, in such cases there will be found a proportion of one to four.

It is useless to insist that mechanical obstacles, in consequence of obesity on the part of one or the other, and especially on the part of both, to sexual congress are the cause. It should be observed that this condition is habitually accompanied by a decided frigidity. In addition, M. Kisch has observed that, though the virile power is preserved, the spermatic fluid is often destitute of spermatozoids (9 per cent.,) and even then they evince but little vitality.

With the woman, whose role in sterility is the most important, obesity is accompanied by a premature menopause; or if continued, the discharge is scant, void of color, and scarcely existent. Catarrhal affections of the vulva and of the uterus are frequent in such cases; and these concomitants are important in this regard.

It has been observed that when a regime, well advised and pursued, has resulted in removing, at least in part, the obesity, the genital sense revives, and with it the prolific aptitudes. On the other hand, if obesity is the occasion of sterility, it does not always entail deplorable consequences, and non-sterile women who are fat are no rarity.—*Weekly Medical Review.*

MEDICAL CHEMISTRY.

RAPID ESTIMATION OF NITRATES IN WATER.

In place of the present somewhat cumbersome methods in vogue for detecting the presence of, and estimating (approximately) the quantity of, nitrates in drinking water, George Harrow (in *Jour. Chem. Soc.*) proposes a new method, which is based upon Griess' color test for nitrous acid, the nitrate being for this purpose previously reduced by zinc dust. The author says:

The method which I have devised for this purpose is founded on Griess' extremely sensitive nitrite test (alpha-naphthylamine and sulphanilic acid), and depends on the conversion of nitric acid into nitrous acid by means of zinc dust; that this conversion is a partial one, and that other products—ammonia and hydroxylamine—are formed, does not affect the delicacy of the test or the accuracy of the determination.

The test solution used consists of

Alpha-Naphthylamine	1 Gm.
Sulphanilic Acid	1 Gm.
Ordinary strong Hydrochloric Acid	25 C.c.

dissolved in about 200 C.c. of distilled water, boiled with a small quantity of animal charcoal, filtered, and made up to 500 C.c.

There are also required standard solutions containing

1.0 part N as nitrates per 100,000
0.1 " " " " " "
0.01 " " " " " "

To prepare these solutions, 0.721 Gm. of pure and dry potassium nitrate is dissolved in 1 liter of water; the resulting solution contains 10 parts of N per 100,000, and may be readily diluted to the strength required. If many water analyses are to be made, it is as well to make up a quart of each of the standards.

A small quantity of zinc dust is also required, contained in a wide-mouthed bottle, into the cork of which a miniature spatula, constructed of brass or platinum foil, should be fixed.

The process is conducted as follows: Fifty C.c. of each water to be tested—and as many as four estimations may readily be conducted at the same time—are placed in beakers (100 C.c. contents) side by side on a sheet of white paper, and with them, in three smaller beakers, 50 C.c. of each of the standard nitrate solutions; to each beaker is now added 10 C.c. of the test solution, and afterwards a very small quantity of zinc dust (7 to 8 Mgm.) by means of the miniature spatula; the quantity added should be approximately the same in each case, and I find that there is no difficulty in effecting this. If nitrate be present in the waters a more or less intense pink color will make its appearance, and this color may be compared with that produced in the three standard nitrate solutions, after the lapse of fifteen minutes; a rough approximation to the truth is obtained in this first experiment.*

To get an accurate result the water must be diluted until the color produced is very nearly like that given by one of the standards; perhaps the greatest accuracy may be obtained with the most dilute standard, and, if it be used, a hundredfold dilution of the water to be tested is frequently advisable; the necessary dilution is, of course, indicated by the first experiment.

The diluted waters are again tested against standards 0.1 or 0.01, and, after fifteen minutes, the colors carefully compared in Nesslerizing cylinders of equal calibre, which may be conveniently graduated at the side. The standard solution occupying 60 C.c. in one cylinder, the water tested is run into the other until the depth of color appears to be equal; a reading is then made of the quantity necessary. Say 45 C.c. were employed: then 45 : 60 :: 0.1 : x (=0.133); and supposing the water to have been ten times diluted, it would contain 1.33 parts nitrogen as nitrates and nitrites.

The advantages of the process are its rapidity, simplicity, and ease of execution, and the small quantity of water required for analysis. Twenty C.c. are sufficient for the purpose, and enable one to make several determinations.

The only precaution necessary, so far as I have observed, is to avoid the addition of large quantities of zinc dust, which would decolorize the solution.—*Amer. Drug.*

*If *nitrites* are present the pink color will, of course, appear without the addition of zinc dust: Griess' test.

NEWS AND MISCELLANY.

THE HUDSON COUNTY, (N. J.,) MEDICAL SOCIETY.

Dr. Thomas H. Manley, of New York was the guest of the Hudson Co. (N. J.) Medical Society on the evening of October 6th and presented an essay entitled "The Etiology or Causation of Inguinal-Hernia, in the Male Sex."

ADVICE TO A YOUNG PHYSICIAN.

The following letter, written eighty years ago by Dr. Benjamin Rush, applies so well to present conditions and is so full of sound advice that we publish it here:

"PHILADELPHIA, April 21, 1812.

"DEAR SIR:—The facility with which a medical education is acquired in our country has multiplied physicians to such a degree that I do not know of a spot in the United States in which you would fix yourself with more advantage than in the one you now occupy. Competition and slow pay are now the conditions of a medical life everywhere. My advice to you is to remain where you are; you will grow with the growth of the settlement. Purchase upon credit, if possible, a small farm; a little debt will make you industrious and furnish you with an excuse to send in your bills as soon as your patients recover. Employ the leisure which a healthy season will give you in agricultural labors; the more you will obtain in this way the more independent you will be of your patients, and, of course, the more you will be courted by them. Happiness does not consist in wealth. A competence, books, alternate labor and ease, to use the words of the poet Thomson, a good wife, a few friends, vicinity to a church, and conduct regulated by the principles of the Gospel constitute the sum total of all the happiness this world is capable of giving, and these may all be possessed and enjoyed in your present situation.

"From, dear Doctor,

"Yours truly and affectionately,

"BENJ. RUSH.

"To DR. PETRIKEN."—*Med. Rec.*

THE CANCER GRAFTS.

"Full many a shaft at random sent," as the poet observes, "finds mark the archer little meant." This remark certainly finds application in the *ricochet* at Berlin of the scandal evoked at Paris by M. Cornil's communication on the grafting experiments. The most careful scrutiny by journalists in quest of provender has failed to fix the crime on any French surgeons, but the attention thus directed to the subject has had for effect to focus the bull's eye glare of public opinion on certain observations rendered by Drs. Hahn and von Berkmann, in the *Deutsche Medizinische Wochenschrift* as long ago as November, 1887. These gentlemen, indeed, gave the results of their experiments in this direction, these results coinciding with those chronicled by M. Cornill's anonymous correspondent. It will be seen, however, from our German correspondence that the whole affair is an old one revived for the dead season, and that the cancer bacillus—as mythical as the sea serpent—has been called into existence to fill a hiatus. It is, indeed, the fact, that years ago both Prof. Hahn and Prof. von Bergmann, in order to ascertain whether cancer could be transferred from one body to another, did persuade some patients who were hopelessly ill from the disease to allow them to try if cancer growing in one part of the body could be made to grow in another, and with the patients' free consent a small piece of cancerous tissue was removed from one breast and inserted into the flesh of the other, which was up to then free from disease, with the result that the transplanted piece "took root" and grew. Such experiments are, in our opinion, however, unjustifiable, as they are a direct violation of the Hippocratic canon that the art of medicine has but two legitimate objects, viz., the promulgation of human life, and the relief of human suffering, and it cannot be said that either was fulfilled in the case of the objects experimented on. Every professional man will regret that any explanatio on such a subject has been called for—a denial would have been infinitely more satisfactory. It is curious that the facts as related should not have excited criticism at the time. Their having been allowed to pass unchallenged looks as if professional indignation were but an echo, and a consequence of outside pressure. We know, of course, that in truth our ignorance is more to blame than our want of humanity. No English surgeon would even have dared to accuse himself publicly in any of our medical societies of such a gross breach of his duty to his patient, for without undue insular pride, we venture to assert he would thereby have irrevocably sealed his professional doom.—*Med. Press.*

THE LAW AS REGARDS TWINS.

When twins are born in France, the last born is considered by the law the eldest! Consequently, if both survive, and, in case of boys, reach manhood, the second is called to the army to serve, being pronounced the eldest. By some extraordinary calculation the medical men who were consulted at the passing of the act years ago came to the conclusion that the last born of twins was always the first conceived.—*Medical Press and Circular.*

WHAT DID SHAKESPEARE DIE OF?

There is a tradition of very respectable antiquity that he died of a fever contracted through going on a drinking bout with Ben Jonson and other boon companions. Mr. J. F. Nisbet, in his new work, "The Insanity of Genius," discusses the question from an entirely new point of view, that of pathology. In the author's opinion, Shakespeare died of paralysis, or some disease akin to paralysis. The signature to the will, he holds, affords strong presumption of this, but he has also other facts to adduce in support of this theory. In 1657, Dr. Hall's medical cure-book was published by James Cooke, "A practitioner in physick and chirurgery." Dr. Hall, as is well known, was Shakespeare's son-in-law, and his book proves beyond doubt that nervous disease existed in Shakespeare's family, a fact which Mr. Nisbet considers accounts for the short average duration of the lives of its members, and the speedy extinction of the line of Shakespeare's direct descendants.—*Medical Times.*

YALOO, THE DOUBLE-BODIED HINDOO LAD.

Dr. Geo. Bleything, having examined the double-bodied Hindoo lad recently brought to this country, has made the following report in regard to him: "I find him to be a remarkable case of arrested development in fœtal life. The boy himself is a fine, bright, well-developed youth of eighteen years, and attached to the extremity of his sternum is the incomplete body of a twin. The arms are given out from the attachment to the sternum of the young man, without scapulæ. The trunk is short and incomplete, but terminates in a pelvis, with which the legs are connected. There would seem to be no separate heart in the parasite, and the pulse, both radial and axillary, is synchronous with that of the autosite. There is anchylosis of the joints in the undeveloped child. The young man is conscious of a sensation when this second body is roughly touched." The parasitic growth appears to give him very little inconvenience, and he is very agile in his movements.—*Bost. Med. Surg. Jour.*

TUBERCULOSIS IN MEXICO.

Dr. D. Orvañanos states that the federal district of the Republic is a proper place for the prevention and cure of consumption. The elevation of the country varies from 2300 to 2900 metres (7550 to 9500 feet). The mean annual barometric pressure is 15.5 C. (29.09 inches). The maximum temperature is 49.2° C. (120.56° F.); the minimum is minus 7.2° C. (19.04° F.). The mean humidity of the air is 60. The rainfall, in winter, is 22.7 millimetres (0.9 inch); in spring, 174 millimetres (6.96 inches); in summer, 359 millimetres (14.36 inches); in autumn, 63.5 millimetres (2.54 inches). The prevailing wind is N.W. The mean annual amount of ozone is 4.4 tint [test not given].

The *climate* is temperate and pretty equal, with great daily changes. Extraordinary irradiation, due to dryness of the air and the absence of wind and clouds; frequent hoar-frosts during the early morning hours, even in June and July; eternal snow at an elevation of 4 kilometres (13,123 feet,) at a distance of only a few kilometres from the City of Mexico. Inhabitants of the federal district, 440,000.

Consumption Mortality.—Consumption is common in the lower parts of the Republic, up to 1,000 metres elevation (mortality, 15 per cent.) It diminishes gradually, as the elevation increases; in the municipality of Mexico, 8.4 per cent.; in Tacubaya, 5.51 per cent.; in Xochimilco (14,000 inhabitants,) 0.94 per cent.; in the villages of Actopam and Ostctepec (2,000 inhabitants each, pure Indians) consumption is unknown. General average mortality, Tacubaya excepted, 2.07 per cent.

Even advanced cases of consumption may may be cured here, as proven by the experience of medical men and post-mortem records. The higher mortality from consumption in the capital and town of Tacubaya is accounted for by the considerable number of people living in these places belonging to foreign countries and other parts of the Republic (150,000); the rural villages of the district enjoy almost complete immunity from tuberculosis. The author accounts for it in the following manner: The surface temperature of the soil often goes down to 0.° C. (32° F.), causing destruction of microbes and of the bacillus of Koch present in it; the surface of the soil is almost constantly dry, due to the lack of fogs, rapid evaporation, and rarified air. The luminous, calorific, and chemical intensity of the direct sunrays are very great, which helps to destroy the germs.

The author ascribes a considerable germicide action to the exhalations of flowers, which are in bloom almost all the time and over all the district, the essential oils of flowers being powerful germicides.—*El Estudio,* April, 1891.—*Satellite.*

Clinical Lecture.

DYSMENORRHŒA FROM HÆMATOMA OF THE OVARY—DOUBLE DERMOID CYST OF THE OVARY—TWO CASES OF FIBRO-SARCOMA OF THE OVARY —REMARKS ON DRAINAGE AND THE AFTER-TREATMENT IN LAPAROTOMY.*

BY B. F. BAER, M. D.,

PROFESSOR OF GYNÆCOLOGY IN THE PHILADELPHIA POLYCLINIC.

Gentlemen:—While our patient is being prepared and etherized, I will show you several tumors which I have removed within a short time. This will be the more interesting and instructive because I fear that our case to-day may prove to be of somewhat similar nature to one of the cases I shall relate.

I have in this bottle a small tumor which is an ovary enlarged to about three times its natural size. On the same day on which this tumor was removed, I removed from another patient this tumor, which you see is large, solid and formidable looking; it weighs 15 pounds. Yet the patient with the smaller tumor suffered far more than the latter. This disproportion between the size of the tumor and the amount of suffering is one of the interesting and important circumstances met with in ovarian disease, and teaches the valuable lesson that the patient who happens to have a small tumor should not for that reason be condemned to a life-time of torture, when we know that her disease is as certainly incurable without operation as is that of the patient whose tumor happens to be large.

The patient from whom the small specimen was removed is 31 years of age, and had one child nine or ten years ago. Since that time she has been sterile. So far, therefore, as fertility is concerned, her ovarian function has been useless. Puberty occurred at the age of 13, and menstruation had been constantly attended with pain in the left ovarian region. For this she had been treated in various ways and by different methods, but without result so far as cure was concerned. Dysmenorrhœa is so often spoken of as resulting from one cause only, stenosis of the cervical canal or anteflexion of the uterus, and as, therefore, amenable to but one plan of treatment, by dilatation, that I can say nothing more important to you than to ask you to free your minds from this idea. The term should be used in its generic sense only, as expressing a symptom for which there are many causes, both general and local.

The patient had been worse since the birth of her child, and recently was almost constantly bed-ridden from pain and exhaustion; she could obtain relief only by the use of morphia, to which she had become addicted. Two years ago she was treated for retroflexion of the uterus to which was ascribed all of her suffering. I believe this was an error; the symptoms were not due to the displacement, but to a diseased left ovary. The trouble was doubtless aggravated by the complication, but the mechanical means used (in the form of a large pessary) for the retention of the organ, served only to increase the symptoms. As was to be expected the patient became worse. The diagnosis was wrong and the treatment necessarily at fault.

When she entered my private hospital she was emaciated and exhausted, and complained of constant pain in the left ovarian region. Upon examination I at once detected a tumor to the left of the uterus, and posterior to the broad ligament, which I knew to be an enlarged ovary. It had the peculiar shape of the ovary, only somewhat more rounded, and it was excessively tender on pressure, and mobile. As the patient approached her menstrual periods the tumor

*Delivered at the Hospital of the Philadelphia Polyclinic.

became larger and more tender, from congestion of the ovarian vessels, and the hæmorrhage into the Graffian follicle, which occurs during the ovulation excitement. Excruciating pain resulted from the swelling and distention, and was described by the patient as resembling the sensation which might be produced if the ovary were within the grasp of a vise. There was also a sense of numbness extending all over the affected side, from the ovarian centre upwards to the præcordial region, even extending to the side of the face and head, and downwards along the line of the genito-crural nerve and its inosculations, to the labia majora, inside of the thigh and to the foot, producing such lameness as to render walking extremely difficult and painful at times. These symptoms and physical signs pointed conclusively to the condition known as hæmatoma of the ovary. As indicated above the tumor results from an undue amount of hæmorrhage into the Graffian follicle and retention of the blood from failure of the outer covering of the ovary to rupture, and discharge its contents into the Fallopian tube to pass off as menstrual hæmorrhage, as is the case when the function of ovulation and menstruation is normally performed. Nature now attempts to repair the damage by bringing about an involution of the hæmatoma, as she does when a normal corpus luteum is formed; but she often fails, and the clot then remains as a small dark body. In some cases the ovary is completely riddled with these masses which, becoming hard, press upon the nerves, and thus add to the patient's suffering and serve to render constant the pain which at first was only present at the menstrual periods.

This disease is incurable except by removal of the affected organ and I at once advised operation. An incision an inch and a half in length, through a rather fat abdominal wall, was sufficient to permit me to complete the operation. Upon bringing the ovary up, I found, as I had expected, the condition here exhibited in the specimen. There was one large hæmatoma the size of a walnut, which is still unruptured, and at least four or five smaller ones in varying stages of subinvolution. At the same time I brought the uterus forward by shortening the round ligament on the left side. The process of shortening was accomplished by doubling the ligament upon itself and including it in the ligature which I used in ligating the pedicle. At the patient's request I removed but one ovary, the other being comparatively normal.

I have met with a good many cases of hæmatoma of the ovary, and have employed various methods for the relief of the patients, but I am more than ever convinced that the proper treatment is the removal of the organ. This operation is attended with but little risk when done properly.

DOUBLE DERMOID CYST OF THE OVARY.

Two days preceding the operation for the hæmatoma I removed these specimens. The patient was 32 years old; she had one child seven years of age and a second four months ago. Two years ago she began to complain of pain in the right ovarian region, which had continued ever since with increasing severity. She had become pregnant, however, and had given birth to a strong, healthy child after a normal labor. Soon after the parturition she left the city, but as she was rapidly losing flesh she returned, and then I saw her. On examination I found the abdominal wall extremely emaciated and quite relaxed, and through it I could detect a jagged mass, very irregular, lobulated, and flattened in shape, and at one point quite tender on pressure. It was very mobile and as large as a child's head. I also found a tumor in the lower pelvis, fully as large as the one in the abdominal cavity. The uterus was pushed up and to the right. The pelvic tumor was immovably fixed but not tender.

I expressed the belief that the pelvic tumor was an incarcerated ovarian cyst, but I was not certain as to the one occupying the abdominal cavity. Its irregular, flattened, lobulated shape and non-fluctuating character, together with its extreme mobility and the rapid emaciation of the patient, led me to fear that it might be a malignant growth, possibly of the kidney, although the urine did not show any evidence of disease of the latter organ. I advised that the child, which the patient was nursing, should be immediately weaned, and that laparotomy be performed as soon as the breasts had dried up.

The operation was performed at the home of the patient. After she was anæsthetized and lying upon the table, the abdominal walls lay flat and relaxed about the tumor in such a manner as to make it look exceedingly malignant in its roughness and irregularity. An incision two inches in length was made midway between the umbilicus and the pubis, and the tumor exposed to view. To my delight I detected the peculiar color of an ovarian cyst. Introducing two fingers, I found it to be free from adhesions

except at the point corresponding to the tenderness, but I could not at first find that it had a pelvic attachment, being apparently free in the abdominal cavity. After examining very closely for a pedicle, I discovered what seemed to be the broad ligament and Fallopian tube stretched and flattened out against the posterior surface of the superior strait, being held in this position by the pelvic tumor. Placing my finger under this apparent pedicle, I was able to trace it to the tumor, and bringing it to the incision made myself sure that it was the Fallopian tube and broad ligament. I now punctured the tumor with a trocar, although it appeared to be almost solid, when there began to flow the peculiar oily substance which is characteristic of dermoid cysts. After more than a pint of this semi-fluid substance had been evacuated the trocar was withdrawn, when the puncture was immediately filled and plugged by a mass of hair. Although the tumor was still quite large, I was able, by manipulation and some force, to withdraw it through the small incision. The pedicle was exceedingly vascular, the veins in the broad ligament being as large as my finger. After ligating the pedicle and separating the tumor, which was of the left ovary, the one in the pelvis was with great difficulty dislodged and brought up to the incision, when it was also punctured. Fluid, in quantity and character similar to that described above, flowed out, when the tumor slipped through the incision. A pedicle of like character as to vascularity and length was ligated and severed. The abdomen was now thoroughly cleansed and the incision closed, neither irrigation nor drainage being used.

The after history was without event, except in a decided evidence of heart failure on the second day. This was controlled by active stimulation kept up during the night. She sat up on the eighteenth day after the operation, and is rapidly regaining her lost weight and strength.

This case has an added interest, apart from the mere presence and removal of the double dermoid disease, in the gestation and parturition during the existence of the tumors. It not only shows the wonderful struggle and persistence of the procreating function, but also furnishes food for thought as to what should be done with these tumors when they are found to complicate pregnancy. There is a growing disposition to operate early in gestation when pregnancy is found to be complicated by ovarian tumor. This individual case went to full term and was safely delivered, but that does not prove that the rule is not a good one.

FIBRO-SARCOMA OF THE OVARY.

The next specimen is of peculiar interest to us, because I believe the case I shall operate upon to-day is of like character. The patient from whom this large, solid tumor was removed is 39 years old, and had one child 16 years ago. Nine years ago she was operated upon for laceration of the cervix uteri. The account given me by her physician was as follows:

Supposing herself to be pregnant, she engaged the physician for the approaching labor, which, however, did not come on at the expected time. When a month beyond the appointed time had passed, her physician called upon her and found her still waiting for the commencement of the labor, presenting the appearance of a woman at full term, ruddy and healthy looking. She said she could feel the active movements of the child. Another month passed, and then suspecting something wrong the physician questioned her more carefully, and found that she had been menstruating regularly, and that there had not been any mammary changes or other rational signs of pregnancy, excepting the abdominal enlargement and the supposed fœtal movements. Examination showed that the cervix was hard, and that the pelvis was occupied by a mass closely resembling the head of a child. The tumor could be felt high up in the abdomen. The doctor therefore properly excluded gestation.

Shortly after this I first saw the patient, and examination informed me that the womb was retroverted and somewhat prolapsed, but movable. When the tumor was moved the womb moved also, which is one of the diagnostic signs of uterine fibroid, or at least that the growth is uterine, and yet from the position of the tumor I believed it was external to, and not connected with the womb. I could not detect any fluctuation. The tumor was smooth and entirely mobile. It was with difficulty I convinced the patient that she was not pregnant. She was positive that she could feel the fœtal movements. This was due probably to the mobile condition of the growth, which moved to accommodate itself to the movements of the intestines; and then the imagination furnished the rest. I made a diagnosis of probable sarcoma of the ovary and advised its removal. A fibroid tumor of the womb would not have attained such size in nine months or a year, a point which aided me not a little

in my diagnosis. After a few weeks of hesitation and doubt on the part of the patient, she consented to the operation, and it was performed at her home.

When I reached the growth, I found it to be so extremely vascular that I believed I had to deal with a fibroid tumor of the womb. I was compelled to make a seven inch incision before I could get the tumor out of the abdomen, and not till then did I learn that the womb was below and independent of the growth. It had no relation whatever with the uterus, except through the ovarian and broad ligaments. These I now clamped and then cut the tumor away, leaving a very large pedicle. I next transfixed and ligated the pedicle and removed the clamps. After cleansing the abdominal cavity the incision was closed without drainage. As the other ovary was healthy I did not remove it. The stitches were removed on the seventh day and she made a good recovery. The tumor weighed fifteen pounds.

FIBRO-SARCOMA OF THE OVARY.

Our patient being now about ready for operation, I will give you a brief history of the case before beginning. She is a single woman, 30 years of age; she entered puberty at 18; the menstrual function has always been performed with difficulty, but otherwise she enjoyed good health until about a year ago. At that time she discovered a lump about the size of her fist in the left iliac region, and she remembers that it was hard and quite mobile. She says she could move it to either side and up and down, as though it were loose in her abdomen. From this time the mass increased rapidly in size. Six months ago she had an attack of la grippe, and this was accompanied with great soreness all over the abdomen extending around to the lumbo-sacral regions. Since this illness she has been going down hill rapidly, and the abdomen as you see, has increased to the size of the full term of gestation; she has become emaciated and is quite cachectic in appearance. She suffers considerable pain in the lumbo-sacral regions, and has great irritability of the bladder. There is also some œdema of the feet and legs. Her catamenia are regular in time and quantity. As you observe, the abdomen is symmetrical and smooth in contour. On palpation a round, firm mass of the size and somewhat the shape of the pregnant uterus at full term is outlined. This mass is not movable within the abdominal cavity, but seems to be firmly adherent to the abdominal walls. The veins are distended and there is a purplish hue of the surface, showing a decided interference with the circulation. There is only a faint suspicion of fluctuation. There is dulness all over the anterior surface of the abdomen with resonance in the line of the colon. Per vaginam, yesterday, the uterus was found to be slightly above the normal in size and seemed to be free from the tumor. It occupies a position below and to the right of the mass. The diagnosis as to the exact character of this growth is obscure, but I believe it to be ovarian, and hope it may prove to be a thick-walled cyst, for I know it is not thin-walled. I fear, however, that it may be a solid tumor of the ovary. Its very rapid development, peculiar conformation, and its relation to the uterus, together with the marked effect it has had on the patient's health, render it almost certain that it is not a uterine fibroid. But, whatever it is the indications are clear for its removal.

I now begin by making an incision two inches in length and expose the tumor to view. I am sorry to say that it has the peculiar purplish color and vascularity common to fibroid tumor of the uterus; but it is firmly adherent to the abdominal wall, and this causes me to hope that it may still prove to be ovarian, for fibroids of the womb, as a rule, are not adherent to the abdominal wall. It will be necessary to increase the length of the incision, so that I may safely separate adhesions and introduce my hand to learn if possible where it is attached. I am glad to say that I can trace its pedicle, which is small, to the region of the left ovary, but I also learn that it is universally adherent to the peritoneal surface and that there are a number of strong intestinal and omental adhesions. I begin the separation of the adhesions by tying off the omentum, when I find that it will be necessary to still further increase the length of the incision to fully six inches. Now you can see how extensive and firm the intestinal attachments are, and what care will be necessary in their separation. As I proceed with the dissection I find it necessary to leave a portion of the outer wall of the tumor in contact with the intestine, for fear of tearing the latter. This results in so much hæmorrhage that I am compelled to ligate the surface of the bowel as we advance. There is considerable hæmorrhage from the torn surface of the tumor, and it will be impossible to check this because of the broad surface denuded, and the impossibility of ligating on the solid mass. With the hope that the tumor is not entirely solid, and that I may reduce its

size and thus facilitate the separation of the adhesions and check the bleeding, I will now plunge a trocar into it. But you see this was a mistake, for the tumor proves to be solid and we are compelled to proceed as we were doing at first. This large surface which I have just now separated is bleeding so profusely because I have wounded the muscular wall of the intestine; it is necessary to double it upon itself and ligate it, and this makes a decided knuckle; even this does not stop the bleeding. I will therefore pass a ligature in a needle and ligate it in the form of a suture. This controls the bleeding and will also serve to unite the torn muscular coat. I now continue the separation and ligation from point to point until we have the tumor entirely free except an attachment to the colon which I next separate, placing here several ligatures. I will now lift the tumor from the abdominal cavity, and am glad to say the pedicle is small and that the tumor is of the ovary. I next quickly grasp the pedicle with a clamp forceps, and cut the tumor away, placing a warm towel immediately over the intestines, while an assistant closes the incision by placing a hand on either side. Before ligating the pedicle I will look carefully for bleeding points that may have been missed, and I find it necessary to place several additional sutures along the line of the intestine. I next transfix the broad ligament with this pointed forceps which has in its grasp a *single* ligature, with which I tie, first towards the uterus, and then towards the outer surface of the ligament, bringing it back again to the point first tied, making three knots. Removing now the clamp forceps, I find the bleeding entirely controlled. I therefore cut the ends of the ligature close to the knot and drop the pedicle. The right ovary is in a healthy condition and I will therefore not remove it, since the patient requested me to leave it if not diseased, although in view of the character of the tumor I believe it would be wise to remove it. You observe that the patient is very weak, being pulseless at the wrist, and I will ask a nurse to administer a stimulating enema, which I always have in readiness, while I make the toilette of the peritoneum and finish the operation as rapidly as possible. But I will first place the sutures for the closure of the incision. These are of Chinese silk, as all my ligatures are, and I carry the needle from without inwards, including the peritoneum and then from within outwards on the opposite side, about three to the inch, until they are all placed. Now carefully removing all clots and fluid and being sure that no bleeding is taking place, I close the abdomen without irrigation or drainage. The dressing will consist of first dusting the line of incision with aristol as a desiccant, covering it with a strip of sterilized gauze and a thick pad of cotton which is surrounded with sterilized gauze, all of which are strapped firmly with adhesive plaster. The patient is now returned to bed, a bag of hot water placed to her feet and a hypodermic injection of morphia and atropia at once administered.

REMARKS ON DRAINAGE, AND THE AFTER-TREATMENT IN LAPAROTOMY.

I think you will agree with me that this was a formidable operation, and that the outlook for the recovery of the patient, in view of the extensive ligation along the line of the intestinal track, is anything but favorable. But we have done our best and must trust the result, not alone to kind nature, but to vigilance and care in the after treatment. One of the gentlemen has just asked me why I did not irrigate and drain in this case? This, therefore, is a very appropriate place for a few words on the technique of the operation and the after management. You observed that I was careful to remove all foreign material from the abdominal cavity, and, as I succeeded in doing so, I believe that irrigation would have been an unnecessary and meddlesome procedure. On precisely the same principle, I did not drain. As there was nothing to drain it would have been unscientific and meddlesome practice to have placed a drainage tube. Now, it is self-evident that if the patient recovers as well without it, drainage was unnecessary, and that she was therefore better off than if I had left a drainage tube projecting into the abdominal cavity, to serve as a certain means of irritation and a possible source of infection and fistula, to say nothing of a predisposition to hernia by weakening the lower end of the cicatrix. Some time ago, while I was operating for the removal of several fibroid tumors, I was honored with the presence of a prominent surgeon who has had a large experience in abdominal work. Considerable hæmorrhage occurred. When I was ready to close the incision and he found I was doing so without irrigation or drainage, he remarked that he could not resist the criticism that I was taking great risk and that he would not himself have the courage to close the wound without first flushing the abdominal cavity and inserting a drainage tube. I replied that I would have more fear

of a drainage tube in a case where I considered it unnecessary, than in closing the wound without it; that I felt confident my patient was better without the tube. My friend said he would watch the case with great trepidation, and if she did well it would be a revelation to him. I am glad to say the patient recovered without a bad symptom. Some of you recall the case.

Greig Smith, in his classical work on Abdominal Surgery, has advanced the proposition, "When in doubt,drain," and this has become an axiom for operators. Some abdominal surgeons apply drainage in almost every case. But I believe the time is not far off when the technique of abdominal work will have been so perfected that the use of the drainage tube will be the exception instead of the rule. (I am now speaking of cases in which extensive peritoneal and cellular suppuration is not present.) I have added two words to Smith's dictum so that it reads for me, "When in doubt, *do not* drain." This is the principle upon which I have been working for several years and I am convinced of its soundness. If I use a drainage tube I must feel sure that it is necessary; if I am in doubt I do not drain. This method is not founded upon theory alone, for I have demonstrated beyond question that the practice is correct. I have now reached the ninety-sixth of my last series of one hundred completed ovariotomies. Of these ninety-six cases there has not been a death from the operation, and I have used a drainage tube only in three, and they were early in the series. In many of the cases adhesions were universal and organized, and some were pus cases. The patients recovered more quickly and are better in every way than those of the series immediately preceding this one, in which I used the drainage tube more frequently. But more of this again.

Regarding the after-treatment. The patient has already had one hypodermic injection of morphia and atropia, and this will be repeated if necessary during the afternoon or night; and if required will be repeated again, especially if she is emotional or there is a tendency to vomiting. Of the series just referred to I do not believe there have been six cases that have not had one or more hypodermics during the after-treatment, and I have nothing but good to say of the practice. The diet will be liberal and will be commenced at once in the form of stimulating enemata. It will consist of half an ounce of whiskey and six ounces of warm water through a fountain syringe, every four hours, until to-morrow at 4 A. M. She will then get barley water by the mouth in teaspoonful doses every hour. If this is well borne, after several doses have been taken, beef juice in similar quantity will be substituted. I do not mean beef tea, but beef juice which is obtained by pressing fresh beef after it has been broiled slightly on one side. If the digestion proves good, the beef juice will be increased to a tablespoonful every two hours, and the patient may then have barley water or plain water *ad libitum*. When feeding by the mouth begins, the enemas are discontinued. When flatus has passed per anus, which usually occurs within forty-eight hours, if the patient is hungry she will get a small cup of tea or coffee with soft toast and probably a soft egg. I rarely give milk in any form, never until the bowels have moved. Since I have discontinued the use of milk and do not use the drainage tube, I do not have to treat tympanites. If the bowels do not move spontaneously within three days, a Lady-Webster pill or Epsom salts will be administered as a laxative. The patient will be turned on her side within twenty-four hours, and earlier if she desires. The custom of compelling the patient who has undergone laparotomy to remain in the dorsal position is a barbarous one. It is not only unnecessary but positively injurious. Two of the most important factors in the after-treatment of these cases are stimulation of intestinal peristalsis, and rest of body. By compelling the patient to occupy the dorsal position, this order is reversed, the result being arrest of intestinal peristalsis and physical exhaustion from the constant and strained position. I believe the practice has contributed not a little to the mortality, and am sure it has caused a great amount of unnecessary suffering.

Examination of the specimen shows the Fallopian tube and some large vessels spread out over the tumor. On section it is found to be quite solid and fibrous in appearance, except at one point where a small cavity is seen. This contains a semi-fluid, yellowish substance which somewhat resembles the fluid found in fibro-cysts of the uterus. Placing this tumor by the side of the other solid one shown you just before the operation, we see how much alike they are in size, shape and consistency. Although they have not yet been examined microscopically, I think they are fibro-sarcomas. Solid tumor of the ovary, of the size of these growths, is very rarely met with, and, although these tumors look very like true fibroids, I think it will be shown that they contain sarcomatous elements.

In that event what will be the future history of the patients? Will the disease return? If, as in these cases, the development is purely local, I think experience teaches that it does not recur. But much, if not everything, depends upon the time of operation. The longer the delay the greater the danger.

[The patient was shown to the class three weeks after the operation. She had made a good recovery.]*

*Since this lecture was delivered, Dr. Baer has completed his last series of one hundred ovariotomies. Two of the last four were of that class of neglected cases in which recovery is always doubtful. In one, a universally adherent 50 pound poly-cyst, the patient was so weak that the radial pulse could not be felt. The patients are doing well.

COMMUNICATIONS.

VALUE OF ANTIPYRIN AS A LOCAL APPLICATION IN INFLAMMATION OF THE MUCOUS MEMBRANE OF THE UPPER RESPIRATORY TRACT.

BY E. BALDWIN GLEASON, M. D.,

SURGEON IN CHARGE OF THE NOSE, THROAT AND EAR DEPARTMENT OF THE NORTHERN DISPENSARY, PHILADELPHIA.

During the fall of 1889 the writer contracted a severe cold as the result of exposure incident to living in a house undergoing repairs. In spite of caution, one cold succeeded another until the resulting laryngotrachitis became so severe that talking at all was exceedingly fatiguing and the voice could scarcely be raised above a whisper. Coughing, especially after meals, was frequently followed by emesis, so that for a considerable time, at least one meal a day was vomited almost as soon as swallowed, and considerable loss of flesh resulted.

The constitutional treatment adopted in this case and some of the others to be cited need not occupy our attention as it is not germain to the subject of this paper. The use several times a day of a bottle inhaler containing hot water and compound tincture of benzoin gave more or less relief. Inhalations of the spray from an atomizer containing wine of ipecacuhana, a form of treatment suggested by Dr. William Murrell, of London* invariably relieved the congestion by producing a large amount of secretion from the larynx and trachea; which being coughed up, relieved the sense of fulness in the throat and chest and rendered talking easier and less fatiguing. Inhaling the ipecac spray even when diluted with one to three parts of water, however, often produced at once reflex vomiting. Indeed so sensitive was the larynx at this time, that even a spray of fluid cosmoline seemed irritating and the impact of powders thrown into the larynx with a powder-blower, was absolutely painful. Prolonged inhalation of the ipecacuhana spray also produced nausea which remained for some time after the inhalation was discontinued. In spite of these disadvantages, however, the spray of dilute wine of ipecac rendered better service than any other remedy that had been used as a local application previous to employing it. The use of powders by means of the powder-blower was almost out of the question. Since no matter what their composition, the mere impact of them upon the inflamed laryngeal mucous membrane produced pain and was followed by violent attacks of coughing which quickly expelled the powder from the larynx and rendered any effect from it except that of an irritant, impossible.

During all this time, nasal symptoms gave but little annoyance. A pledget of absorbent cotton saturated with a 4 per cent. solution of cocaine was inserted within each nostril every morning when required and relieved at once the stenosis and checked the free discharge, and this effect of the cocaine could be maintained for several hours by spraying the nose with a 4 per cent. solution of antipyrin. At bed time the application of cocaine and the use of the antipyrin spray rendered it possible to sleep with the mouth closed until nearly morning. So great indeed was the relief afforded by the use of a 4 per cent solution of antipyrin as a spray within the nose, that it was finally inhaled, being drawn by deep inspirations through the larynx and trachea and as far into the bronchi as possible. These inhalations of antipyrin spray were repeated at first from eight to twenty times a day. Within a week or twenty days, all signs of laryngeal and tracheal disease had disappeared. Since that time, the writer has frequently prescribed antipyrin, both alone and in combination with cocaine, menthol, &c. in various combinations as an analgesic application to the inflamed mucous membranes of the upper respiratory tract, not only when the inflammation was catarrhal but also when of specific origin, and always

*On cases treated with ipecacuhana spray at the Westminster Hospital, by William Murrell, M. D., F. R. C. P., *The Medical Register*, May 5, 1888.

with satisfactory results. Two to four per cent. solutions of antipyrin have also been prescribed in a few cases of conjunctivitis and chronic urethritis, with the result of diminishing congestion, irritability and discharge. Applied in solution to the mucous membrane of the eye, nose, larynx, or urethra, it produces at first a smarting sensation and seems to act as an irritant in proportion to the strength of the solution used. This smarting sensation, which, however, does not occur in the pharynx even when strong solutions are used, lasts but a few moments and is followed by a sensation of relief and comfort, when the mucous membrane to which it was applied was before inflamed and irritable. The analgesic effect of antipyrin solutions when applied to inflamed mucous membranes lasts for several hours, and may apparently be maintained indefinitely, if the solution be applied at sufficiently frequent intervals. Given internally, antipyrin, not only exerts a local analgesic effect upon the mucous membrane of the stomach if it be inflamed; but is a powerful antispasmodic producing this effect it is said by diminishing the excito-motor power of the cord. Applied locally, antipyrin solutions seem to also act as an antispasmodic, diminishing the reflex cough of certain nasal affections and the reflex gagging and retching so annoying in certain forms of pharyngitis. Beside all this, antipyrin is a powerful antiseptic; a five to ten per cent. solution being more active according to Caravir than Van Sweeten's liquid.

When a four per cent. solution of cocaine is applied to the inflamed mucous membrane of the nasal chambers, the sensations from the very first are pleasant. The mucous membrane soon becomes pale and bloodless and shrinks with the so-called erectile tissue beneath to a small bulk. Secretion is checked, but not to an extent to make the nose feel dry and uncomfortable; while increased breathing space and the stimulating effects of the cocaine absorbed, produce a feeling of buoyancy. By a single application of four per cent solution of cocaine to the nasal mucous membrane, all the more distressing local symptoms of a "bad cold in the head" may generally be checked in a few moments, but the relief lasts for but half an hour or so. It is however far otherwise when a solution of cocaine applied to the posterior wall of the oro-pharynx. Instantly a feeling of discomfort is produced; the pharynx feels as if suddenly parched by a current of hot, dry air, or as if a ball of absorbent cotton had been left in the pharynx; gagging, retching and even vomiting occur as the patient vainly strains to dislodge a supposed foreign body. This disagreeable effect of cocaine when applied to the posterior pharyngeal wall seem due to a sudden checking of its secretions, because the same disagreeable sensations occur when a dry powder or a strong astringent solution is applied to the entire posterior pharyngeal wall. Cocaine and strong astringent solutions may however be applied to the tonsils and pillars of the fauces without producing any disagreeble results. Indeed, acute cortical tonsilitis may be treated with most excellent results by carefully painting the tonsils every half hour with a four per cent. solution of cocaine or twice a day with a solution of nitrate of silver of the strength of one or two drachms to the ounce, care being exercised in either case that none of the solution reaches the posterior pharyngeal wall.

Far different are the sensations produced by the spray from an atomizer filled with a four per cent. solution of antipyrin. Thrown upon the inflamed mucous membrane of the nose it produces at first, a most disagreeable smarting and burning sensation, only partially relieved by frequent sneezing. When, however, the burning and smarting sensation passes away, as it does in a few moments, the anterior of the nose presents somewhat the same appearance as if a weak solution of cocaine had been used. The mucous membrane and turbinated tissues are pale and somewhat shrunken. There is no local anæsthesia however, but local *analgesia* which persists for four or five hours; and during this time the discharges from the inflamed nasal mucous membrane are very much diminished. Yet, so great is the primary irritating effect of solutions of antipyrin when applied to the nasal mucous membrane, that it is not well to employ them of a greater strength than four per cent. and only then after the nasal mucous membrane has been anæsthetized by cocaine. In some cases of hay fever, it is impossible to employ antipyrin solutions at all with benefit as they seem to act only as irritants. When applied to an inflamed posterior pharyngeal wall, powdered antipyrin or a spray of its solution produces no primary irritation, but at once a feeling of relief and comfort. After several applications, the reddened mucous membrane becomes distinctly lighter in color and, in some instances, assumes almost normal appearance.

Applied to the larynx, a four per cent. solution of cocaine produces no disagreeable sensations, unless some of the fluid reaches

the pharyngeal wall. The mucous membrane is anæsthetized and becomes pale and bloodless; but so transitory is this effect, that the secretions seem in no wise diminished, but rather increased in amount as the effects of the cocaine last but a few moments and are followed by a certain amount of reaction. When powdered antipyrin or a strong solution of the drug is applied to the laryngeal mucous membrane, it produces a sharp burning sensation, which however is but momentary and is followed by bleaching of the mucous membrane and diminution of its secretions. If the voice was previously husky from inflammation, it improves in quality. If talking was previously painful, a single application of powdered antipyrin produces a certain amount of analgesia, so that use of the voice is not so painful. The local analgesia is not complete, because the disease in such cases ordinarily involves parts deeper than the mucous membrane.

The following cases will illustrate the therapeutic applications of the drug:

Case I.—Acute Coryza with Catarrhal Conjunctivitis.—A married lady, thirty years of age, "caught cold the previous evening by sitting in a draft." Both nasal chambers are occluded and a profuse nasal discharge requires an almost constant use of the handkerchief. The eyes are suffused and congested. The papular conjunctiva is intensely red and at the outer portion of the right upper lid are a few swollen papillæ, which produce the sensation of a foreign body and greatly increase the patient's discomfort. She states that she cannot use her eyes without pain. Treatment consisted in washing the nasal mucous membrane with the spray of an atomizer containing an alkaline antiseptic solution; large pledgets of absorbent cotton being then placed between the lower turbinated body and septum, and a drop of a two per cent. solution of antipyrin is instilled into each eye. After sufficient time has elapsed for the cocaine to produce its characteristic effects, the pledgets of absorbent cotton are withdrawn and the interior of the nose is sprayed with a four per cent. solution of antipyrin and afterwards with a three per cent. solution of mentholin fluid cosmoline. The patient now says that she feels entirely comfortable; she can breathe through her nose, and its discharge is checked, and her headache is gone. Her eyes too have altered their appearance; they are no longer suffused nor is the ocular conjunctiva injected. The papular conjunctiva however, is still redder than normal and another drop of the two per cent. solution of antipyrin is instilled into the eyes. It does not produce the same amount of smarting as did the first drops. She is directed to take powders containing one-third of a grain of calomel and five grains of the bi-carbonate of sodium at intervals of an hour until six powders have been taken and to use the two per cent. antipyrin drops and an atomizer containing a four per cent. solution of antipyrin every two hours. The next morning she reports that the calomel powders have produced one or two loose evacuations, that her eyes have ceased to annoy her and that she is, in fact, free from all symptoms of her cold. However, she was directed to continue the treatment for one day longer.

Case II.—Acute Folicular Tonsilitis.—A boy fourteen years of age who had caught cold the night before, since which his throat has been so sore that swallowing was painful. Upon inspection, the entire oropharynx appeared red and congested. The tonsils were swollen and covered by an exudate from the inflamed follicles. The breath is somewhat fœtid. There is some elevation of temperature. An alkaline, antiseptic spray was thrown through the nose into the naso-pharynx. This brings down considerable mucus from above the tonsils and affords considerable relief. As the nasal mucous membrane is somewhat inflamed, it is coated with a light coating of calomel and protected by a layer of fluid cosmoline which is thrown into the nose as a spray. The tonsils were next washed with an alkaline antiseptic spray and as much as possible of the exudate removed by means of a pledget of absorbent cotton wrapped about a probe and dipped in a solution of peroxide of hydrogen. By means of the powder blown, the tonsils and oropharynx were then covered with powdered antipyrin. As soon as the powder has had time to dissolve in the secretions of the parts, the patient expresses himself as feeling very much better. He was directed to take at once a wine glass full of Hunjadi water as a cathartic, and to have a friend blow in his pharynx and upon his tonsils one and one-half grains of antipyrin every two hours. From this treatment, the patient experienced at once a great deal of relief and the fauces presented their normal appearance on the third day.

Case III.—Hypertrophic Rhinitis and Chronic Pharyngitis.—This patient, a commercial traveler, came to me for treatment July 7th, 1891. I made an examination of his nose and throat some months before that date. He was one of the most robust men

that I ever met. Not noticeably fat, his weight must have been about three hundred pounds; yet he stated that his throat had been for years a continual source of discomfort and anxiety to him, and that he had given up an advantageous position in a western city because the climate seemed to make his throat worse. In fact, while there during one of the numerous acute exacerbations of his ailment the symptoms became so alarming that he thought he was surely going to "choke to death," and was sure that he would "never survive such another attack." He stated furthermore that his throat was almost raw from continual hawking, and that he had been to several specialists without permanent benefit. He was a man of most excellent habits, and used neither tobacco nor liquor.

His nasal chambers presented the ordinary appearances seen in chronic rhinitis. There was a small ecchondrosis in the left nasal chamber and some hypertrophy of the turbinated bodies, but not enough to produce stenosis or suggest the urgency of operative interference; although doubtless the condition of his nose had much to do with his distressing pharyngeal symptoms. His entire fauces were intensely red and congested and so exquisitively sensitive that even the tongue depressor had to be used with the utmost care to prevent retching. It was impossible, at his first visit, to use either the laryngoscope or rhinoscope as the mere suggestion of putting a mirror in his fauces almost produced emesis.

Office treatment consisted in washing the nasal chambers with the spray from an atomizer containing an alkaline, antiseptic, sedative, solution. Secretion in the nose and naso-pharynx was by no means abundant, and the spray brought down but a moderate amount of mucus, which with much gagging and retching, was finally expectorated. The clean nasal and naso-pharyngeal mucous membrane was then sprayed with fluid albaline and a small amount of finely powdered calomel distributed over it with the powder-blower. The fauces were sprayed several times at short intervals with a twenty per cent. solution of antipyrin and the patient was instructed to inhale as much of the spray as possible. This was all that was done at the first visit, but my patient left me feeling much more comfortable, with his pharynx distinctly lighter in color, and for the next four or five hours there was but little hawking and gagging. At his second or third visit it was possible to use both the laryngoscope and rhinoscope, and make applications to the congested mucous membrane of the pharyngeal vault and larynx. At home he used several times a day an atomizer containing a four per cent. solution of antipyrin, directing the spray into his pharynx. He also took, at first three times a day and afterwards only at bed time, eight grains of the bromide of sodium and three grains of the iodide of sodium. From July 7th, to July 25th, he made eight visits to my office, at which date his throat gave him so little inconvenience that he ceased his visits. I saw him next, September 24th. The pharynx presented an entirely normal appearance but was still somewhat sensitive. He was directed to resume the use of the antipyrin spray and occasionally take at bed time a mixture containing bromide of sodium.

Case IV.—Chronic Laryngitis with Bronchitis.—A man about thirty years of age, married, and a professional singer, inasmuch as he is a member of a church choir and obtains a considerable income from singing at social gatherings, weddings, funerals, etc. His first visit to my office was made in June, 1890. He stated at that time that he had suffered from a severe cough for some months and had lost in weight. That expectoration was scanty during the day, but that each morning the expectoration was profuse; and that he felt oppressed each morning and unable to work until repeated coughing had dislodged a large quantity of mucus. His voice had become treacherous and frequently showed signs of failing him while singing; so that singing was much more fatiguing than formerly. It was often very difficult, sometimes impossible to sustain his notes. He had lost the power to sound one or more of the higher notes at all, and the character of his voice had changed and was losing its purity of tone. One object in coming to me was to ask advice as to the advisability of giving up singing entirely. As it was a source of considerable revenue to him, I advised him emphatically not to do so, but to use his voice as little as he could aside from filling all his professional engagements. Constitutional treatment consisted in the administration of cod liver oil, and tonics, whilst out door exercise was also advised. He inhaled each morning, when necessary, the spray from an atomizer containing equal parts of wine of ipecacuhana and water and continued the inhalations until the sense of oppression in his chest had been relieved by the profuse expectoration which these inhalations produced. Several times a day and more especially at bed time he inhaled the spray from an atomizer containing a four per

cent. solution of antipyrin. Twice or thrice a week a powder consisting of equal parts of powdered sulphate of zinc and starch was thrown into his larynx and as far as it would go into his trachea by using the powder-blower at my office during forced inspiration. Under this treatment, his general health rapidly improved and he increased in weight from 130 to 152 pounds. Expectoration greatly decreased in amount. His sleep was no longer disturbed by coughing, nor was it necessary to use the spray of wine of ipecacuhana in order to relieve congestion of the bronchial tubes and dislodge the amount of mucus that had accumulated over night, as the antipyrin spray not only relieved the congestion of the parts but also controlled excessive excretion. The voice also gradually improved in quality, and the power to sound the high notes that had been "lost" was regained with the ability to sustain his notes during singing. During the first months of treatment he was in the habit of taking a teaspoonful of the fluid extract of coca in a glass of sherry a few moments before singing as a stimulant; but ultimately he came to the conclusion that he sang better without it, and at the same time he stated to me that he did not think that he had ever in his life before been in better health or voice.

Previous to January 1891, I used antipyrin locally in the larynx only as a spray and in dilute solutions. At this time, however, my attention was attracted by a paper by Drs. E. Coupard and E. Saint-Hilaire upon "De Quelques Usuages de l' Antipyrine Dans Les Affection de la Gorge et du Larynx. † In this paper, the authors advise the application of concentrated solutions of antipyrin (four to sixteen grammes of antipyrin to ten grammes of water,) and state that solutions of antipyrin of this strength are caustic and produce a severe burning sensation. ‡ Numerous cases are cited exhibiting the beneficial effects of these applications not only in acute and chronic laryngitis but also in tubercular laryngitis even in advanced stages of the disease. Since reading this valuable and interesting paper, I have used fifty to one hundred and fifty per cent. solutions of antipyrin in various inflammatory affections of the laryngeal mucous membrane; sometimes making my applications by means of the spray from an atomizer, some times by means of a pledget of absorbent cotton wrapped about a probe and passed dripping with the solution into the supra-glottic portion of the larynx. Lately I have used almost entirely powdered antipyrin, throwing it into the larynx and sometimes into the trachea during inspiration by means of a powder-blower. When thrown upon the inflamed mucous membrane of the larynx, antipyrin produces a burning sensation, sharp in proportion to the amount of the powder used. This burning sensation, however, lasts but a few seconds and is quickly followed by a sense of comfort. If the parts be now inspected it will be found that their redness and congestion has in a great measure disappeared. More antipyrin may now be thrown upon the laryngeal mucous membrane if it be thought necessary. When a large amount of antipyrin is thrown into an exceedingly sensitive larynx, it produces the same effect as any other powder: violent cough, sometimes even spasms of the rima glottidis of short duration, gagging and even vomiting: so that the powder is expelled before it has had time to dissolve in the secretions and produced an analgesic affect. It is well, therefore, where the larynx is exceedingly sensitive to at first throw into it only a small quantity with extreme gentleness and after an interval a larger quantity.

Case V.—A recent graduate of the medical department of the University of Pennsylvania, pale, thin, overworked, and with a family history of tuberculosis. Had suffered with hypertrophic rhinitis and chronic pharyngitis for years. August 21st, 1891, he contracted a severe cold, but remained untreated for over two weeks, at the expiration of which time he came to my office for examination and treatment. In addition to the ordinary symptoms resulting from severe coryza, he complained of dysphagia. Not only was swallowing difficult and painful, but two or three mouthfuls of water swallowed rapidly would often produce vomiting. His voice was toneless and almost whispering. Talking for a few moments was exceedingly fatiguing and caused sharp pain shooting from the larynx up the posterior pharyngeal wall, while at the same time the eyes became suffused and the voice husky. During the previous two weeks he stated that he had lost sixteen pounds in weight. He was exceedingly alarmed as to his condition, and said, "if this is phthisis, I should like to know it." Taken in connection with his general appearance and family history the existence of such a cause for the condition of affairs was by no means improbable. The mucous membrane of the soft palate

† Revue de Laryngology, D'Otology et de Rhinology. Jan. 15th, 1891.

‡ Ance titre l'antipyrine est caustique et produit une sensation de brulure tre vive, mais oui disparait au bout de queloe secondes.

was anæmic, especially at the junction with the hard palate; but not of the ashy gray color peculiar to phthisis. The oro-pharynx was moderately congested and had upon it several patches of swollen and inflamed papillæ. Both arytenoids were swollen and red, but did not present the œdematous appearance characteristic of laryngeal phthisis. The suppra-glottic mucous membrane was reddened and the cords moderately congested. The left cord seemed to move more sluggishly than the right. It will scarcely advance the purpose of this paper to describe the condition of the parts above the oro-pharynx, or dwell upon the constitutional treatment, except to state that he took one-thirtieth of a grain of strychnia three times a day. At his first visit, cocaine, antipyrin and menthol were applied to the nasal mucous membrane in the manner already described. The swollen and inflamed follicles on the pharyngeal wall were touched with a solution of nitrate of silver, one drachm to the ounce of water, and the pharyngeal wall covered with antipyrin by means of the powder-blower. Antipyrin also was thrown gently upon the supra-glottic laryngeal mucous membrane. This treatment, as far as the larynx and pharynx was concerned was repeated daily during the first week; every other day during the second week, and at longer intervals during the third week. Referring to the notes of his case which the doctor kindly placed at my disposal, I find the first application of antipyrin gave complete relief as to the dysphagia, and rendered talking much easier. This relief lasted for about six hours, but that the benefit from each subsequent application persisted for a longer period. At the end of the first week his dysphagia and dysphonia had disappeared entirely, and hence the visits to my office at less frequent intervals during the second and third weeks. During the three weeks that he has been under observation, his general health has steadily improved and he has regained six pounds of the sixteen lost during the first two weeks of his illness. At the present writing his condition is about that previous to his last illness. He is still anæmic and somewhat weak, his voice is somewhat feeble and inclined to be "squeaky," as he describes it at times; but he thinks that it is constantly improving in this respect. It is a matter of regret that the requirements of his profession prevent his enjoying the advantage of an interval of rest and recreation in the country, and certain hygienic measures, the value of which we both appreciated. Certainly, under the circumstances, the improvement in the local symptoms, at least, must be attributed largely to the applications of antipyrin.

Locally, antipyrin has also been used with marked benefit in several cases of advanced tubercular laryngitis and pharyngitis; and syphilitic pharyngitis and laryngitis; but it seems needless to lengthen this article by detailing these cases. In all cases of inflammation of the mucous membrane of the upper respiratory tract that I have been called upon to treat, antipyrin used in the manner described has seemed to give good results as a local analgesic and anti-spasmodic whose effects could be maintained for a long time if applied at sufficiently frequent intervals.

418 S. Nineteenth St., Phila.

SUFFERING FROM OVARIAN TROUBLE. *

BY J. N. MARTIN, PH. M., M. D.,
ANN ARBOR, MICH.,
PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN, UNIVERSITY OF MICHIGAN.

I chose this subject, not so much to air any knowledge I may possess, as to elicit discussion and the report of cases from those present who are particularly interested in gynæcological work, and to give briefly some of the mistakes I have noticed frequently made in the diagnosis of ovarian disease, either from ignorance or carelessness, or both.

I trust that the grouping of some of these errors collated by those especially interested in gynæcology, and presenting them collectively will have some tendency to diminish the carelessness and ignorance too apparent in this branch of medicine.

I do not claim infallibility for this Section, but we who devote most of our time to this line of work have not only the right to express our opinions concerning it, but it is also our sacred duty, both to our brother practitioners and to our patients.

Grave injustice is done our profession by incorrect diagnosis: Drs. A., B., and C. examine a patient; Dr. A. gives one opinion, Dr. B. another, and Dr. C. still another; the result is the patient loses faith not only in these three physicians, but in the profession at large, and it is brought into disrepute in the eyes of the public.

I ask for correct diagnosis for a still higher

* Read before the Michigan State Medical Society, June, 1891.

season, the welfare of the patient. To express an opinion that a disease exists when it does not, often entails a long, expensive, tedious course of treatment, and much mental anguish without any return, while to allow the disease to progress to an advanced stage, undiscovered, may prove even more disastrous.

I believe in honesty in the practice of medicine as well as in other professional or non-professional work, and we should not diagnose after a very hasty and superficial examination, "ovarian trouble," "ovarian disease," "ovaritis," or "ovarian tumor." An opinion should be withheld unless we have exhausted all means to inform ourselves both from a positive line of procedure and by a process of differential exclusion. Without these, we are all apt to make grave errors, and sometimes even with all these precautions.

I have seen many patients, both in my hospital and in my private practice, who have been blistered time and again for "ovarian trouble," because they had suffered from pain in the side, many of them, as they said, had felt their ovaries, when swollen, high above the ilium, and some of them by the assistance of their physicians.

As illustrations of careless diagnoses, I will cite a few cases: Last fall, a patient from Illinois consulted me on account of ovaritis and "rheumatism" of the right leg; she had been advised by a physician to go to Mt. Clemens and take mineral baths for her general "rheumatic" condition. Suspecting pelvic disease, with the aid of my assistant, Dr. Lynds, I made an examination; we found a large malignant growth involving nearly all of the pelvic structures; the patient died two months later, as a result of the same.

A few weeks later, at my clinic, we examined a patient from the Upper Peninsula who had been blistered for ovarian neuralgia and had received much treatment for "rheumatism" of the left leg, and œdema of the same. She finally went to a neighboring city to consult a physician who had devoted considerable time to gynæcology; he examined the patient and pronounced the "rheumatism of the leg" cancer of the uterus and appendages. She came to me, hoping for relief. I confirmed the diagnosis of the last physician and, as the disease was too far advanced for operative procedure, she returned home to die.

I might relate several similar cases that have come under my observation in the Hospital clinic as the hospital staff can testify. Among my private patients I have examined two such within a month. I have learned to look with suspicion upon "rheumatism" and œdema of one limb.

To illustrate another class of incorrect diagnosis from carelessness, etc.: Mrs. B., from Indiana, entered the Hospital February 10, 1890. She was very nervous and debilitated, and her bowels were obstinately constipated. An examination revealed a retroverted uterus without adhesion, but no evidence of enlargement or inflammation of her ovaries for whichshe had had long continued treatment. Tonic laxatives and general tonics were prescribed, the retroversion treated, and patient left the hospital April 8th, much improved.

Another patient, Mrs. P., aged 48, entered the Hospital April 29, 1890. For several years she had noticed an enlargement of the abdomen and experienced a dragging sensation in the left side. Her physician diagnosed an ovarian tumor, and advised an operation. One year previous to her entering the hospital, she had a chill, followed by fever and soreness in the side. The same physician then gave the opinion that she had inflammation of the pedicles of her ovarian tumor. An examination revealed a disc of adipose tissue in the abdominal walls so often found, at or near, the time of menopause. There was no dulness on percussion, no enlargement ex cept from fat, and everything was negative by bi-manual examination. The patient went home much relieved. A letter from her recently informs us that the relief has been permanent; she had worried much over the thought of a serious operation.

A patient came to me from the central part of the State in April last, for an examination. I noticed from her anxious expression, as soon as she entered my consulting room, that she was much troubled. When I attempted to get a history of her case, she became so nervous that she could scarcely speak. She said she had suffered frequently since the birth of her last child (seven years ago, when she had a pelvic inflammation) from pain on both sides; she also gave a history of dysmenorrhœa, menorrhagia, and of more or less pain during locomotion. She had consulted a physician in her city, who, after a hasty examination, said her condition was suspicious, and perhaps her disease was of a cancerous nature. On examination, I found a plastic deposit binding down a somewhat retroverted uterus; and in the cervical canal, near the external os, was a sub-mucous fibroid the size of a cherry with considerable erosion

about the end of the cervix, but the cervix was soft and the canal patulous, wholly unlike their condition with cancerous infiltration. A few days later, with the help of my assistant, the little tumor was easily removed. Word from her husband, a few days after the operation, was, "My wife is ten years younger and much more than that, happier."

Not long since a physician told me that he had removed several ovarian tumors the size of a goose egg by rubbing on the skin over the ilium an ointment, which he prepared for that purpose. He has had a large general practice and believed implicitly in his diagnosis of these cases and the efficacy of his ointment, although he had made but a half dozen vaginal examinations in twenty-five years, except at confinements.

The following cases will illustrate of how little value blistering and the use of ointment, liniments, etc., are in certain cases; in fact, how fruitless all treatment under certain conditions except operative procedure.

Mrs. C., age 31, married and had borne three children, was brought to the Hospital on a stretcher, from the western part of the State. Since the birth of her last child, four years ago, she had not been well, but for three years, she had had irregular menstruation, each period was from nine to thirty-eight days, and accompanied by severe pain. She had suffered all the time, but during her periods the pain in her ovaries was so intense that she was often deranged. She had been treated almost constantly for three years but without benefit; the patient said, "I would rather die than live in my present condition." I examined her November 14, 1890, and found the right ovary and tube prolapsed into Douglas' cul-de-sac, and somewhat immobilized by adhesions and extremely sensitive; the left ovary in its normal position but irregular in outline. On November 21, 1890, I operated on her, assisted by Dr. Lynds and my hospital staff, in the presence of the medical class and several physicians, as were the other patients I shall report under this head.

I found the right ovary and tube in the cul-de-sac, and the ovary bound by its distal end to the uterus and several other adhesions "glueing" the parts together. I broke up the adhesions and removed the tube and ovary as the tube was distended and the ovary contained many cysts; the left tube and ovary were removed for the same reasons. The patient made an uninterrupted recovery, she frequently said during convalescence that she suffered much less pain and of a different character than previous to the operation. She left the hospital December 20, 1890, free from pain and feeling well and happy. Several letters received from herself and her physician since her return home contain exceedingly favorable reports. She had for three months previous to coming to the hospital been confined to her bed, and, as I said, was brought to the Hospital on a stretcher. The next Sunday after reaching home, she walked to church and is now doing most of her own work.

Another similar case, Mrs. D., age 26, and the mother of two children, ages two and four respectively. She gave a history of suffering dating back ten years, when she was thrown from a sleigh and injured in the right inguinal region; since that time she had suffered from dysmenorrhœa and many nervous derangements, but nearly all the pain was in the right ovarian region. In fact about the only time she had been even comparatively free from pain was during her first gestation. After the birth, she was worse than before; she had been confined to her bed much of the time and when up she was unable to do any work. She had been in the hands of eight or ten physicians and had received much treatment of the uterus, had been blistered scores of times, and had, as she expressed it, "taken a drug store of medicine." They had spent all of their means trying to cure her. Through the kindness of her home friends, she was enabled to come to the University Hospital. She entered December 5, 1890, with every feature indicating suffering. She was much reduced, her general condition was bad. I found the uterus slightly enlarged and some endocervicitis. Both ovaries with irregular outlines and enlarged; the right ovary and tube were bound down and extremely sensitive.

I decided to make an exploratory operation after an attempt to improve her general condition. On February 10, 1891, the patient having become somewhat stronger, I operated on her. At that time she was ready and anxious for the operation. The ovaries and tubes were "glued" together and bound down by adhesions. After breaking up the adhesions, I removed the enlarged tubes and cystic degenerated ovaries. The ovarian tissue proper was small in amount, but the ovaries contained several cysts ranging in size from that of a pea to a large cherry. The operation, like

the others, was done under full aseptic precautions. She suffered but slightly from shock, did not vomit once, and the same evening, she said the old pain was gone. The only complaint was of some smarting along the line of the abdominal incision. Her temperature and pulse were normal four days after the operation. She made a rapid recovery, and left the hospital March 20th in excellent condition.

I wish to report another somewhat similar case that has not made a rapid recovery. Mrs. P. entered the Hospital January 6, 1891. She gave a history of suffering dating back to 1885, when she had an abortion. She complained of severe pain in both ovarian regions all the time. She had been treated by many physicians and they had spent all their means on physicians without the least benefit. An examination revealed a tumor in the right broad ligament, the tubes both greatly enlarged and all the parts painful to touch. I advised an exploratory operation with the understanding that I was to do what was indicated after abdominal section. I operated on February 24, 1891, and found a cyst of the right broad ligament, twice the size of the uterus; both tubes were twenty or twenty-five times the size of their normal diameters and greatly lengthened. There were many and large adhesions binding the parts together, and to the other pelvic structures.

After long and tedious work, I succeeded in liberating the tubes and ovaries which I removed together with the cyst of the broad ligament. Not much blood was lost and notwithstanding the operation was over two hours in length she suffered but little from shock. The patient felt so well after three days that she was determined to move about in bed without the assistance of the nurse. Contrary to orders, she would rise in bed, grasp the top of the bed, and draw herself up. Every precaution was taken to prevent it, but she persisted in violating our directions. The first trouble was a stitch abscess, followed by another. After four weeks there was evidence of deeper suppuration. A vaginal examination located it in the cul-de-sac. I evacuated it per vaginam. Since that time, she has been doing much better, but is not making a rapid recovery.

Another patient, Mrs. H., entered the Hospital October 7, 1890. She had suffered from much pelvic pain for fifteen years which began with an acute pelvic inflammation and had been repeated many times. She suffered intensely at the time of her periods. She had also taken much medicine and had been treated by many physicians, regular, irregular, and all kinds of quacks without any relief; in fact growing worse from year to year. She came to us a physical wreck in every sense.

Th examination was unsatisfactory. Irregular and indefinite masses were found in both sides of the pelvis and quite immovable. I could not outline anything definitely. I decided to operate with the hope of removing the ovaries and establishing an early menopause; to which the patient and her husband readily consented, but both said, after hearing the probabilities discussed, that I should make an exploratory operation, and if the tubes and ovaries could be removed without much danger, I should remove them, but if not, to close up the wound.

After opening into the abdomen, I found such masses of adhesions binding together the ovaries, tubes, uterus and intestines, I saw I could not proceed further with any degree of safety and without violating my agreement with the patient and her husband, so I closed up the wound. She made a rapid recovery from the operation and was soon in the same condition as before.

I would like to report one more case, Mrs. B., age 29, and mother of six children, entered the Hospital March 26, 1891. For four years she had suffered from a tumor which began in the right inguinal region; she complained especially when on her feet much as the tumor then dropped down more into the pelvis and disturbed the pelvic organs. Sometimes the pain was equal to that of childbirth and at times she had convulsions. She had applied many things externally as advised without benefit. Last fall a physician urged her to go to my clinic.

An examination revealed a freely movable tumor in the abdomen, the upper part of which, when the patient was on her feet, was as high as the uterus in the fifth or six month of gestation. It was so regular in outline and so firm that I considered it a fibroid with a long pedicle. The patient was ready and anxious for an operation and I operated on April 2, 1891, and removed the tumor, which was attached by a long pedicle to the right tube and ovary. It proved to be a dermoid tumor and contained a large mass of bone, much long hair, and considerable fatty material. It measured 22 inches in one circumference and 16 inches in other. Patient's temperature did not go above 100°, nor pulse above 86 after the operation. She made a splendid recovery and left the Hospital May 16th, perfectly

free from pain and in an excellent condition in every sense.

Not even the best ovarian tumor resolvent applied faithfully over the abdomen could have removed this growth. I confess I have not sufficient faith in the contiguity of the abdominal applications to remove pelvic growths. I might report other cases, but these will illustrate this part of my paper. There are several in this section who can duplicate these. They all forcibly illustrate that without proper diagnosis and surgical treatment, we cannot hope to benefit this class of cases.

I do not wish to convey the idea that I advocate abdominal operations without good reasons for so doing. The reckless laparotomies, as practiced by some, I denounce, as I do reckless work in any branch of medicine. Those who have been thoughtful and conscientious enough to investigate the results, and especially the ultimate results of these operations must have concluded that they mean much more than abdominal incisions, removal of tumors, ovaries, tubes, etc., stitching up the wound and getting the patient back to her bed alive.

1. Some patients are benefited or cured.
2. Some remain as bad as before.
3. Some are made worse.

By properly selecting the cases, the first class can be increased, and those that come under the other divisions can be diminished. Such cases, if possible, by careful and thorough investigation should be decided according to the best interests of the patient, and not according to the wishes of the one desirous of making a reputation as an operator. There is often a great difference between an operator and a surgeon. I believe that many patients are subjected to laparotomies who might be cured by other and less severe means; but some conditions demand operations. As to my views of the general to the local diseases of women, I refer the hearers to my address of last year before this society. I make no plea for a new method of my own of making correct diagnosis, but earnestly ask for a closer adherance to and observance of the well established ones. A good history of a case often throws much light upon it.

For examination, the patient, should be placed in the dorsal position, her shoulders slightly elevated and limbs flexed; she should be in a warm room, and on a firm bed so that her hips will not sink down into the bed; the clothing should be perfectly loose; the rectum and bladder emptied and the examiner's hand should be warm. I have found an anæsthetic an invaluable aid in difficult cases in diagnosing diseases of the ovaries, tubes and ligaments. I have examined a good many patients when it was impossible to make a satisfactory examination without it. A great many, I believe, in examining these cases pass the finger too far anteriorly and thus do not reach the ovaries, tubes, and all parts of the uterus. When the parts are relaxed by an anæsthetic, there is little difficulty generally in making a satisfactory examination.

If I were to answer the question, "How often is it necessary to anæsthetize patients for examination?" I would reply, as often as we find those that we cannot thoroughly examine without it, or else we should not express opinions upon their conditions.

I have mentioned no names of physicians, patients or places. I did not write this paper to make personal attacks upon any physicians, or embarrass any patients; only to set up a few guide posts that I trust will keep some on the same road, and I expect a good many in this section will set up other guide boards that will help to keep me from straying from the right path.

CHRONIC INFANTILE GASTRO-ENTERO-COLITIS. *

BY A. S. MAXSON, M. D.,
MILTON JUNCTION, WIS.

I have a rare case of chronic infantile gastro-entero-colitis worthy of consideration. The individual was an infant born one month prematurely. At the time of birth it weighed three pounds and six ounces; and appeared like a miniature grandmother with shriveled skin drawn over its tiny bones and a very large head and abdomen as compared with the balance of its body.

The infant was put to the breast as usual, but the milk was vomited and purged, soured and in hard curds, the passages soon turning green except the curdled milk which remained white. This condition was sought to be remedied by bismuth, chalk mixture, pepsin, with and without acids, and similar remedies, but of no avail until a change of diet was made to dextrine, when the passages soon appeared tolerably well.

Since the dextrine would not nourish the infant sufficiently, it was put back to the

* Read before the Central Wisconsin Medical Society, September, 1891.

mother's breast with a simular result to that above. The baby was perfectly wild to get anything that it could drink. From dextrine mixtures to breast and back again in a vain effort to make the baby assimilate its mother's milk, it was changed for four weeks.

Now, it was tried on various nourishments, with the following results: Cow's milk diluted with two parts water and lime water, or cow's milk mixed with dextrine disagreed with it. In foods containing cow's milk in its natural form the milk would be vomited, curdled and soured, or appear as curds in the passage, though but a teaspoonful of milk was added to the food. Cow's milk with pepsin acted like clear milk. Pancreatonized milk would curdle enough to make trouble unless the digestion was so nearly completed as to be bitter, in which case the infant soon tired of it and refused it. Whey and cream afforded an incomplete nourishment. Strippings from cow's milk diluted with three or four parts of water and lime water acted much the same as milk. Condensed milk agreed for a short time until thrush appeared, which could not be controlled until the child was taken from this food. Oatmeal gruel, strained, fermented readily in its bowels. Dextrine did not nourish it. Wells and Richardson's baby food, and especially Horlick's food, fermented in its bowels. Reed and Carnrick's soluble food agreed with the baby, but did not nourish it well. Still it did the best of anything tried. Later a cow's milk was found that agreed with it for a short time. Thus we worried along, going from one food to another. The course of the disease was not constant, but every two or three weeks the baby would reach a climax. Her breath took on a peculiar, musty odor, and in a few hours she vomited and purged decomposing food with much mucus for twenty-four to thirty-six hours; then she was a week recovering from a subacute gastro-intestinal inflammation.

In the outset of these exacerbations calomel, rhubarb, turpeth mineral, ipecac, or any drug tried did no good, but hastened the attack. However, after the vomiting, Squibb's bismuth in large doses, twenty grains every two hours, quickened recovery and checked the secretion of mucus. The fermentation in the bowels with diarrhœa at other times, was helped by corrosive sublimate. Thus with great care in dieting, the child passed four and one-half years, scarcely a month elapsing without an exacerbation culminating in vomiting and purging of food and mucus, followed by a subacute inflammation of its stomach and bowels. At last a remedy was found which terminated this condition from the beginning of its use. This remedy was *powdered myrrh*, given in divided doses of from nine to twelve grains a day, either in capsules or mucilage of acacia with glycerine and liquorice.

SHOCK, FOLLOWING CONTUSION OF THE ABDOMEN, CLOSELY RESEMBLING CEREBRAL CONTUSION, WITH REPORT OF A CASE.

CHAS. B. WILLIAMS, M. D.,

RESIDENT SURGEON PENNSYLVANIA HOSPITAL, PHILADELPHIA.

Contusions of the abdomen unattended by lesions of the viscera are rarely fatal; yet it is possible for rapid death to follow such injuries either from concomitant shock or from a condition of the solar plexus analagous to cerebral contusions.

Case.—Frank S.—age 10, was admitted to the Pennsylvania Hospital during the service of Dr. Morton, Oct. 1, 1891, with the following history: While engaged in jumping with some other boys he slipped and fell against one of the corners of a large box of dry goods, striking his abdomen in the epigastric and umbilical regions. On admission to the hospital his condition was one of considerable shock. He seemed very dull and stupid and could be aroused only with great difficulty. His pupils were normal; temperature, 97; pulse, 54, slow and full; and respiration, 20 per minute. He lay curled up upon his side and complained of pain in his abdomen in the umbilical region. Shortly after admission he vomited. There was no history of head injury and there were no symptoms present to indicate any injury to the abdominal viscera. In fact his general condition resembled strongly a case of cerebral concussion. Temperature 3 hours after admission was $99\frac{2}{5}$; pulse, 74; and respiration, 20 per minute. His treatment was rest in bed; clothes dampened with lead water and laudanum applied to his abdomen, and milk diet. His bowels were moved by a single enema. On the following day his temperature, pulse and respiration were normal, and all that he complained of was slight soreness in his abdominal muscles. All symptoms of shock had disappeared and he was discharged from the Hospital cured.

Society Reports.

AMERICAN ORTHOPEDIC ASSOCIATION.

FIFTH ANNUAL SESSION, HELD AT WASHINGTON, D. C., SEPTEMBER 22ND, 23RD, 24TH, AND 25TH, 1891.

ORTHOPEDIC SURGERY AS A SPECIALTY.

Dr. A. B. Judson, of New York, in the President's Address, said that orthopedic surgery is specially the domain of physical demonstration, where subjective symptoms give place to objective signs, where treatment is chiefly mechanical, and where results are recorded in degrees of a circle, and fractions of an inch. It exists and thrives as a specialty, because the general practitioner concurs with the public in committing patients who, from the nature of the case, generally recover with some deformity and disability to the care of experts.

Dr. N. M. Shaffer, of New York, defined orthopedic surgery as that department of surgery which includes the prevention, the mechanical treatment, and the operative treatment of chronic or progressive deformities, for the proper treatment of which special forms of apparatus or special mechanical dressings are necessary.

Dr. V. P. Gibney, of New York, proposed a definition as follows: That department of general surgery which includes the prevention, the mechanical treatment, and the operative treatment of chronic or progressive deformities.

ORTHOPEDIC NOSOLOGY.

Dr. W. R. Townsend, of New York, advised the construction of a uniform nomenclature for orthopedic affections to facilitate the taking of histories, and to increase the value of reported cases. A committee was appointed for this purpose.

THE LATE MR. THOMAS.

Dr. A. J. Steele, of St. Louis, paid a friendly tribute to the late Mr. Thomas, of Liverpool, a corresponding member of the Association, whose methods have been so widely discussed and whose influence is felt in many branches of orthopedic practice.

CRURAL ASYMMETRY AND LATERAL CURVATURE.

Dr. H. L. Taylor, of New York, described two instances in which the leg was two inches, and one and one-eighth inches short, respectively. Both cases were in young women. The short limb was larger and stronger, the shortening was chiefly below the knee, and there was no lateral curvature.

Dr. A. Hoffa, of Wurzburg, Germany, described a specimen which proved that in one instance the shortness was due to union of the neck and shaft of the femur at an acute instead of an oblique angle.

Dr. F. Beely, of Berlin, illustrated with specimens of lateral curvature and ingenious models, the changes which occur in the bodies of the vertebræ preceding rotation, explaining how the paraspinous sulous is shallow and broad on the concave, and deep and narrow on the convex sides, a condition which is reversed in the lumbar region by the absence of ribs.

SPINA BIFIDA AND CLUB-FEET.

Dr. H. A. Wilson, of Philadelphia, related the case of a child of four years. The ordinary methods of reducing the deformity of the feet excited suppuration, which resisted treatment for six months, as long as the patient remained under observation. There were sensory paralysis and deficient circulation in the lower extremities. The same intolerance of surgical treatment thwarted all attempts to treat the spinal tumor.

Dr. L. A. Weigel, of Rochester, had had similar trouble with a similar case, but found that when the child was older, it was possible to treat the deformity of the feet with success.

Dr. A. E. Hoadley, of Chicago, related a case of spina bifida, in which good results had followed an operation in which he did not attempt to repair the vertebral deficiency, but had simply turned up large flaps, and united them by silk sutures.

Dr. T. M. L. Chrystie, of New York, reported a case of congenital equino-varus, with absence of great toe and contiguous bones of the instep. Mechanical treatment speedily reduced the deformity, with a gain of symmetrical gait.

Dr. W. E. Wirt, of Cleveland, related an interesting and unusual case of club-hand and club-foot, with other congenital malformations.

Dr. Hoffa said it was evident that all cases of club-foot do not have the same causation. The cases reported were due to some fault in the earliest stages of development.

SPASTIC PARALYSIS AND SPINA BIFIDA.

Dr. W. N. Bullard, of Boston, reported a successful operation by Dr. C. L. Scudder, of Boston, for the relief of spastic paraplegia in a child with spina bifida. He thought the paraplegia was not due directly to the spina bifida, but to the accompanying hydrocephalus. He advocated electrical treatment, and faradization, rather than galvanism.

Dr. Weigel reported a case in which division of all shortened tissues, and the use of a brace, had secured a favorable result.

DEFORMITY AFTER KNEE-JOINT EXCISION.

Dr. J. C. Schapps, of Brooklyn, said that after excision the two united epiphyses make a mass of soft bone in each end of which is inserted a long lever. With this leverage, it is possible to restore and maintain a straight limb by simple mechanical treatment.

Dr. A. M. Phelps, of New York, thought that recurrence of deformity can be prevented by liberal resection of the hamstrings.

Dr. Hoffa said that relapse often occurs from incomplete removal of diseased tissue, and that when excision is done in early life, and all disease removed, marked shortening will not occur.

Dr. Beely said that flexion could be prevented by over-correction, but at the risk of further over-correction as the result of locomotion. Apparatus designed to prevent recurrence of deformity should relieve the limb from the weight of the body.

Dr. Taylor objected to free division of the hamstrings, as these muscles are useful in balancing the pelvis on the femur, even after motion at the knee is abolished.

Dr. J. D. Griffith, of Kansas City, had prevented flexion by removing all the disease and without dividing the hamstrings.

Dr. Schapps said that in many patients under ten years, excision was to be preferred to mechanical treatment.

KNEE TROUBLES IN LOCOMOTION.

Dr. Shaffer related a number of cases in which an elongated patellar ligament had caused pain and difficulty in locomotion.

Dr. A. M. Vance, of Louisville, thought that the ligament might become shorter if not constantly stretched by use. Rest was indicated.

Dr. Gibney cited a case in which rest for one-and-a-half years had not caused shortening.

Dr. Shaffer said his patients had been benefited by giving lateral support, thus converting the joint into a true hinge.

ATROPHY IN JOINT DISEASE.

Dr. E. G. Brackett, of Boston, argued that atrophy is due to disease and not entirely to reflex irritation.

Dr. A. G. Cook, of Hartford, said that atrophy of the foot, often very marked, can be only the atrophy of disuse.

Dr. J. K. Young, of Philadelphia, believed that the atrophy in question is the result of reflex interference with nutrition. In hip disease, it appears first in the thigh muscles, especially the adductors.

ATROPHIC ELONGATION.

Dr. Roswell Park, of Buffalo, described the atrophic elongation conspicuous in the lower extremity. As the result of disuse from disease, with avoidance of pressure on the bone ends, the bone lengthens more rapidly than its fellow. This is illustrated in growing children with disease of the tibia or femur, and is noticeable in some cases of hip disease.

TREATMENT OF HIP DISEASE.

Dr. Phelps said that traction and fixation should be enforced to prevent destruction by intra-articular pressure. Ankylosis is the result not of fixation, but of disease. The patient should be put to bed from three weeks to four months, and should then wear the lateral traction fixation splint which was exhibited. Children under three years are placed in the plaster-of-Paris portable bed, which was also shown.

Dr. Wirt exhibited a new device for traction, in which the force of the lever is changed into rectilinear instead of circular motion, without key, screw-driver, wrench, buckle, or strap.

Dr. R. H. Sayre, of New York, said the invention gave accurate and easy adjustment in the direction of traction, but in the direction of relaxation, the control was defective.

Dr. A. J. Gillette, of St. Paul, was satisfied with the results obtained by the use of Thomas' splint.

Dr. Vance said he practiced fixation at the hip, but believed much depended on the surroundings of the patient.

Dr. Shaffer believed the best results can be obtained by the use of the long Taylor traction splint. He thought results should not be reported till six years had passed, as relapses were not uncommon.

Dr. Ridlon, of New York, said a splint

should secure immobilization by antero-posterior leverage, as in Thomas' splint, by an action identical with that of the Taylor spinal brace.

Dr. Stelle approved of the combination of the English method of rest with the American plan of traction.

Dr. Taylor practiced rest in bed with traction in the acute stage, to be followed by a splint which allows locomotion.

Dr. Sayre thought but few cases required lateral traction. When the inflammation had ceased, he applied passive motion. If the pain and tenderness following, last more than twenty-four hours, the passive motion had not been rightly used.

Dr. E. M. Moore, of Rochester, believed that a joint only *moderately* inflamed, demands motion. He employed traction with a certain amount of motion.

CONGENITAL DISLOCATION OF THE HIP.

Dr. Phelps exhibited apparatus for the treatment of this affection, and described his method, and its results.

Dr. E. H. Bradford, of Boston, had modified the apparatus in previous use by adding an appliance with which the patient is allowed to walk about. The joint is thus protected as in convalescence from hip disease. Those appliances he had made of aluminum for the sake of lightness.

Dr. C. C. Foster, of Cambridge, said the best recorded result had been obtained by Dr. Buckminster Brown, whose patient was treated by mechanical means in bed.

Dr. A. Hoffa had operated by deepening the acetabulum, which is practicable from the thickness of the pelvis at this point. At first, he sawed a periosteal flap over the trocharter, but this is unnecessary. Two months ago, he examined his first case, two years after the operation, and found a movable joint, freedom from the characteristic gait, and absence of lordosis.

Mr. Howard Marsh, of London, divided these cases into, (1) Those in which the bone slips about on the wall of the pelvis, and (2) Those in which it is fixed. The majority belong to the second class, and in these, operation is useless, but is more properly applicable to those cases of the first class in which the head is high up and movable. The anterior position is the most favorable, because lordosis, which depends on the backward displacement of the head of the femur, is absent.

Dr. Ridlon said that, as subjects for treatment, anterior dislocations are more hopeless than posterior ones.

Dr. De F. Willard, of Philadelphia, said treatment should be by forcible attempts at reduction, to excite inflammation, followed by traction and systematic exercise.

MALIGNANT DISEASE AND POTT'S DISEASE.

Dr. Judson reported three cases in which Pott's disease and malignant disease of the vertebræ had been confounded by himself and other observers. In one, the diagnosis was made ante-mortem. The patients were four-and-a-half, thirty-five, and forty-two years respectively. The chief diagnostic points are, (1) Deformity present in Pott's disease, absent in malignant disease; (2) Local disability, and (3) Local pain, both absent in Pott's, and present in malignant disease.

Dr. Willard had seen two cases in which his diagnosis was confirmed post-mortem.

Dr. Gibney reported a case in a man of forty years, in which he and others had been baffled in diagnosis. There was sarcoma of the fifth and sixth cervical vertebræ.

Mr. Marsh related the case of a child which was extremely difficult to diagnosticate, and which proved to be malignant in character.

SYPHILITIC POTT'S DISEASE.

Dr. Ridlon said that in this form, the onset is more rapid, the pain and disability greater, the kyphosis sharper in outline, and abscesses often appear before deformity. If recognized lesions of hereditary or tertiary taint are present, treatment should be by large doses of mercury and iodide of potassium.

Dr. B. Lee, of Philadelphia, referred to cases of this origin, which had come under his observation.

POTT'S DISEASE IN THE OLD.

Mr. Marsh had observed instances of suppurative tuberculosis in the metacarpus, tarsus, testis, cervical glands, knee and hip in eight patients between sixty-three and seventy three years. But senile tuberculosis of the spine is most rare. He had seen two cases. The patients were sixty-four and sixty-five years respectively. The College of Surgeons of London possessed an osseous specimen of the action of senile tuberculosis of the upper cervical vertebræ. In his "Studies of Old Case Books", Sir James Paget had recorded a case of Pott's disease in a gentleman of fifty-five, attended with angular curvature.

Dr. Sayre recalled the case of a patient,

age, fifty-five, who recovered from Pott's disease with paraplegia and abscesses.

POTT'S DISEASE AND PREGNANCY.

Dr. T. H. Myers, of New York, had collected twenty-five cases of labor in fifteen patients recovered from Pott's disease. In no instance, did caries recur. But of seven cases in which the disease developed during pregnancy, three died, and three were left paraplegic. Normal parturition often follows in cases of deformed pelvis whose measurement would indicate that it was impossible. These patients should be examined by the obstetrician early in gestation.

Dr. Taylor knew of many cured patients whose marriage had been followed by the birth of healthy children.

Dr. G. W. Ryan, Cincinnati, thought it was a question of allowing the tuberculous to marry. He knew of married women deformed by Pott's disease, who had borne and raised healthy children.

Dr. Steele said one of his patients recovered from Pott's disease and had borne six healthy children.

Dr. Lee said that one of his patients with a large lumbar kyphosis, had borne twelve children who, with the mother, are all in good health. He thought Pott's disease, even in the lumbar region, rarely produced narrowing of the pelvis.

Dr. Vance had seen a number of cases in which this deformity had not made labor of more than average difficulty.

PARAPLEGIA IN POTT'S DISEASE.

Dr. Brackett said that relief from paraplegia may be confidently expected from continuous extension and fixation, even in cases of eighteen months' standing. This should be continued for some time after recovery.

Dr. Young reported two cases of complete recovery, in which there had been absence of sensation, a feature always of grave import.

Dr. Shaffer referred to a case in which the autopsy showed that a portion of the eighth dorsal vertebra had nearly cut through the cord, leaving but a slender thread.

Dr. Hoffa said that in these cases, the spine should be put absolutely at rest. He had collected thirteen operations within the vertebral canal. Two died at once, two recovered, and would perhaps have done so any way. In the others, there were immediate good results but relapses soon occurred. The operation has no great future before it, and should be limited to those cases in which the processes alone are affected.

Dr. S. Ketch, of New York, had now under treatment a patient who had been paraplegic for five years, but he still maintained a hope of effecting a recovery.

Dr. Hoffa suggested that an abscess may be exerting pressure on the cord.

Mr. Marsh said paralysis rarely depends on the pressure of the abscess; but (1) On softening of the cord, (2) Pressure of a displaced sequestrum, and (3) Most common, on pressure from exudation. He would only operate after thorough trial of rest.

Dr. Willard said he could not absolutely diagnosticate the cause. When there are extensive inflammatory deposits about the arches, laminectomy may relieve the posterior pressure and allow expansion of the cord.

Dr. Lee said that in all cases of this form of paraplegia, suspension would materially hasten recovery.

ABSCESSES IN POTT'S DISEASE.

Dr. Townsend thought that, as a rule, these abscesses should not be opened. In some cases, aspiration should be done, and in others, the cavity should be opened and drained to prevent sepsis and danger to life. His views were based on the history of 380 patients, 75 of whom had abscesses.

Dr. Young suggested the division of lumbar abscesses into external and internal, according to their relation to the psoas fascia.

Dr. Vance advocated aspiration, repeated as often as fluid is detected. In this way he cures 3 out of 5 cases. The depot is thus kept small, and the extent of subsequent operations, if necessary, is limited.

Mr. Marsh had rarely obtained a good result by the use of the aspirator.

Dr. Ryan said he had found aspiration to be a poor dependence. When interference becomes necessary, he believed incision to be the most conservative and effective procedure.

Mr. Marsh said that in his observation, it is best to open freely, evacuate thoroughly, and then apply pressure to assist in closing the cavity.

Dr. B. E. Hadra, of Galveston, said that on general surgical principles, such abscesses should be evacuated.

Dr. Willard would let dormant and caseating foci alone, liquefacting collections, he would aspirate and inject with iodoform emulsion, and if true pus were present, he would incise, wash out with sublimate solution, and avoid undue manipulation which might cause fissures which would let the

tuberculous poison into the system. He would then suture the incision, and inject iodoform and boiled olive oil.

Dr. Bradford said that, while he did not think the danger from opening large abscesses was so great as had been thought by some, he was aware that absorption of such abscesses is not at all uncommon.

Dr. J. E. Moore, of Minneapolis, said the evacuation of a spinal abscess is a matter of great surgical responsibility, as it is an aseptic cavity, difficult to protect from infection after operation.

Dr. Hoffa would open only those abscesses which cause severe pain, or are likely to give rise to septicæmia.

Dr. Lee would never open an abscess of this kind unless compelled to by the conditions mentioned by the last speaker.

Dr. Ketch said there was danger that in our anxiety to treat a secondary feature, we neglect the disease itself.

Dr. Shaffer would not say that incision was never advisable, but generally it is wrong to open one of these abscesses. A very large abscess cannot be washed out, and its disappearance may be confidently expected, especially if efficient mehcanical treatment is practicable.

Dr. Myers said that it was proven, (1) That it is impossible to completely remove bacilli from the abscess cavity, and (2) That bacilli-infected wounds, at times, heal primarily. Infection is more imminent after incision, because the wound lays open channels of absorption.

WIRING THE VERTEBRAL PROCESSES.

Dr. Hadra suggested that the spinous processes at the seat of the disease be exposed and then firmly wired together to secure rest, and prevent deformity. The operation, as he had performed it for fracture of the cervical spine, was extremely simple and effective.

Dr. Sayre thought the wires would not bear enough force to remove the weight from the vertebral bodies, and that outside protection would be necessary to prevent lateral and rotatory disturbance.

Dr. Judson thought it was a question whether wiring was applicable through the long periods in which consolidation is delayed. Intolerance of the skin always prevents such pressure as we would like to make on the kyphos. The method proposed, circumvents this difficulty.

Dr. R. Whitman, of New York, said that due consideration should be given to the difference in development between the growing and adult spine.

Dr. Ketch did not see how the proposed operation could take the place of apparatus.

Dr. Moore said it was a most simple and harmless procedure, and notwithstanding the theoretical objections, he would accept the first favorable occasion to try it.

PROGNOSIS AND TREATMENT FOR POTT'S DISEASE.

Dr. Ketch had learned from 75 cured cases, that in length of treatment and degree of deformity, the upper region of the spine is most favorable, and the middle least of all, that paraplegia more frequently accompanies disease in the upper than in the lower regions, and that cases of traumatic origin recover sooner than those of tubercular origin. Sudden deaths sometimes occur in cervical caries from interference with respiration.

Dr. F. Bartow, of Buffalo, said that the earliest important sign of the dorsal and lumbar regions is lateral curvature, dependent on nervous tenderness. Apparatus should be constructed to oppose the rotation accompanying the lateral curvature, as well as the antero-posterior deformity. He used the plaster-of-Paris jacket applied to effect the above objects.

Dr. Foster said that extension in *bed* is the best method in the acute stage. Extension should be made by light weights, the cords leading over the head and foot of the bed and attached to waist-belts, chest-belts, and head-straps.

Dr. Weigel reported a case of cervical Pott's disease, with abscess and paraplegia, successfully treated by extension in bed.

Dr. Ridlon had kept patients in bed from three to four years, and had never seen a case which was not benefited generally or locally.

Dr. Ryan said recumbency was the ideal treatment, but it is in many cases impracticable. He had found split plaster jackets efficient after the acute stage.

Dr. Lee said that many years ago, when the plan had fallen into entire disuse, he was the first to adopt suspension from the practice of Dr. J. K. Mitchell. The apparatus was Le Vacher's head support and jury-mast attached to a chair or go-cart, or to a doorway swing.

Dr. Sayre said that in the cervical and upper dorsal region, a metal posterior splint supported on the pelvis should be used with a jury-mast, and the lower dorsal and lumbar regions, a plaster of Paris jacket with a jury-mast. Recumbency should be practiced in

the acute stage; children should be placed in the wire cuirass.

Dr. Ketch had been disappointed with the plaster-of-Paris and jury-mast in the cervical and upper dorsal region. He commended the Taylor apparatus and chin-piece. In the lumbar region almost any supporting apparatus will secure a good result.

Dr. Taylor said that the antero-posterior lever secures rest and protection and combats deformity. Old and neglected cases are especially amendable to treatment, just as ankylosis is later and rarer than is generally supposed. Abscesses and paraplegia do not forbid a favorable prognosis.

Dr. Bradford said that the plaster-of-Paris jacket was the readiest method, but had its disadvantages, that a stool brace gave better support, but demanded more skill and care, and that recumbency was the surest way to prevent deformity, but, as a rule, was impracticable for the long periods covered by the disease.

TYPHOID SPINE.

Dr. Gibney reported an additional case of typhoid spine, in a man of forty-five years, in which, different from the cases previously reported, there was marked deformity in the cervical region, dating back to typhoid fever at the age of twenty-two. Two years of pain and disability had immediately succeeded the typhoid attack. Usually, the symptoms had not appeared till one or two months after the fever.

Dr. Hadra recalled an epidemic of typhoid with so much tenderness on pressure of the vertebræ that the affection was at first thought to be meningitis.

RHEUMATIC SPONDYLITIS.

Dr. Ryan said that this rare affection should not be confounded with rheumatoid arthritis of the spine. It is usually accompanied by rheumatic manifestations elsewhere. In the early stage, the symptoms resemble those of tubercular spondylitis. Latter, the deformity is not angular but resembles that of senile kyphosis. Treatment should be directed to the relief of pain by support, cautery, and medication. In the chronic form, when pain has lessened, mobility should be encouraged by passive motion.

Dr. Hoadley deplored the confusion which is found in the nomenclature of these conditions which produce such a variety of results. He thought both rheumatism and osteo-arthritis were microbic diseases. If ligamentous structures interfere with motion, passive motion was proper.

Dr. Lee was reminded of a case which was at first thought to be spinal myalgia, but which proved to be gouty disease of the cartilages, an infrequent affection. Apparatus afforded relief, but of course not a cure.

Dr. Ryan said that gouty spondylitis is generally attended by manifestations in other parts of the body. He had failed to state that his patient had limited respiratory movements.

Dr. Vance related a case in which there was, in addition to the spinal affection, complete immobilization of the thorax with chiefly diaphragmatic respiration.

Dr. Bartow had seen a case in which relief was afforded by the spinal jacket.

Dr. Gillette reported a case which, at first glance, resembled the deformity of Pott's disease, but which proved to be rachitic in its etiology. Improvements followed a few days after suspension was begun.

TORTICOLLIS.

Dr. Whiteman inferred from the study of 264 cases, that torticollis was more frequent in females than in males, and that the two sides of the neck were equally liable. Acquired torticollis, being often the result of suppurating cervical glands, should be treated at first by mechanical support to secure rest and prevent deformity. Later, division of contracted parts, with careful after-treatment, should be practiced.

Dr. Hoffa said that cases of fœtal origin have immediately after birth an atrophy of the face and head.

Dr. Whitman thought that the asymmetry of the face and head was a late feature of torticollis due to muscular action on the growing bones.

SACRO-ILIAC DISEASE.

Dr. Lee said the sequence of events is as follows: (1) Injury of the synchondrosis, (2) Subacute inflammation, (3) Irritation of the nerves of the joint, transmitted to the nearest plexus, (4) Resulting pain in the sciatic. The sciatica should be considered the result, not the cause, of all the trouble. In 9 cases out of 10, neuralgia is the effect and not the cause of any trouble. As stooping in sacro-iliac disease is injurious, he had devised a handy instrument with which the patient can pick up an object from the floor while remaining erect.

ELECTION OF OFFICERS.

Dr. Benjamin Lee, of Philadelphia, was

elected President, and Dr. John Ridlon, of New York, Secretary, for the ensuing year.

SELECTED FORMULÆ.

TREATMENT OF URTICARIA.

Quinquad recommends, in cases of intermittent urticaria, quinine, but preferably arsenic. In the chronic form, baths and hydrotherapy in all forms are to be absolutely forbidden. On the other hand, wrapping the patient up in cotton batting is often excellent. Internally alkalies, arseniate of soda, etc., are indicated.

For the pruritus he advises:

℞ Aq. lauro-cerasi.....grammes l.
Chloral..... " v.
Aquæ..... " cc.
M.

Or,

℞ Ether.....grammes xxx.
Tepid water..... " lx.
M.

Also a powder for dusting on the surface:

℞ Amyli.....grammes l.
Zinci oxid., grammes x; or
Acid salicyl..... " v.
M.

When fresh outbreaks supervene, one-fourth of a milligramme of aconitine in divided doses will prove serviceable.—*La Tribune Médical.*

ANTISEPTIC GAUZE.

For plugging the uterus, Bar has employed with advantage a gauze medicated with retinol iodoform. It is used as follows: The gauze, after being boiled in a strong carbolized water and well dried, is dipped in the following mixture:

℞ Retinol.....ʒij.
Wax.....ʒjss.
Iodoform.....ʒj. M.

Tampons made with gauze, prepared in this manner, are especially useful, inasmuch as they are apt to leave a good coating of iodoform upon the vaginal or cervical surface, and thus assure complete asepsis of the mucous membrane.—*Boston Med. Surg. Jour.*

NITRATE OF SILVER IN ICTERUS.

Nieceche recommends the following prescription for catarrhal icterus:

℞ Argent. nitr.....grammes. 0.06 (gr. j).
Aqua. dest..... " 180.0 (f ʒvss).
M. Tablespoonful three or four times daily.

Dietetic regulations must not be neglected. —*Med. Chir. Rund.*

GLYCERINE JELLIES FOR THE HANDS.

The *Ch. and Dr.* gives the following formulæ:

(1)

℞ Tragacanth.....gr. lx.
Glycerine.....ʒij.
Water.....ʒiv.
Extract of rose.....gtt. vi.

(2)

℞ Gelatine.....ʒij.
Glucose.....ʒj.
Glycerine.....ʒvj.
Water.....ʒiij.
Oil of rose.....gtt. v.

TREATMENT OF SEBORRHŒA OF THE SCALP.

Liebreich employs the following prescription in the treatment of seborrhœa of the scalp:

℞ Spirits of ether.....ʒjss.
Tincture of benzoin.....ʒj.
Vanillin.....gr. ss.
Heliotropin.....gr. iij.
Oil of geranium.....gtt. ij.

Signa "For external use, combustible." —*Wiener Medicinische Presse.*

CREOSOTE PILLS.

A German paper gives the following as the best formula for making creosote pills:

℞ Creosoti.....mxc.
Pulv. rad. althææ.....gr. lx.
Calcis ust.....gr. xij.
Aquæ destillatæ.....gtt. vj--viij.

Misce et adde

℞ Sacchari albi.....gr. xc.
Boli.....gr. lx.
Ut fiant pilulæ, cxx.

—*Chemist and Druggist.*

ACETANILID AND CAMPHOR.

Cshesmiutzeff recommends that camphor be given with acetanilid in order to overcome the depressing effects of the latter. He has had good results with this combination in the treatment of pneumonia:

℞ Acetanilid.....gr. iij.
Camphor.....gr. jss. M.

For one capsule. This may be repeated in four hours.—*Boston Med. and Surg. Jour.*

GARGLE FOR CHRONIC LARYNGITIS.

Ragonean recommends the following mixture to use as a gargle in the treatment of chronic laryngitis:

℞ Tinct. of capsicum fastigiatum....gramme 0.50.
Syrup of blackberries.....grammes 50.
Decoction of quinquina.....grammes 150.
M. Sig. To be used night and morning.

—*Rev. de Laryn. d'Otolog. et de Rhinologie,* Sept. 15, 1891.

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO, (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

A NEW TREATMENT FOR TUBERCULOSIS.

The disastrous failure of Koch's supposed discovery for the prevention and cure of tuberculosis is yet only too fresh in the minds of the profession, and with the exception perhaps of Germany, the birth-place of the famous lymph, tuberculin has been almost completely laid aside as not only a useless agent in the treatment of consumption, but exceedingly dangerous to inject into the healthy or affected organism.

The clinical use of tuberculin, which seems to have received a deadly blow at the meeting of the Congress for the study of tuberculosis, held in Paris on July 27th to August 1st, 1891, is now followed by the announcement of a new treatment, proposed this time by Lannelongue, which attracted great attention at that gathering.

The method of Lannelongue, which was foreshadowed in 1879 by that of M. LeFort, has nothing in common with that of the German pathologist. The French author does not deal with vaccinating processes, with subcutaneous injections of any cultured microbe, nor with any specific remedy that directly attacks the tubercle bacillus. Lannelongue uses a solution of *chloride of zinc* which, when injected subcutaneously, acts not directly upon the tubercular foci, but on the tissue that surrounds these, forming dense fibrous investments around the tubercles and transforming and rendering the tissue insusceptible to the action of the bacilli, * and bringing about secondary changes.

The chloride of zinc seems to act the same on healthy tissues as it does on diseased ones. Thus, from experiments on healthy animals it was found that injections of the drug produced a fibroid change in the normal anatomical elements, and by repeating these experiments on animals previously rendered tuberculous, the same results were obtained

* For the technique of the treatment see article in the Periscope.

when the zinc was injected outside and around the tubercular tissue. The process sometimes ended in abscess, but usually it gave rise to the new formation of fibrous tissue, with disintegration and absorption of caseous matter, destroying, in this manner, morbid products. This action of the medicament was not limited to the tissues near the point of injection, but went beyond them.

These phenomena imbued the mind of the French observer with the idea of trying the process in the treatment of tubercular tissues. With the assistance of M. Achard, a series of experiments was instituted in the Hospital Trousseau, the results of which are embodied in the memoir read before the French Academy of Medicine during the sitting of the Congress. Thirty children, suffering from tubercular disease of the knee-joint were subjected to subcutaneous injections of the chloride of zinc, a treatment which, as it may be observed, is simplicity itself. In twenty of these cases that had received 9 or 10 injections during a period of three months, the most excellent results were produced. The swelling was much diminished, a formation of new tissue took place, and articular motion returned. For fully a month after the establishment of these happy changes, no return of abnormal phenomena was noticed, the patients continuing to improve, to gain in weight and apparently to enjoy all the prerogatives of perfectly healthy individuals.

Are these significant facts sufficiently strong to sustain the opinion that the cases under consideration were permanently cured? A cure can be said to be completely established when there is total disappearance of the bacilli from the organism; therefore, as Lannelongue himself has remarked, it can not be asserted from this preliminary study that such a victory has been attained. And yet, in a piece of tubercular tissue extirpated from one of the cases after the zinc treatment, there was revealed, on careful examintion, a fatty and fibrous change, *but not a single bacillus.* An injection of this new substance into a rabbit produced no effects whatever during a period of two months after the inoculation. But, may not there have been made in this particular case a wrong diagnoses in regard to the previous existence of tuberculosis? The author himself prefers to accept the responsibility of a wrong diagnosis rather than go beyond the limits marked by conscientious and thorough investigation.

On the whole, these researches are of extreme interest, and the results so far obtained of great practical importance.

Book Reviews.

THE POCKET ANATOMIST. Founded upon Gray. C. Henri Leonard, A. M., M. D., Professor of the Medical and Surgical Diseases of Women and Clinical Gynæcology in the Detroit College of Medicine. Fourteenth revised edition, containing Dissection Hints and Visceral Anatomy. Detroit Mich., 1891. The Illustrated Medical Journal Co., Publishers. Cloth 297 pages, 193 Illustrations; price, postpaid, $1.00.

The fact that this little book has reached the 14th revised edition, and that the sale has exceeded 12,000 copies, is sufficient evidence to show that it supplies a desired want. The illustrations are copious, and taken from Gray's Anatomy,—in fact, the author has made such literal use of this standard work that *The Pocket Anatomist* is a sort of a condensation of it with additions here and there. The paper is thin and glossy—unfortunate defects.

SELF-EXAMINATION FOR MEDICAL STUDENTS: 3,000 questions on Medical Subjects arranged for self-examination; with the proper references to standard works in which the correct replies will be found. Philadelphia: P. Blackiston, Son & Co.

This miniature work comprises about 3,000 questions on Anatomy, Physiology, Materia Medica, Therapeutics, Chemistry, Practice of Medicine, Surgery, Obstetics, Gynæology and Diseases of Children. The questions have been selected with regard to their bearing on practical medicine, and are such as would likely be asked in the quiz room and examinations. In order that the student can always find correct answers references are made to Gray's Anatomy, Gould's Dictionary, and various Quiz Compends by the same publishers.

There can be no doubt that the self-examination contemplated in this vest-pocket companion can be made very beneficial, but, on the other hand, a series of such questions

of such limited scope as those before us cannot have other than a prejudicial effect on the average student, because the inevitable tendency will be to confine his self-examination to the narrow limits of the questions asked. Such a book can only be acceptable when it is founded on text-books, and not on compends, which in themselves are bad enough.

PERISCOPE.

THERAPEUTICS.

THE TREATMENT OF TUBERCULOSIS BY INJECTIONS OF CHLORIDE OF ZINC.

The technique of operation as outlined by Dr. Lannelongue at the recent Congress for Tuberculosis at Paris is as follows:

I. *Non-Suppurating Tubercular Affections.* In osteo-articular tuberculosis of the hip, the limb is placed in a good position and extension maintained during the whole course of treatment. The injections are made upon the posterior surface of the neck of the femur, outside the capsule, upon both the superior and inferior borders, and upon the anterior aspect at its junction with the body of the femur. The needle is thrust in behind the great trochanter not far from this bony prominence so as to avoid wounding the sciatic nerve. To reach the inferior border of the neck, the needle is deviated downward and inward, and to reach superior border and a portion of the anterior surface of the neck it should be made to penetrate upward and immediately in front of the great trochanter. When the surface of the neck is felt the needle is drawn back so as not to inject into the articulation, but into its periphery.

In osteo-articular tuberculosis of the knee the leg is maintained in a position of extension by means of a splint. The injections are made over the different parts of the synovial membrane, commencing at the superior cul-de-sac. The needle is entered a short distance from the margin of the fungosities, penetrating each time as far as the femur; the injections are always made under the periosteum, the quantity injected varying from 10 drops in a child ten years old to one-third or one-half more in adults. The inferior synovial reflexion on each side of the patellar tendon is acted upon by injecting over each tuberosity of the tibia immediately below the articular margin of the epiphysis.

In tubercular affections of the ankle, the foot is maintained in a position at right angles to the leg. The injections are made in front over the anterior border of the tibia under the tendons, on the inside below the malleolus, and behind along this process. From 12 to 15 drops are injected in a child six to ten years of age.

In tubercular arthritis of the shoulder joint, a series of punctures varying from four to six, is made across the deltoid, over the external, anterior and posterior aspects of the humeral neck.

In tubercular arthritis of the elbow-joint the forearm is kept semi-flexed at first by a bandage and later by a plaster-of-Paris dressing. The fungosities at the elbow project over the superior extremity and sides of the oleocranon. The same procedure is applicable as in the knee.

In white swellings of the wrist the fungosities frequently extend to the sheaths of the extensor and flexor tendons of the hand; they start almost always from the radius and ulna. Consequently the injections are made at the level of the reflected cul-de-sac, over the forearm in front and behind, care being taken to avoid the nerves and arteries, and in the same manner at the level of the superior extremity of the metacarpal bones.

In tubercular arthritis of the hand and fingers one injects on each side of the lateral surface of the diaphyses, near their articular extremities.

In non-suppurating tubercular affections of the glands, the injections are made at different points around the ganglion and into the deeper parts. They give rise to an acute suppuration. In cases of tubercular nodules of the soft parts the same procedure may be applied with excellent results.

II. *Cold Abscesses of the Joints.* The treatment in these consists of punctures and and washing out of the cavity of the joint with sterilized water or an antiseptic solution. If the fluid does not reaccumulate and no reaction follows compression is employed; otherwise the same procedure is repeated. If a phlegmonous process develops multiple incisions are made, and if the articular surfaces, cartilages and bones are found disorganized the affected parts are removed, after previously injecting the periphery with the chloride of zinc solution so as to act upon the fungosities. The injections are repeated several times.—*Internat. Jour. Surg.*

THE CAUSE AND CURE OF BALDNESS.

Baldness, like obesity, is one of those

minor evils which could probably be much more thoroughly kept under control, if people would take more pains and begin earlier with their treatment.

Dr. M. Joseph Tyson, who writes upon idiopathic and premature baldness in *The Lancet*, makes some observations which quite corroborate this view. Thus he sums up the causes of baldness as insufficient exposure of the hair to the sun and air, close, ill-ventilated hats, excessive mental work and worry, the influence of heredity, venereal and alcoholic excesses, constant washing, and the neglect of using some oil or pomade. These causes vary in importance in different cases.

It can be plainly seen that this remedy is not a single or simple one.

Children, he says, should as much as possible do without caps, and hats when worn should be of the lightest description. During the hot season, a stouter hat is necessary for the prevention of sunstroke. A head covering should never be worn indoors, in trains, or in closed carriages. The kinds of material employed is of importance. In summer and still weather straw appears to be the best, on account of its lightness and permeability. In winter, hats made of light felt, well ventilated and unlined, are to be recommended. The ordinary tall hat, and the thick, heavy, unventilated top hat, cannot be too strongly condemned. Of course, nothing special can be said regarding hereditary or nervous influences. In concluding, however, he mentions a few minor points of treatment which should not be forgotten. Too constant washing of the hair is unnecessary, as well as harmful. Once a week is quite often enough for cleanliness, as well as for maintaining the strength of the hair. The same remark applies to constant brushing, for continual brushing, especially with hard brushes, should be avoided. There is a common notion that greasing the hair is vulgar so many persons fall into the other extreme, and never apply any pomade at all. After the hair has been washed it is certainly beneficial to apply some form of simple grease or oil. When the head-hair is becoming rapidly thinned, some stimulating material, such as ammonia and cantharides, added to the oil, will increase its good effects.

Dr. Tyson does not take into account one possibly important factor in causing baldness, viz., that of contagion. It has been held on good authority that many cases of baldness are parastic, and due to micro-organisms gathered from unclean brushes and combs.—*Med. Record.*

ABSORBENT LINIMENTS (LINIMENTA EXSICCANTIA) IN SKIN DISEASE.

Professor Pick, to whom belongs the merit of introducing medicated gelatines in the therapeutics of the skin, has suggested (*Prager Med. Wochenschrift*, 1891, No. 21) an important improvement in the method of preparation. Bassorin is a gum, unlike gum arabic, almost insoluble in water, in which, however, it swells to a syrup-like mass, which, when applied to or gently rubbed on a surface, dries as a very thin delicate covering. Linimentum exsiccans, the name which he gives to the preparation, can be prepared either by heat or cold. The constituents are 5 parts tragacanth, 2 parts glycerine, and 100 parts of distilled water. In small quantities it is best prepared cold, the finely-powdered tragacanth being well rubbed up with the other constituents, until it forms a homogenous syrup or lanolin-like mass. For preparation in large quantities it is best prepared warm, yielding in this way an aseptic mass which remains aseptic. The liniment so prepared is ready for use, and when allowed to dry in thin layers on inflamed and congested skin produces a feeling of coolness followed by a feeling of tension. The application is free from all the disadvantages connected with fatty substances. With the simple liniment compound liniments can be formed containing oily substances, such as oleum fagi, cadini, Rusci, ichthyol, styrax, balsam of Peru, etc., in proportions of 5 to 10 per cent. Insoluble substances, such as chrysarobin, oxide of zinc, the white, red or yellow precipitates of mercury, iodoform, iodol, salicylic acid, etc., can be added to it in various quantities until it may acquire the consistence of a paste, increasing its drying qualities. Pick found that a 10 per cent. tar liniment produced as much effect as a simple tar preparation, and on account of the smaller amount of absorption could be used more freely without danger.—*Brit. Med. Jour.*

THE TREATMENT OF ERYSIPELAS.

In the *American Journal of the Medical Sciences*, for July, 1891, Dr. Charles P. Allen publishes his conclusions as to the best method of the treatment of erysipelas, based upon his personal experience in the treatment of fifty-six cases and the reports of four hundred and sixty-six cases occurring in the Charity Hospital, New York.

In the first place, he recommends internally such symptomatic treatment as the nature of the case seems to require. Antipyretics only in case of high or persistent fever (over 103½° to 104°); then antipyrin in dose of at least gr. xv to xx for an adult, guarded by alcohol; cooling drinks. Calomel or saline aperients in full doses if constipation. If much weakness, alcoholic drinks given freely, especially at critical periods, and iron or iron and quinine; digitalis if much fever and prostration; bromide for delirium; antipyrin or phenacetin for headache, with cold applications to head, and as concentrated and nutritious a diet as possible.

Second, locally, he paints the patch and surrounding margin of the healthy skin thickly with ichthyol in collodion, ʒj to ʒij to ℥j. If the scalp is the region affected, a watery solution or ointment of ichthyol can be employed. To arrest the spread, he makes an attempt either with the band of adhesive plaster or by scarification, or both, the latter to follow the former, in case the disease spreads beyond the adhesive strips. In erysipelas of the face, which has not yet reached the forehead, or at least its upper part, he would apply a band tightly about the forehead and just above the ears, cutting the hair in a strip around if necessary to secure firm pressure. The chances of arresting the process here should be at least equal to those of checking the spread upon an extremity, for we have a hard bony base over which to make our compression. If the boundary is passed, then he should at once have the scalp shaved and apply another band higher up. The hair should be cut in any case in which the scalp is invaded or threatened. Then the same application of ichthyol in collodion can be made, as to the face or other part. If there be much tension, swelling, heat, and discomfort (which is not apt to be the case under collodion), any oily substance can be applied over it.

In treating erysipelas, the uncertainty of *prognosis* must always be kept in mind. Cases, in all appearances mild in the beginning, may become severe and prove fatal, while formidable-appearing areas may suddenly cease spreading spontaneously. It is scarcely more safe to say a case will progress favorably (though the great majority do) than to claim that the particular line of treatment instituted has prevented an unfavorable termination, or proven abortive, unless a whole series of cases under a given method have terminated in a shorter than the average time.

Naturally, when the erysipelatous process has its sources in a pus collection, such as an abscess, pustule, ulcer, foul wound, carious tooth, diseased duct, etc., the first care must be to secure as prompt and thorough disinfection and cleansing as possible. Pus must be destroyed and purity maintained. A solution of peroxide of hydrogen will often be found useful in effecting this purpose. In such cases a spontaneous halt may be hoped for. In the same way a diseased mucous membrane must be cared for; excoriations, ulcerations, rhinitis, or other disease of the nasal mucous membrane or affection of the throat must be looked after. It is probable that every case of facial erysipelas starts from local solution of continuity either upon the skin or adjacent mucous membranes, and we simply call some cases "idiopathic" or "genuine" when we fail to find the point where the micrococci have entered.

As a prophylactic measure in those predisposed to repeated attacks, great care should be taken to discover and cure affections of mucous membranes, carious teeth, ulcerations, or other disease processes or conditions as possible means of maintaining the tendency. Recurrences after apparent cure must be kept in mind and treatment continued sufficiently long to prevent them. —*Ther. Gaz.*

MEDICINE.

HYSTERICAL LARYNGEAL DYSPNŒA.

In the night of May 13th I was asked by a medical man to see a young woman, who, it was thought, would require tracheotomy. She had very marked laryngeal dyspnœa, with stridulous inspiration and marked retraction of the chest. At intervals the laryngeal spasms became so extreme that no air entered; she struggled for breath, the pulse nearly stopped, and then with a stridulous inspiration air began to enter again. On examination of the larynx I found there was no laryngitis, but the cords were strongly adducted. Her voice, though weak, was clear. Inhalation of a few whiffs of chloroform and the application of a hot sponge over the larynx had no effect. The history of the case was that a fortnight previously she began to suffer from these attacks of dyspnœa, which were very frequent and severe for the first few days, and then had gradually diminished in frequency and severity until they had quite ceased by May 10th. On the night of the 12th she had a

severe one, but was never quite so bad as on the following night when I saw her. For a week before the attacks began she had suffered from rigidity of the muscles of the back. She had lately complained of "cramps" in the arms and legs, which I thought might be hysterical tonic spasm, and so so decided to try galvanism. This I did over the larynx and in the course of the pneumogastric nerves, using thirty cells, but beginning with twenty. In five minutes the spasm, which had been urgent for five hours, had ceased. I then examined her larynx, and found the cords well abducted at the end of phonation. During that night there was only one very slight and short recurrence, and there have been only two since (May 17th), most trivial in character. Dr. Charles A. Morton, in the *Brit. Med. Jour.*

THE GERMICIDAL POWER OF THE BLOOD.

The blood is known to have germicidal properties, and these properties have recently been studied by Von Fodor, who reaches some interesting conclusions. He finds that increased alkalescence of the blood raises its germicidal power very much. The drugs which do this most effectively are the carbonates of sodium and of potassium. By the alkalinization of the blood of rabbits he made a large per cent. of them refractory to anthrax. Hydrochloric acid had no effect on the germ-destroying power of the blood, while quinine actually lessened it.

These observations are of interest in connection with the observations of Bordas who asserts that he has discovered the specific microbe of acute rheumatism, it being, he thinks, an organism allied to the micrococcus pyogenes.

On the other hand, the statement that quinine lessens the germicidal power of the blood is absolutely untrue, as regards the plasmodium of Laveran at least. We are accustomed to think also that hydrochloric acid is a good drug to take in order to prevent the infection of cholera and other germs which get in by way of the stomach. Von Fodor's observations, therefore, cannot have a general application.

He states that temperatures up to 39° C. or 40° C. also increase the fighting power of the blood against pathogenic organisms.—

ABSENCE OF THE PATELLAR TENDON-REFLEX IN INTERSTITIAL KERATITIS.

Lang and Wood (*Royal London Ophthalmic Hos. Reports*, Vol. XII., p. 312,) have recorded the results of their examination of sixty-two cases of interstitial keratitis in reference to the presence or absence of the patellar tendon-reflex, from which they conclude:

1. That in about 30 per cent. of all cases of interstitial keratitis the knee-jerk is decidedly subnormal.

2. That in about 10 per cent. of all cases it is entirely absent—all known cases of subnormal tendon-reflexes, outside of the constant fact that the local eye-disease exists, having been eliminated.

3. It is probable also that in a very small percentage of cases of diminished and absent knee-jerks the usual constitutional dyscrasia cannot be demonstrated.

4. That it is rare to find a case of exaggerated patellar tendon-reflex interstitial keratitis when unaccompanied by some of the affections known to produce the former. —*Ex.*

THE COCAINE HABIT.

In a summary of recent papers upon the cocaine habit, now regarded by some as "one of the three scourges of mankind," Dr. Edmund Falk points out that it has a characteristic clinical picture: on the one side in the cachexia or bodily ruin, on the other side in the moral impairment and pronounced mental affection. Patients who use cocaine alone—and those who have endeavored to wean themselves from morphine by its aid, and so added cocainism to the morphine habit—appear marasmatic. The skin is of a pale yellowish, almost cadaveric tint and withered feel; the extremities are cool and covered with cold sweat. The eyes are deeply sunken, glistening, and surrounded by a dark ring; the pupils widely dilated. Appetite is lost; digestion disturbed. Salivation with dryness of throat may be complained of, and further, partial sensory disturbances or total analgesia. From the paralyzing action of cocaine upon the blood-vessels, patients complain of palpitation and breathlessness, troublesome sweating and noises in the ears, and also syncopal attacks and dyspnœa. The pulse is more frequent and easily compressible. They suffer from a want which must be satisfied; they become nervous, trembling, and fall into a wretched condition of neurasthenia. Speech is disconnected and scarcely be understood; impotence and incontinence of urine may appear. Sleeplessness sets in

early. One of the most characteristic effects of this habit is the occurrence of muscular twitching, tonic and clonic convulsions, and finally, epileptic attacks in which the patient may die. The mental symptoms may take the form of hallucinations, usually of general sensation, but not infrequently of sight as well. General mental weakness may set in rather early, to be observed in a loss of memory and unusual prolixity in conversation and correspondence. When the drug is withdrawn, besides the vasomotor symptoms there may be seen depression, impairment of will-power, weeping, etc. The chronic form does not protect from acute intoxication.—(*Therap. Monatshefte*, No. 12, 1891.)

PARTIAL EPILEPSY OF THE SUB-CORTICAL ORIGIN.

Duflocq, in a contribution to the study of cerebral localizations, reports an interesting case of partial epilepsy in which the case of the paroxysms—an old and well-encapsulated blood-cyst—was without any point of contact with the cortical layer of the brain, but was completely separated from the gray substance by an absolutely healthy layer of white matter. The patient was a hatter, forty years of age, who gave a history of a fall from a step-ladder twenty years before, striking upon his head. There was no loss of consciousness and no subsequent pains in the head. He had had no syphilis, nor had he ever handled the acid nitrate of mercury. Three days before his admission into the hospital he was suddenly taken with a form of aura, consisting of a construction which began at the epigastrium and in a few moments mounted to the throat, thence radiating toward the left side of the jaw. The patient heard a loud noise, which seemed to resound in the left half of the head and the left side of the chest at the left side of the semi-lunar space. Severe pains in the head were felt, which persisted throughout the attack. The attack commenced at the moment the painful constriction reached the throat. The first phenomenon was a drawing of the tongue backward, so that respiration was impeded; then the head was turned slightly toward the left and inclined upon the left shoulder. The left corner of the mouth was drawn toward the ear; the mouth was slightly opened and held so. The eye did not participate in the convulsions. The movement extended to the shoulder, but the muscles of the arm and forearm remained relaxed. The head was strongly held by muscular contraction to the left shoulder during the paroxysm. The end of the crises was marked by a pretty abundant salivation, which commenced a little previous to the end. The tongue was hard and could not be drawn out. The patient could emit only unitelligible and hoarse sounds, but memory and consciousness were well preserved. The pulse was regular and the respiration preserved its normal rhythm. After the attack there existed a facial paresis. There was no febrile elevation. Successive attacks were followed by loss of consciousness, increasing stupor, and death five days after admission. Trepanation was performed on the morning of the last day, with very marked amelioration of the symptoms. The patient spoke, drank and watched a game of dominoes, but death occurred in the evening.

The autopsy revealed no deformity of the cranial walls. The brain and dura and pia mater were intact. The left hemisphere was normal. Examination of the surface of the right Rolandic region showed nothing abnormal. The fissures were clearly marked and the gray matter presented its usual coloration. An antero-posterior section, made just above the plane of the corpus callossum, revealed a brownish-red mass in the middle of the white substance corresponding to the lower extremity of the ascending frontal convolution. This mass was rounded in form and the size of a billiard-ball. It was surrounded by two concentric zones—the inner one clear yellow and of a slightly softened consistency; the outer one was of the consistency and ordinary appearance of the white substance. Finally, toward the surface of the convolution was a perfectly intact band of gray matter. A vertical and transverse section at the level of the foot of the ascending frontal (the frontal section of Pitres) showed the approaches to this rounded mass to be reddish in color. The mass was found to be composed almost entirely of the white substance of the lower frontal fasciculus (the foot of the ascending frontal), and the region of the island was intact. The external capsule was far distant from the diseased focus. There was no atheroma of the arteries of the base of the brain. The brownish mass was firm and was composed of a central portion of a mahogany-colored detritus, slightly foliated and manifestly consisting of blood. Around this was a shell firm and thin.

It is quite exceptional to see a tumor situated in the white substance give rise to a partial epilepsy. Duflocq has searched med-

ical literature and has succeeded in finding only three cases which are analogous to the one above reported—those of Osler (*American Journal of the Medical Sciences*, January, 1885), Taddeo de Hyeronomgs (*Riform. Med.*, 1887), and Bouveret (*Lyon Méd.*, September 28, 1884). The clinical study of the patient above recorded reveals a certain number of functional troubles which appeared at the same moment as the epileptic crisis and which constituted it. These are the traction of the tongue backward, the retraction of the labial commissure, the opening and contraction of the mouth, the constriction of the pharynx, and the alteration of the voice. To each of these troubles a cortical centre corresponds, which numerous experiments and a few rare clinical observations have located in the lower third of the ascending frontal convolution. But it was in the white substance immediately adjacent to this limited region that the autopsy of this patient showed the existence of a hard, small, and perfectly circumscribed focus, of very old date, and one which could not have determined any lesion in the vicinity. All the centres involved indicated in a very positive manner that the seat of the lesion was the foot of the ascending frontal convolution; and if it is established that partial epilepsy may be of subcortical origin, the operator should feel authorized to search, in analogous cases, even in the white substance subjacent to the cortical centres for the original cause of the epileptiform seizures noticed in the patient.—*Revue Médicale*, Feb. 10, 1891.

RELATION OF ASTHMA TO OTHER DISEASES.

Dr. Samuel West, in *The Practitioner*, after a careful study of this subject reaches the following conclusions: Asthma must be regarded as a reflex neurosis, the symptoms of which are spasm of the bronchial muscles, of the diaphragm, and of other inspiratory muscles associated in many cases with more or less vasomotor disturbance in the bronchi.

The theory necessitates the assumption of a peculiar unstable condition of the respiratory centres, the nature of which is at present unknown, but which constitutes the essential predisposing cause of the disease, and which in all probability is the only heritable part of it.

In all this the resemblance of asthma to epilepsy is very close, and Hughlings Jackson does not shrink from curtly defining asthma to be "a respiratory convulsion," and I presume that he regards it as possibly, in many cases, a congenital affection, for he proceeds to attribute it to "the discharge of imperfect (? small) respiratory centres."

It is interesting to find that this theory brings us back to the view originally propounded in his *Zoonomia* by Erasmus Darwin, who stated that *asthma convulsisum* had the same character as all other cramps and epilepsies, and that it could originate like them from nearly all distant parts of the body.

HYSTERICAL TREMOR.

Dr. Remond, in the "*Gazette des Hopitaux*," gives us two cases of this curious affection. The first was a man, fifty-four years old. He had not been a drinker, nor had he ever contracted syphilis.

Two months before, while witnessing a review, he had been knocked down by the horse of a cavalryman and very much frightened. This was followed by violent headache, and his legs and arms trembled so that he could not hold anything in his hands, and he was hardly able to stand erect. When in repose, his hands do not move; but if he tries to carry a glass of water to his mouth, he is utterly unable to do it on account of the trembling.

The knee-jerks are slightly exaggerated. Ankle-clonus absent. Pupils small and equal; no nystagmus. Voice slow and jerky. Anæsthesia of the legs and arms; there was also anæsthesia of the pharynx, and just above the right eye there was a very painful point.

Here were two sets of symptoms, one pointing very strongly to multiple sclerosis and the other to hysteria. Which of the two was it?

Small doses of bromide were given, along with elaborate directions, and much stress laid upon the wonderful healing power of the remedy. In less than a month all the symptoms had vanished and the patient demanded his discharge.

It is hardly necessary to say that the affection was undoubtedly hysteria.

The second case was that of a roofer, thirty-eight years old. One year ago he experienced a severe fright in falling on a roof. A chimney stopped him and saved his life; but when he was picked up he was paralyzed on one side and aphasic. He was removed to the hospital, and cured in five months and a-half.

Two weeks ago, after a severe mental shock, he fell down unconscious, and when he came to himself he was affected with

trembling, which has grown worse ever since. In the right arm it is a tremor resembling paralysis agitans. When any movement is attempted the tremor in the right arm ceases, but the member moved is affected with tremor which closely resembles that of multiple sclerosis. His speech is slow and halting, but the tongue does not tremble. There is almost complete anæsthesia of the entire surface of the body. The knee-jerks are exaggerated; ankle-clonus present. When attempting to walk, he cannot hold himself erect without assistance, and the body is affected with continual shocks.

This case left the hospital before the crucial test of cure could be applied. These two cases belong in the same category, however. It is always hysteria, that protean neurosis, imitating first one disease, then another, occasionally superposing itself upon other affections, but never combining with them.—*Jour. Nerv. Ment. Dis.*

SURGERY.

THE PRESENT STATUS OF THE TREATMENT OF URINARY CALCULUS.

Every few years we find the practice in any particular form of disease undergoes radical changes, so that the methods in vogue in the near past are almost entirely superseded by newer and more modern ones; or possibly, the profession reverts to an operation largely practiced in the past, one which has remained quiescent for a number of years, only to be again brought forward.

In regard to the affection under consideration, the modern (present day) sentiment appears to be as follows:

1. Wherever possible, resort to litholapaxy.

2. If litholapaxy is contra-indicated by a sacculated bladder, a high degree of cystitis, stricture of the urethra, or an irritable, contracted bladder, one of the cutting operations must be performed.

3. If the stone is not very large, and can be extracted by that method, the median perineal method is preferred.

4. If the stone is very large, or if there is reason to suspect the co-existence of tumors of the bladder, or any other reason calling for a complete exploration of the interior of the bladder, resort should be had to supra-pubic cystotomy.

5. The existence of cystitis, or other necessity for drainage of the bladder, calls for the lateral operation.

From the above summary it at once becomes evident that the range of lateral lithotomy has been largely curtailed, while that of litholapaxy has been wonderfully increased. In fact, the crushing operation is now almost universally recognized as the operation of choice whenever possible. The grounds upon which this decision rests are that the crushing operation is less risky; it is applicable to all ages; the time of convalescence is very short compared with the other operations, and the mortality is much lower.

The chief objection against litholapaxy is the possibility of leaving some fragment of the stone in the bladder, to act as a nucleus for a new stone. This oversight has frequently occurred, but the fragment has always been detected early, and is easily removed by reintroducing the lithotrite.

The dangers and difficulties of the median operation are usually slight, but its range of successful application is limited. The time necessary for the healing of the wound is an objection.

Supra-pubic cystotomy is somewhat difficult of performance, more paraphernalia are required, and the dangers of complications are perhaps greater than those of any other operation for the relief of this trouble.

At present the tendency is to almost entirely banish lateral lithotomy from the list of surgical procedures applicable to this affection, preference being given to either the median or supra-pubic operation. Time only can determine whether this condition of affairs will continue or not. Some surgeons still cling to the lateral incision and are loth to discard it.

In this editorial we have endeavored to present to our readers, in as concise form as possible, the views held by the leading surgeons of the day, and have aimed to avoid expressing any prejudiced or biased views. To sum the whole matter up in a few words, we can say—this is an age of litholapaxy.—*Cincinnati Lancet and Clinic.*

A PLASTIC OPERATION OF THE ULNAR NERVE.

Prof. Dittel showed a washerwoman, æt. 22, who had the upper arm lacerated by a pressing machine on December 8th, 1890, and who was received into Hospital on the 9th. In the middle of the upper arm the laceration had carried away a large quantity of tissue, exposing all the deep structures.

About seven ctm. above the internal condyle the stump of the ulnar nerve was observed, but the proximal section could not be found for some time, but when it was discovered five ctm. of its length had been carried away with the lost tissue. Sensibility and motility were absent over the area of the ulnar supply. The wound was dressed antiseptically, and in a few days sensibility was restored. Four weeks after the wound had granulated, and January 12, 1891, he commenced the union of the ulnar nerve by taking a flap from above and lowering the nerve about 1½ ctm.; another from below of about 5 ctms. The edges of the two flaps after coaptation were fastened by three catgut ligatures. On April 5th, the electric current produced contractions and active movement of the whole hands.

Dr. von Fillenbaum related the history of a case where an officer in his company had a cut over the right condyle. In the month of August, stitches were applied and the skin united by first intention. The following week the hand commenced gradually to be powerless and become soon unable to hold a sword. The thenar, antithenar, and interossei muscles began to waste. In November he was taken into Hospital and electric treatment commenced, but without success. On examining the arm, a hard scar about the size of a bean was discovered. It was tender on pressure and diagnosed a neuroma. On opening up this scar the ulnar nerve was found to be twisted round and separated from the distal end by adherent tissue. This was cleared away, the two ends of the nerve freshened and brought together with a stitch and four fine silk ligatures in the neurolemma. Healing took place in eight days, and a week after the electric current produced contractions, the muscles began to increase and functional activity to improve.

Prof. Weinlechner said that in the dividing of mixed nerves, the sensibility was seldom lost, as the collateral nerves soon supplied the defect resulting from the injured trunk.—*Med. Press.*

TEST OF COMPLETE CHLOROFORM NARCOSIS.

Guelliot (*Journal de Médecine de Paris*) claims that the absence of the cremasteric reflex, is one of the best and readiest means of determining complete chloroform narcosis. The quickness and force with which the reaction is produced is some index of the degree of narcosis. The point seems to be one well worthy of consideration by the practical surgeon.

HERNIÆ IN MEDIAN LINE OF THE ABDOMEN.

In an exhaustive article on this subject, in *Volkmann's Samml. Klin. Vortr.*, Dr. Witzel states that these hernia originate from congenital clefts in the linea alba. They are usually situated above the navel, and a little to the right or left of the median line. The predisposing causes comprise distension of the anterior abdominal walls, rapid emaciation, trauma, over extension of the trunk during exertion. Owing to intra-abdominal pressure, the superitoneal fat, which is only loosely attached to the abdominal wall, is forced through the opening in the fibrous tissue, and this is followed by protrusion of the peritoneum, and later of other structures (omentum, stomach, intestines.) The hernia, which is small at first, increases very rapidly. The symptoms consist of gastric affections, pains in the upper region of the abdomen, nervous disturbances, which are present from the first and increase in severity. The diagnosis is readily made by abdominal palpation, which should never be omitted in cases where these symptoms are present. The examination is best made at different times. After a meal and in the upright posture the tumor is more prominent; in the dorsal position it disappears entirely; forced respiratory movements cause an enlargement. The small hernia can be easily reduced by pressure, and under favorable conditions, the cleft in the abdominal wall can be felt. The larger ones can be compressed and diminished in size, but cannot be made to disappear completely, a round soft tumor remaining. As regards treatment, if the hernia is fully reduced, a truss will afford great relief; in other cases the radical operation is indicated. The pedicle should not be simply transfixed and excised, but the fatty layer on the sac should be incised, the sac isolated and opened, in order to make sure that no adhesions of the omentum remain.—*Oest.-urgar. Centralbl. f. d. Medicin. Wissensch.*, No. 23, 1891.

THE RADICAL CURE OF INGUINAL HERNIA IN THE FEMALE.

This was the subject of a communication to the Société de Chirurgie by M. Lucas-Championnière, which has been reported in the *Gazette Hebdomadaire.* He has performed many of these operations on females

who had suffered much from hernias; he believes that a certain number of the cases were congenital. He operates as follows:

"I dissect very carefully the sack into the abdominal cavity; the dissection made, I divide the sack without hesitation and the round ligament which, no doubt, becomes attached to the wall. I have never had any unfavorable result from this mode of operating.

"The connection of the sack with the genital organs is very interesting; the ovary is often within the sack or in its orifice; it is normal or sclero-cystic or atrophied. I have often removed it.

"Another interesting feature is, that in the female the canal is more distended above than below, so that the suture of the walls of the canal is easily and satisfactorily done, and in a remarkable degree assures the permanence of the cure without bandages.

"One of the most valuable results of the operation is the removal of the pain caused by the hernia. The cure remains complete. In one of my patients, the one in which the hernia descended as far as the knees, the walls closed and withstood, without injury, two periods of gestation and two natural labors. In order to give assurance to the patient, I allow her to wear a belt with a pad, but limit its use to five or six months."

At the next meeting of the Société M. Berger took exception to some of the remarks of M. Lucas-Championniere, regarding the pathological anatomy and the etiology of these forms of hernia:

"There are," he said, "in the female two kinds of inguinal hernia: one in which the sack is not in immediate connection with the round ligament, is without adhesions, may be very easily separated, for there is no danger, as in the male, of wounding the different parts within the chord—these are the acquired hernias. In the others the round ligament is closely united with a very thin sack, which is very easily torn—these are the congenital hernias.

"Even in these cases I have always been able to isolate the ligament and to separate it from the pellicle of peritoneum which covers it. However, the preservation entire or the division of the round ligament is of very little consequence.

"I have not observed the lesions of the neighboring parts so often as M. Championniere; I have never met the ovary; I have seen the Fallopian tube sometimes, but I have always found it easy to turn it back into the abdominal cavity and to close the peritoneum quite near the place where the canal was detached.

"To effect a radical cure, I take great care to carry the dissection of the sack very high up, and to separate at the same time the adjoining peritoneum; for this reason I divide the anterior wall of the canal very extensively; I fasten its pedicle high up within the abdominal cavity. I then endeavor to restore the inguinal track by suturing, step by step, and for these sutures I prefer silk to catgut, because it is not so easily absorbed. This restoration of the inguinal canal seems to me to be of the greatest importance.

"Mr. Championniere thinks that the greater number of hernias are adherent; he dissects the sack very high up, even to the ligament, and does not fasten the pedicle."—*Sanitarian.*

GYNÆCOLOGY.

ON PLUGGING THE CERVIX UTERI INSTEAD OF VAGINA IN UTERINE HÆMORRHAGE.

Plugging the cervical canal in cases of severe uterine hæmorrhage (other than post-partum) will be found more effectual and much more comfortable to the patient than the older method of plugging the vagina.

The want of a simple means for completely filling the cervical canal has long been felt, but I think it will be found a simple matter by the use of an instrument constructed as follows: It is simply an improved form of sliding depositor, the difference being that, instead of the canula being pushed forward on the rod, the latter is made to retreat into the canula by the pressure of the fingers on projecting side-bars, and so the cotton plug dressing the top of the rod is pushed home with certainty into the cervix. It may be urged that in cases of metrorrhagia or very early abortion a sponge-tent or sea-tangle would be an easier mode of treatment, and quite as effectual. But besides the inconvenience of having to place a tampon in the vagina as well, to insure retention of the tangle or sponge, we have also the great liability to sepsis, and I certainly prefer being on the safe side.

The size of the os being determined by digital examination, a piece of absorbent cotton is to be neatly wound round the projecting point of the instrument for about two inches of its length, and thickly enough to fully

fill the canal. The cotton plug is then to be saturated with whatever antiseptic styptic the operator prefers—saturated solution of alum in glycerin, iodine tincture, or turpentine; but I have a strong dislike for iron.

A large-sized cylindrical speculum is then introduced and the os and cervix syringed with hot water, so as to wash away all clots. The cervix is then to be steadied with a tenaculum, held in the left hand, while the plug is passed into the cervix, with the depositor held in the right, as far as possible, and, on pressure being made on the side-bars while the thumb supports the base of the instrument, the plug is pushed off the rod and the depositor withdrawn.

The whole operation can thus be done without assistance. If the plug has been made of the proper dimensions, which, of course, must depend on the judgment of the operator, and inserted fully into the cervical canal, there need be no anxiety as to the result, and the antiseptic and astringent action of turpentine, which I generally use myself, leaves nothing to be desired.

The plug may be safely left till expelled by uterine action, when, if the hæmorrhage continue, the practitioner will be prepared to adopt other measures—washing out, or curetting the uterus, or both. With a sponge-tent or sea-tangle in the womb it is always an anxious time for the practitioner, but with the plug properly in position he can take his own time about further interference.—*Dr. Alex. Duke in Satellite.*

TWO NEW METHODS FOR THE CLOSURE OF RECTO-VAGINAL FISTULÆ.

Le Dentu (*Ann. de Gyn.*) proposes a new method for cases of recto-vaginal fistula. He prepares a flap in the shape of a half-moon, immediately below the vaginal opening into the vagina, then refreshes a corresponding surface above the fistula, and unites the flap to the refreshed surface. In this way there results a valve-like closure.

It is not applicable when the fistula is high up in the vagina, or when it opens into the vulva, or is very large.

Felizet describes still another method. He splits the perineum transversely to a point above the fistula. In this way two fistulæ result, a vagino-perineal and a recto-perineal. The first is closed by sutures, and the latter is opened up through the sphincter and anterior rectal wall in the same manner as for the ordinary fistula in ano. The gases and fæcal masses escape through the free opening, and allow the vaginal fistula to close.

OBSTETRICS.

HÆMORRHAGE FROM THE MEMBRANES DURING LABOR.

Ballantyne (*Edinburgh Medical Journal*, No. 581, p. 1006, 1891) reports the case of a pimipara who had uterine hæmorrhage during the first stage of labor; examination failed to reveal any cause for hæmorrhage; labor proceeding, slight hæmorrhage occurred and the patient was delivered spontaneously of a small and feebly developed fœtus. A slight amount of hæmorrhage followed the birth of the child; but no unusual bleeding occurred after the delivery of the placenta; the child perished of heart failure soon after birth. During the lying-in state slight fever occurred during the second and third day, with an attack of urticaria and painful swelling of the breasts.

When the placenta and membranes were examined the placenta showed a small apoplexy with areas of fibroid thickening; around the aperture where the membranes ruptured there was a vascular zone varying in breadth from three-quarters of an inch to two inches; the blood vessels of this zone were situated either in the chorion or in the shreds of the decidua attached to its surface. Two primitive villi were found in this zone; an intra-mural fibroid was found in the lower segment of the uterus, which may have favored the hæmorrhage by maintaining a vascular condition of the parts.—*Amer. Jour. Med. Sci.*

SUBCUTANEOUS INJECTIONS OF CAFFEINE IN THE TREATMENT OF PEURPERAL HÆMORRHAGE.

Misrachi (*Jour. de mêd.*, March 8, 1891) recommends this method of using caffeine for cases of post-partum hæmorrhage in which a rapid effect is required. It is of special advantage to the country practitioner, who may at the time be attending cases of infectious diseases and whose hands may not be sufficiently disinfected to justify a digital examination of the genital organs of the parturiant patient. The author states that caffeine will act more rapidly than ergot and more efficiently than ether, though the latter is more rapid in its action as a stimulant. The caffeine should be administered in a solution containing a grain and a quarter of the substance, and this may be

repeated if necessary until five grains have been used. A better solution may be obtained by dissolving the caffeine in warm water with benzoate of sodium. It is recommended that packages containing both these materials form a portion of the contents of the obstetrician's bag.

CŒLIOTOMY FOR RUPTURE OF THE PARTURIENT UTERUS.

The treatment of ruptured uterus when this grave injury results during the progress of labor is, fortunately, a subject that is not likely to be often considered in general practice; but the possibility of the accident being encountered even when wholly unexpected, makes it incumbent on all practitioners to be at least decided on the steps of a remedial nature that would elect to follow in such an emergency. It is by no means improbable that a number of cases of death after delivery, and which are attributed to the influence of shock, are in reality due to spontaneous rupture of the uterus. It is likely, too, that the excessive mortality recorded in connection with the operative treatment of the condition when occurring during parturition is allied to delay in adoption to the necessary measures with a promptitude which in this more than any other surgical emergency is especially called for. In recent years a good deal has been said and written in defense of immediate abdominal section on the formation of a diagnosis of ruptured uterus; and it is particularly among American surgeons that the whole question has been discussed, the term cœliotomy being now revived by them for application to this division of abdominal surgery particularly. The expectant treatment cannot possibly be successful in any but the most trivial example of the injury, and from the nature of the lesion involved, whether originating in mechanical injury, or through the spontaneous action of the organ, it necessarily follows that only the most radical procedure can be productive of benefit; and that only when it is promptly pursued. In a paper read before the American Medical Association at this year's meeting, Dr. Coe, of New York, described four cases of rupture of the parturient uterus in his own practice, in only the first of which did success reward his efforts to save life by performance of cœliotomy. In this the womb ruptured in consequence of improper attempts at version, and the application of forceps in the first stage of labor, and the operation of cœliotomy was done within two hours after the accident. The uterus was removed, and the pedicle treated extra-peritoneally. In all the other three cases operation was delayed till many hours after occurrence of rupture, and in each death took place from shock. In advocating resort to the measure he suggests in these cases, Dr. Coe deprecates any intention of recommending heroic treatment in every instance. But he very properly insists that in so desperate a condition as rupture of the parturient womb, the surgery that is prompt to relieve by radical methods is the most truly conservative in its results, and that the patient's best interests are consulted most closely by him who estimates the extreme gravity of the circumstances in which she is placed by the occurrence of the accident. The operation moreover, is not necessarily contra-indicated by reason of the unfavorable statistics associated with it so far. These may, without doubt, be expected to undergo improvement *pari passu* with a readier diagnosis and the avoidance of delay in resorting to operation when rupture is clearly evidenced.—*Medical Press.*

PÆDIATRICS.

ABDOMINAL MASSAGE IN THE TREATMENT OF CONSTIPATION IN CHILDREN.

Karnitzky's method of treatment (*Journ. de Méd.*) was used by him in twelve cases of chronic and twelve cases of acute constipation in children from eight to eleven years of age. The following are his conclusions:

1. Abdominal massage may produce effects upon the alimentary tract, in connection with digestion, which are not inferior to those produced by purgatives.

2. Habitual constipation may be easily cured by massage without the aid of purgatives.

3. The younger a child is the more readily can the constipation be cured.

4. The younger a child is the milder should the manipulations be, and the shorter the *séances.*

5. The duration of the *séances* should be from three to ten minutes according to the age of the patient. Longer *séances* are inadvisable, and may even be harmful and aggravate the condition of the patient.

6. Abdominal massage may be regarded as the best means of treatiug constipation in children. Purgatives should only be used in exceptional cases.—*Archives Pœdiatrics.*

HYGIENE.

ETIOLOGY OF DIPHTHERIA.

Dr. Klein (*Nineteenth Annual Report of the Local Government Board*, 1889–90, p. 143) gives the results of a new series of researches on diphtheria. He examines false membranes as cover-glass preparations after treating as follows: A particle of fresh membrane is well skaken in a test tube of 10 cubic centimetres boiled salt solution; this is poured off, a new quantity is added, and the whole is again well shaken; by this means the superficial part of the membrane is cleansed from the surface organisms. The sample of the diphtheritic membrane is well rubbed over the cover glass, the film so formed is dried, stained in a 2 per cent. watery solution of rubin for twelve hours at the ordinary temperature of the room (or in an incubator for half an hour), and well washed in water. A contrast stain is obtained by treating with methyl-blue aniline water for from two to five minutes. As a result of his observations, Klein holds that the organism he has found is identical with that described by Loeffler, but that the so-called involution forms (wedge shaped, conical, etc). are not involution forms at all, as they are invariably found, even in very recent cultivations. He obtains cultures by washing the membrane repeatedly, and then inoculating with a drop of the last salt solution on to the surface of nutrient agar or on gelatine. In 12 out of 22 cases he found an organism that does not grow on gelatine at ordinary temperatures; this he looks upon as a pseudo-diphtheria bacillus. The other organism found in all 22 cases grows on gelatine, but Loeffler has recognized the fact that it is the same as the one he described, and that the other organism, which does not grow in gelatine, and was found in 12 only out of 22 cases, is the pseudo-bacillus. The pseudo-bacillus dies rapidly when its cultures are kept at the ordinary temperature for a few months. The true diphtheria bacillus remains active for eighteen months. It grows actively in milk at a temperature of 19° to 20° C., not nearly so readily at 36° to 37°. The organism is destroyed at a temperature of 60°, continued for five minutes. As regards the position of the organism in the diphtheria membrane, Klein agrees with other observers. From inoculation experiments it was found that fresh (that is, two to six days) gelatine, agar, or broth cultures are very virulent, that agar cultures after eight days, and gelatine cultures after five weeks, are "less virulent, and cannot be relied upon as uniformly infective to guinea-pigs." The author agrees with other observers that the bacillus when inoculated produces a chemical poison at the seat of inoculation. From a considerable number of experiments he comes to the conclusion that a diphtheritic condition may be induced in cats by superficial inoculation of the cornea or conjunctiva with cultures of the diphtheria bacillus or by subcutaneous inoculation into the groin. A distinct local disease similar to that produced in the guinea-pig is set up; there is marked congestion of the viscera and typical cloudy swelling and fatty degeneration of the kidney similar to that met with in the human subject. When inoculations are made simultaneously into the cornea and into the groin local reaction is obtained, but the constitutional and visceral changes were not nearly so distinctly marked.—*Brit. Med. Jour.*

DENTAL ASEPSIS.

There is reason to suspect that Listerian dogmas have not yet permeated the dental department of surgery, and that there is room for improvement in relation to the antisepsis of the instruments employed in the dental art. We do not go so far as to advocate the extraction of teeth under the carbolic spray, but there are undoubtedly some very tangible risks involved by negligence in this respect, foremost among which is the possibility of transmitting syphilis and blood-poisoning. The mouth is itself the perfect model of an incubator for the spores of bacteria, fulfilling all the requirements as to heat and moisture, besides providing suitable media for their development. The dentist therefore cannot be too scrupulously careful in providing for the freedom of his hand and of his instruments from "misplaced matter," *alias* dirt. Nothing is more likely to secure for him the confidence and esteem of patients than an ostentatious observance of the laws of surgical cleanliness. For this reason we are disposed to advise the methodical use of antiseptics. Not, indeed, that they are essential to cleanliness, but because the antiseptic method, when conscientiously carried out, ensures the purity which is indespensable for perfect safety. The best agent for the sterilization of instruments is probably boiling water, which promptly places any marauding microbes *hors de combat*. It has the premier advantage of being easy of application and of not damaging the steel. "Anti-

septic dentistry" would make a good war-cry, but unless all dentists practice this they will have fallen short of their mission.—*Medical Press.*

MEDICAL CHEMISTRY.

BENZOYL-EUGENOL, OR BENZEUGENOL.

Following up a suggestion by Dr. A. Nannotti, an Italian physician, regarding the use of oil of cloves for the treatment of tuberculous affections, Dr. H. Thoms, chemical adviser of the firm of J. D. Riedel, Berlin, has been working with the object of producing a body or bodies in which the properties of eugenol (the chief constituent of oil of cloves) might be associated with those of other substances which have proved to be of the therapeutic advantage in the treatment of tuberculosis antiseptically. Obviously, oil of clothes is far too irritating for subcutaneous injections, so Dr. Thoms aimed to get neutral compounds of it which would split up in the system. These he has found in benzoyl-eugenol and cinnamyl-eugenol. The former is obtained (*Pharm. Centralhalle*), by a process which is patented, in colorless and odorless crystals with a slightly bitter taste. The crystals melt at 70.5° C., are scarcely soluble in water, but dissolve easily in hot alcohol, chloroform, ether, and acetone. The body is neutral, and gives with concentrated sulphuric acid a purple-red color. *Cinnamyl-eugenol* is odorless, colorless, and tasteless. The crystals melt at 90° to 91°, and behave like the benzoyl compound towards solvents and sulphuric acid. It would appear that these bodies resemble benzosol (benzoyl-guajacol). At present their therapeutic properties are under investigation.—*Chem. and Drugg.*

PRODUCTION OF CURARINE.

Laborde and Meilliére point out (*Rep. de Pharm.*) that the alkaloid of curare is characterized by its insolubility in most neutral menstrua, but is soluble in water. The commercial article is a perfectly pure and colorless extract, which contains two other alkaloids besides curarine. These have the same solubilities as the latter, but differ from it in their physiological action. They are distinguished from curarine by the varying rapidity with which their dialysis is effected. Curarine by itself passes over in a double salt of zinc and cadmium, which may be decomposed by sulphuretted hydrogen. The alkaloid is then purified by boiling in 80 per cent. alcohol. It may be obtained in a less pure condition by extracting the curare with chloroform, to which has been added a certain quantity of carbolic acid.

NEWS AND MISCELLANY.

THE FIRST COLORED FEMALE DOCTOR.

Novelties in the way of doctors *quoad* race, sex, sect, condition, etc., have become somewhat rare of late. We have recorded the evolution of the first Chinese doctor, the first female homœopathic doctor, the first lady medical Brahmin, etc. Despatches now furnish us with the report that the first colored lady medical doctor has just passed the Alabama State Board and is qualified to practice medicine. The reports are modest in that the doctress is said to have passed with simply a high average. We trust that Doctress Dillon will be successful. The colored physicians whom we have met have been modest, earnest, and industrious, and they have shown better than many others the capacity for progress of their race.—*Med. Record.*

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

The 17th annual session was held at St. Louis, October 14, 15th and 16th, 1891, President Dr. C. H. Hughes, in the chair. The attendance was large, the papers numerous and valuable. Dr. I. N. Love, the incomparable chairman of the Committee of Arrangements, and his able assistants, deserve unstinted praise for their provision of receptions, rides, dinners, suppers, banquets, fine weather and full moon. Dr. C. A. L. Reed, of Cincinnati, was elected President, Dr. E. S. McKee, Cincinnati, re-elected secretary; Dr. C. S. Bond, Richmond, Ind., 1st Vice-President; Dr. J. H. Stucky, Lousville, 2nd Vice-President; Dr. Joseph Ransohoff, Cincinnati, Chairman Committee of Arrangements. Place of meeting, Cincinnati, Oct. 1892.

ARE DRUNKARDS RESPONSIBLE FOR CRIMES COMMITTED WHILE UNDER THE INFLUENCE OF ALCOHOL?

Much has been said upon this subject of late, and most that has been said has been in the negative. The affirmative have, as a rule, thought reply not necessary, and yet

the observing must have noted a growing tendency upon the part of the alienist to regard the drunkard as irresponsible for acts committed while drunk. In his seventeenth annual report of the Cincinnati Sanitarium the eminent superintendent. Dr. O. Everts, makes the following timely remarks:

Common sense and common law (which is but an expression of common sense tested by experience) hold men responsible for remote, as well as immediate, consequences of criminal acts. No man is permitted to plead his own wrong in mitigation of his offenses. Common law, and common sense, recognizing intoxication as a vice, hold inebriates responsible for crimes, although committed while incapable of self-control, and oblivious to the consequences of their acts. The school of neuropathic doctors who recognize all of the antecedents of inebriety to which it is sequential as pertaining to disease, holds inebriates irresponsible for their crimes, as they were from the beginning incapable of resisting their morbid appetites, or doing otherwise—unaided—than to become drunkards. Whatever the logic of such inferences, sustained by whatever facts, it is not probable that such extreme views of the irresponsibility of drunkards will ever generally obtain. Society—that co-operative condition of mankind, in which the rights, or necessities, of the many are recognized as superior to the rights or necessities of the few, in the interests of which laws are made and executed; the necessities of which constitute the only rational criteria of the responsibility of man to man—can not afford to exempt a class of offenders from responsibility, whether sane or insane, while they are, at the same time, exempt from legal restraint, because of alleged infirmities. Necessity is not often sentimental.

MEDICAL LEGISLATION AND MEDICAL EDUCATION.

At a recent meeting of the Faculty of the Marion-Sims College of Medicine, the dean, Dr. Young H. Bond, introduced the following resolutions, which were unanimously adopted:

WHEREAS, the position taken by this college upon the two questions of medical legislation and medical education has been intentionally confounded; and

WHEREAS, notwithstanding the fact that, at the last meeting of the Missouri State Medical Association, the report on medical education offered by Dr. McAlester, and having as its central idea a three years graded course of lectures, was, on motion of your dean, with the aid of the votes of all the members of this Faculty then present, adopted, it has been sought to have it appear that this college is not favorable to higher medical education; therefore, to the end that our position upon the question of medical education be clearly understood, be it

Resolved, That after the session of 1891–'92 the Marion-Sims College of Medicine will exact as a condition to graduation in medicine of all its students, who may not have previously matriculated attendance upon a graded course of lectures extending over three years. And be it further

Resolved, That our position upon the question of medical education does not in the least abate or compromise our objection to what we regard as the attempted enactment of unjust, inefficient and class medical legislation, and that this Faculty favors an examining board as the fair and rational solution of the problem of medical legislation and medical education as well.—*Memphis Med. Month.*

THE YANKEE MEDICAL STUDENT.

Our English contemporary, the *Hospital Gazette*, states that the Yankee medical student has not very much to be thankful for. First of all, the medical "diploma mills" turn out their thousands of ill-trained and indifferently educated youths to take part in the professional struggle for existence, and then no kind legislation has interfered for the purposes of restricting the practice of medicine to native graduates. His woes, therefore, are tangible, but now Mr. McKinley has got passed a tariff, in virtue of which the tax on microscopes has been raised sixty per cent., so that an instrument which costs ninety dollars in Germany will at wholesale cost one hundred and fifty dollars in the States. This will hardly have the effect of stimulating microscopical work, and the cost will, of course, increase *pari passu* with the minuteness of the object to be magnified, seeing that the higher the power the greater the initial cost and therefore the more crushing the protective duty.—*St. Louis M. and S. Jour.*

Clinical Lecture.

SUPPURATIONS OF THE HAND AND FOREARM.

BY PROF. LE DENTU.

DELIVERED AT L'HOSPITAL NECKER.

Gentlemen: I will take the opportunity to speak to you on a practical point of the greatest importance. You have seen me make an incision on the forearm of a woman, 42 years of age, occupying a bed in the Lenoir ward, and each one of you, perhaps, has been astonished at seeing me cutting not only the superficial layers, but penetrating deeply into the muscles of the forearm. It was there that I found the seat of suppuration.

The history of this patient is quite simple. On the 19th of May she was pricked on the thumb by a corset steel (notice the date for it is only eight days ago), and she was satisfied with wrapping the injured finger in a rag moistened with arnica. On the following day she began to experience upon the thumb sharp pains which soon extended to the forearm, and finally the elbow. When she entered the Hospital, four days after the accident, there was established, beginning at the point of the original lesion, an œdematous redness extending along the palmar eminence and upon the dorsal portion of the corresponding hand, as far as the forearm. The œdematous swelling was considerable and the pain so acute that, in order to relieve this, I had to make an incision upon the dorsal surface on the level of the commissure between the thumb and the index finger, but without success, as I found no pus there. Neither this procedure, nor the bathing of the arm and the antiseptic dressings applied, produced any relief in the intense sufferings of the patient. Moreover, the fever persisted and yesterday I found signs of a deep inflammation of the forearm. There was noticed only a slight redness, but the inferior extremity of the forearm presented a cylindrical form and a clammy condition. Upon the anterior surface, about two fingers' breadth above the wrist, I felt a deep fluctuation. You have seen me chloroformize the patient and give exit to the purulent collection which occupied all the muscular space opposite the pronator.

I will now take occasion to give you some ideas about suppurative inflammations of the wrist and forearm, a very interesting study, one which has not of late been examined thoroughly. Among the authors of the beginning of the present century, Boyer for example, none has devoted a single chapter to suppurations of the hand, although Berard, in his dictionary, has given a short history of the subject. Velpeau, however, was the first to make a good study.

From the time of Bauchet two types of the disease have been recognized: a clear, phlegmonous form; and the second, no other than a synovitis of the tendinous sheaths. This is probably the first time in which a difference has been established between an inflammation of the tendinous sheaths and that which is developed otherwise.

Regarding the study of deep phlegmons, Dolbeau, about 1867, introduced in a general way a new idea, that of lymphangitis. He would explain how from a wound of the wrist or hand, wherever situated, the infectious products (to-day we speak of them as microbes) would be absorbed by the lymphatics and arrested at the point where the future phlegmon would appear. This is the pathogenesis admitted to-day with regard to the origin of adeno-phlegmons. As in an instance in which we may have first a simple adenitis, then a ganglionic phlegmon or an adeno-phlegmon, so in the case at present under consideration, there was at first a lymphangitis, followed by a peri-lymphangitis in the cellular tissue. I may not be perhaps entirely justified in speaking of a

lymphangitis of the forearm, since Sappey has described along the path of the deep lymphatics of the forearm small ganglia which are sometimes rudimentary, presenting an appearance of confluent lymphatics, and it may be that the deep suppurations referred to are nothing else but adeno-phlegmons of those ganglia. However, this being a matter of hypothesis, it seems to me that Dolbeau's theory relative to deep abscesses being the result of a lymphangitis, is true on the whole. Nevertheless, I am obliged to act reservedly regarding a broad generalization of such a theory.

This theory has been combated especially by Gasselin who has endeavored to demonstrate that suppurative synovitis of the hand is of a primary nature, whereas Dolbeau considers it as a secondary manifestation. Gasselin bases his arguments upon certain facts. The principal of these is the description he has given in one of his clinics of the hand of a patient who died from the results of a phlegmon caused by a puncture of the little finger. On post-mortem examination a suppurative inflammation limited to the sheaths was found. To this argument Gasselin adds that the theory of Dolbeau cannot be demonstrated from an anatomical point of view. Now, this is true, but it is precisely one of the characteristic features of lymphangitis to exhibit the seat of suppuration far from the primary lesion, and we do not hesitate in attributing to a lymphangitis an abscess of the axilla, coming on several days after a wound of the hand. The second objection of Gasselin is that these abscesses must be situated along the passage of the radial and ulnar arteries, because it is through such tracks that the principal lymphatics go. Again, not only can it be seen that the abscesses follow these paths, but it must not be forgotten that lymphatics accompany interosseous vessels, and they are precisely the ones that are found to be affected. Finally, Gasselin has remarked that these phlegmons are always observed after lesions of the thumb and little finger. Now, this assertion is too absolute, and if in our patient the wound is situated on the thumb, it is remarkable that it should occupy the dorsal face of the first phalanx. In regard to tendinous stiffness and consecutive adhesions, these are probably due to a plastic synovitis of a secondary nature, similar to that observed in carpal and digital articulations.

We will admit, then, two forms of suppuration of the hand: the primary suppurative synovitis and the lymphangitis with a distant abscess. I will endeavor to show you how to make, from a clinical point of view, at least in a certain number of cases, the diagnosis between primary synovitis and lymphangitis.

The first and most important thing to consider is the seat of and nature of the lesion which is the starting point of subsequent troubles. I will recall to your minds that the external carpo-phalangeal synovial sac sends a prolongation to the end of the flexor of the thumb, and that the internal carpo-phalangeal synovial sac sends a similar one to the head of the first phalanx of the little finger. Thus, the deep lesion bearing upon the palmar face of these two fingers must be due to a direct wound of the synovial sac. A second valuable sign is the *position of the fingers*, which is somewhat characteristic. In cases of synovitis they always bend towards the palm of the hand, this flexion becoming more and more pronounced. On endeavoring to extend the fingers more or less forcibly, an extremely sharp pain is produced, and sometimes, at the beginning of the disease, a kind of starchy crepitation is perceived. This phenomenon is of short duration and not of frequent occurrence in suppurative synovitis; it shows the existence of a plastic exudation, which is rapidly followed by suppuration. It is much more frequently observed in the primary synovitis, without wound, particularly in the rheumatismal and blenorrhagic forms of this disease. You must also look for the pain produced by simple pressure, limited to the anatomical direction of the sheaths, at least during the period which precedes that of pus formation, When a liquid exudation supervenes, a fluctuation is established which still remains, generally, limited to the region of the sheaths.

On the other hand, let us examine the signs of a lymphangitic phlegmon. I have told you all about the wounds in the case of synovitis. If, therefore, instead of a deep lesion you come across a simple excoriation situated on the dorsal face or the lateral side of any finger, you may be justified in thinking of having to deal with a lymphangitic phlegmon. The deformity of the fingers appears in a less rapid manner; it is possible to extend them at the onset of the affection, but later their condition assumes a similar character to that of the previous form described, since, unfortunately, there may come a certain degree of synovitis.

With regard to the œdema and the swelling, I may remark that in the case of lymphangitis, they are more diffuse and tend

rapidly to invade the dorsal surface of the hand.

The principal seat of suppuration is the interdigital space, especially the first one if the point of entrance is at the index finger. At this point the infiltration may be abundant, and as the fluctuation is apt to be deceiving it is well to verify it by practising an exploration. The œdema is very diffuse.

In a lymphangitic phlegmon the suppuration comes on in a very irregular manner, and is apt to appear at any point. Frequently, it makes its appearance from the start on the dorsal surface. On the anterior region it is developed in the connective tissue surrounding the median nerve, but it does not stop here, for it is rapidly diffused along the origin of the last four fingers. At this period it is difficult to make a differential diagnosis, for the same thing occurs in cases of synovial abscesses which rapidly invade the connective tissue, and at a period somewhat advanced of the two varieties of inflammation the suppurative focus occupies the same limits. In synovitis, however, the passage of the pus above the wrist is almost inevitable and shows itself from the very beginning.

I must here insist on the manner of searching for the fluctuation. You must bear in mind the duration of the malady. As a general rule it is rare for the pus to occupy a circumscribed spot before the 16th or 18th day; nevertheless, in synovitis where the cavity is already formed, the abscess may be formed about the 3d or 4th day. Remember, there is no region where the œdema resembles a fluctuation so much as in the hand, particularly in the space that separates the index finger from the thumb, for at this place the skin is loose and is easily raised by any infiltration. When it is necessary to find out the existence of pus above the wrist, an exploration must be practised in a certain manner, as the thumb in such cases plays an important role. You place one of your own thumbs transversely above the wrist, and the other lengthwise on the palm of the hand. Let me remind you that pressure must be exercised in such a manner that a pushing sensation is felt from within towards the surface. But in the present case, this transmitted sensation is not easily produced because the pus can with difficulty pass through the narrow canal that lies between the two suppurating foci.

In the case of our patient, this manœuvering does not aid us in establishing the existence of any focus in the palm of the hand, but only a collection in the forearm. On placing my two thumbs transversely above the wrist, at a distance of three fingers' breadth from each other, I feel a deep fluctuation. Add to this that there exists a superficial redness and an œdema on which the thumb leaves an impression. Besides, there is a sharp pain produced, and a feverish condition (39° C.,) is likewise present. Sometimes, at a period when the collection of pus is complete, there is a sufficiently marked stoppage of the pain and other general symptoms. This phenomenon cannot be considered as indicating a resolution of the phlegmon. For a different reason it is but rarely observed in the hand, because the palmar aponeurosis by its resistance maintains a tension of the tissues.

I have now arrived at the consideration of the treatment of the different varieties of phlegmons of the hand. The indications for interference in such cases may be divided into three periods. At the outset, or first period, about the tenth to the thirteenth day, if, fortunately, you are immediately called, begin by practicing an incision and disinfecting the part that has been the starting point of the infection. Antiseptic baths for the hand and forearm produce the happiest results. I am in the habit of using a solution of carbolic acid, not stronger than 1 to 400 because I have found that a concentrated solution is apt to produce erythema and sometimes a vesicular eruption. There is another treatment which at the present time is but little followed, but which, nevertheless, should not be entirely laid aside. I have reference to local bleeding. In certain cases this may bring about a resolution of the inflammation, and when you have to deal with a phlegmon that is not accompanied with serious symptoms, and which does not require an immediate interference before the 10th to the 13th day, you will find this method of local bleeding of great utility, especially when aided by the application of leeches over the wrist. As to dressings, cataplasms must be prescribed in order to keep the wound or wounds well covered. You may with propriety use muslin compresses dipped in a solution of corrosive sublimate, of the strength of 1 to 2000, or of boric acid of the strength of 30 to 1000, to which a little laudanum may be added. You must be careful to see that the dressings are sufficiently large to cover well the inflamed parts, placing over those dressings sticking-plaster or rubber so as to keep them moistened till evening or until the following morning, when you must renew them.

During the second period, or that of sup-

puration, you must abandon all local bleeding. You will still use antiseptic bathing as this will continue to produce excellent results, but the time has now arrived when the bistoury must act. When and in what manner exactly is the instrument to be employed? This is more a question of topographical anatomy, and I must refer you to a special treatise on the subject.

The principal dangerous obstacle to be met with is the superficial palmar arch which you will remember is situated a little above the middle fold of the hand. Sometimes it may be of an abnormally large size. Do not, therefore, make an incision on the level of this fold. Incise either under this fold in the inferior part of the hand, or above a line which is prolonged from the hand along the internal border of the thumb. Always incise in a vertical way, because the inferior portion of the hand lies parallel to the collateral arteries and nerves of the fingers, and if you should happen to be in the superior portion of the hand you must be careful not to injure the median nerve. Taking all this into consideration, after you have divided the palmar aponeurosis, replace the bistoury by a convenient drainage tube. I will point out to you particularly that on the dorsal surface of the hand, on the first interosseous space, the trunk of the collateral arteries of the index finger and thumb, and which arises on the level where the radial artery perforates that space, is sometimes very long and often very bulky and short—circumstances which increase the danger of cutting it. If such accident occurs you must secure the two ends of the vessel severed.

When you are called to interfere in the third period, you are, unfortunately, obliged to deal sometimes with a hand that has been transformed into a sponge impregnated with pus: the sheaths are everted or open; the carpal articulations are filled with matter and produce, on moving, a cracking noise; and all other functions are abolished. In such cases amputation is indicated; but this is a necessity which ought not be decided upon too hastily. In all instances, as in those in which early interference is resorted to in order to limit the inflammation, an adequate treatment should be adopted with a view to avoid tendinous and articular stiffness, which, if such cases are abandoned to themselves, may be the cause of permanent infirmities. Therefore, you must prescribe aromatic bathings and massage. You should apply forcible movement to all articulations. Sometimes you will have to work against the coming on of these sequelæ for a period varying from two to six months.

COMMUNICATIONS.

CITY STREETS AND THEIR RELATION TO PUBLIC HEALTH.

BY SENECA EGBERT, A. M., M. D.,

INSTRUCTOR IN HYGIENE, UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

The relationship which a city's streets and passage ways have to the health of its inhabitants has received some consideration in the past from sanitarians and students of preventive medicine, but not, by any means, all that it deserves. Though it may not be a reason for this neglect, it is a grave fault that in most large cities the interests of the contractor are more looked after and cared for by those in authority than is the welfare of the tax-payers and citizens; and that it is almost impossible to have what promise to be beneficial improvements fairly tried when these tend in any way, as they often do, to decrease the financial profit to those actively interested in "the job."

A change for the better, however, is beginning to be noticed in some, especially in our western cities; and perhaps it is not too much to hope that the time is coming when our municipal authorities may think *first* of those who have raised them to power, and lastly, if needs must be, of the pockets of their intimates and followers. I say nothing of the greater hope that all this class of "city fathers" may some day give place to men who will have at all times the best interests of their city and people at heart, for that requires almost an excess of faith and patience.

The field and work which the avenues of a city, from the grandest to the meanest, offer to the sanitarian are broader than one would at first imagine them to be; and it is only to touch upon a few of the points that may be considered that I venture to offer the following notes:

It goes without saying that wherever the business life of a city is most active, in that vicinity will the value of land be high, and there will then be a tendency to make the streets and alley-ways as narrow as possible and the buildings on either side of them as

high as the law or the purses of the owners will allow. Another locality where the same narrow passage-ways and high buildings prevail will be the tenement districts, even though somewhat distant from the "busy marts of trade", for here the greedy and unrestrained landlord will try to extract as high a rent from as little space as he may. It is only as we go further away from the heart of a city and among those of a better condition than the very poor that the streets become wider and the air spaces greater about individual buildings and dwellings; but in many places it is only among those who are really well-to-do that the streets have the width they should have and that there is fair opportunity given for ventilation and the access of sunlight, two of our most powerful agents in the prevention of disease.

On *a priori* grounds, then, we should consider the conjunction of high buildings and narrow streets to be effective agents for evil against the health and vitality of the dwellers therein.

The younger Parkes says: "The health of a town largely depends on the width of its streets, the general heighth of the buildings, and the amount of yard space at the rear of each which separates it from its opposite neighbor. Contrast the health and vitality of the occupants of houses in wide open streets, with those who live in narrow courts closed at one or both ends—the courts themselves being often surrounded by higher buildings, or built back-to-back, or with the smallest possible intervening space. In such places the air is almost always necessarily stagnant, as the passage of the wind is obstructed by the surrounding buildings. The sun's light for many months in the year cannot penetrate, with the result that the ground is never thoroughly dried, and the air in contact with it remains continually damp. Impure gases and exhalations, evolved from the inhabited dwellings, are not at once swept away by the wind, and consequently accumulate in the air of the court and its surroundings. Suspended organic matters tend to subside in the still air, which being thus both damp and impure, produces that state of low vitality and predisposition to disease that characterizes the inhabitants of such places.

Zymotic diseases, when once introduced, spread rapidly through the vitiated air; the enfeebled constitutions of the inhabitants presenting but slight resistance to their onset. Absence of sunlight appears to have a specially injurious effect on child life, which like plants, becomes blanched and weakly when reared in semi-darkness. When it is added that in many of these courts and alleys the houses have no thorough ventilation, the windows being only in the front of the house, it is not to be wondered that the general death rate is sometimes double or even treble that of the healthy parts of the town, and that the mortality amongst infants and young children is something appalling."[1]

Looking to the facts, we find that comparatively few have investigated this matter, but that the results already obtained are, to say the least, striking.

In England Ransome, Barry and Smith have all investigated the relation of street width and town ventilation to the mortality from phthisis, and in this city (Philadelphia) Drs. Flick and Howard B. Anders have made valuable contributions to our knowledge of the subject. Perhaps I shall economize space and time if I review briefly the article of Dr. Anders on "Street Width": Its causal relation to the mortality of phthisis,[2] and make use of some of the quotations from the other writers of which he has availed himself. He says: "In order to demonstrate whether any relation, positive or negative, existed between street width and the mortality rate of phthisis in Philadelphia, I began a topographical study of such cases in the Fifteenth Ward which died during fifteen years, from 1874 to 1888 inclusive. For the basis of the research this ward was selected for several reasons, as follows: 1. Because of the large number of deaths reported; 2. On account of the streets, typically very wide, narrow and medium in width, which it contains; 3. Its elevation and its proximity to Fairmount Park, circumstances which would convey double force to a positive relation between a high mortality rate from phthisis and narrow streets in that vicinity; 4. A great number of streets running diagonally to the main ones; 5. A proportionably larger population in the wider streets; 6. The presence of several large penal institutions." The area of the ward is about one square mile. The Board of Health records for the time in question were carefully examined, and doubtful cases traced or eliminated till there were left 1665 authentic ones, or 94 per cent, of all recorded."

A large map of the ward was then made, and the aggregate number of deaths for each block transferred to this map, on close study of which, thus completed, Dr. Anders ob-

[1] Practical Hygiene, page 228, Blakiston, 1890.

[2] Vide University Medical Magazine, October 1890.

serves: "That the number of deaths from phthisis on a very wide street is proportionately small compared with almost any one narrow street." Taking the streets running east and west which are forty feet or more in width, and excepting two of them which have but little back ventilation to their dwellings, owing to other buildings close in the rear, the average death rate per square for the time given was 3.7; while that for the streets under forty feet wide with the same direction was 6.1 per square. Doubtless the same ratio holds good for those streets running north and south or diagonally, for there is no reason why it should not.

Again, "A large mortality in the narrow streets near the Park (Fairmount) is particularly significant, for it points out that though a better atmosphere be near at hand, if not freely accessible for ventilating purposes it avails nothing."

"The observations show that there is plainly and generally a high mortality rate from consumption associated with street narrowness in not a small part of Philadelphia. From the assumption then of the well-known fact that the major portion of the city's population lives in narrow streets, (although this is not true of the Fifteenth Ward), and from the fact, as before proven, that the death rate from phthisis is relatively high among these residents, the conclusion is logically justifiable that the relation between a high mortality and narrow streets is a positive and vital one."

If this be true of Philadelphia, that boasts of having more individual *homes* for her population than any large city in the world, what may we expect of those places where the great mass of the poorer classes dwell in lofty over-crowded tenements whose entrances and outlooks are only upon courts, alleys or streets so narrow that the sun can scarcely light up the depths for more than an hour or two a day, and where a breath of fresh air is a thing almost unheard of and unknown?

Ransome finds the same relationship between a high phthisis mortality and narrow streets in English cities, and Barry and Smith have shown that this same mortality in "back-to-back" houses is high, something that Anders also noted in his work.

If, as Dr. Flick says, "the same conditions which intensify the contagion of the diseases long acknowledged to be contagious, increase the operation of that of phthisis," is not the converse likely to be true, and where we find the mortality from phthisis high may we not also expect a high mortality and morbidity from all the contagious maladies common to the locality?

I know that it can be reasonably and strongly urged that those who dwell in the narrow streets and by-ways of which we have been speaking are especially subject to those other conditions which lower vitality and predispose to high morbidity and mortality from any cause; viz., poor and insufficient food and clothing, exposure to inclement weather, unhealthy occupation, etc.; but still, those of us who believe at all in ventilation for our dwelling rooms and houses, must admit also its necessity for our streets. "The free course of pure air through *wide, unobstructed streets* is as clearly necessary for the proper ventilation of cities as it is for the ventilation of habitable rooms. Indeed, without the former the latter would be certainly incomplete and defective. Streets are the ventilating flues of cities and they should be ample in width."[3]

Knowing the evil, what remedies are to be proposed? It is evident that these must vary with the conditions present in each case. However, they may be formulated somewhat as follows: In those business portions of a city where property is high in value, where the buildings are for commercial purposes, and where the street width is necessarily limited, the proper authorities should see that in all buildings ample provision is made for abundant ventilation, the air being brought from a reasonably clean place, for proper room-space for the occupants, and for the prompt removal of all collections of waste matters deleterious to health; and these requirements should be maintained by frequent and strict inspections. Many occupations now considered unhealthy would not be especially so, were the ordinary laws of Hygiene fairly observed by those having in charge the care and oversight of the place in which the work is done.

The same rules should be applied in those localities where tenements abound and where the streets are already narrow and cannot be widened; but no new buildings for tenement purposes should be permitted on these streets, or, for that matter, on any other, unless they are planned in accordance with the latest and most approved sanitary laws.

All new streets are to be laid out as wide as possible, even at the sacrifice of personal

[3] Anders: loc. cit.

or private interests; and, above all, the people should be instructed as to the value of individual homes with as much air-space about them as possible, and to be encouraged in obtaining such homes as permanent residences; this not only for sanitary reasons, but also for the moral effect upon them as citizens. Proper legislation and municipal care for the interests of the laboring man can also do much toward making him feel secure in his property rights and giving him an interest in the city's health.

In this connection it may be well to quote from the model by-laws of the Local Government Board of London; "The width of every new street intended for use as a carriage road must not be less than 30 feet; if saving narrow, filthy ways and alleys with foul not to be used as a carriage road it must be at least 24 feet wide, and open at one end. Twenty-four feet is the least width allowed before the frontage of any new building; and the aggregate amount of yard space at the back of such a building, and belonging to it, must not be less than 150 square feet, and whilst extending the full width of the building it must not in any case be less than ten feet wide, and must be wider when the height of the building exceeds fifteen feet, the yard space at the back of the house being increased with the height of the house up to thirty-five feet."[1]

Street cleanliness. This will evidently depend on two factors; the character of the street pavement, and the thoroughness and frequency with which the contracts for street cleaning are carried out. It goes without saying that a street pavement should be as smooth and durable in its character as is possible to secure with due regard for true economy. Experience has gradually narrowed the choice of the materials of which a much used city pavement may be made to the granite or Belgian blocks, to asphaltum, and of late years, to vitrified bricks. Of these I suppose the Belgian block would naturally be selected by most persons as the most serviceable for use in the business portion of a city and where the traffic and traction were especially heavy, relegating the other materials to use only in that part given up to residences or where traffic is light. However, it is questionable whether the asphaltum and brick, will not be found to be equally serviceable for all localities, *if they be properly laid*, inasmuch as the traction over them is so much easier than over the rougher granite and the wear and tear consequently so much diminished. Certain it is that the vitrified brick, after being exposed under fair conditions to the severest tests, has agreeably surprised its warmest advocates.

Should it happen that one or the other of the two smoother ones may in time be substituted for the rougher one of the three, a gain in sanitation will be made in more ways than one. It will be much easier to keep the streets in that condition of cleanliness in which they should be, but which is so rarely to be discovered. Then more of the population, especially of the sedentary classes, will be encouraged and induced to make use of the bicycle, the poor man's horse, and to gain benefit from the physical exercise that otherwise they would lose. The rumble and noise of street traffic that goes to make up the roar of a great city would be considerably lessened, and this, unnoticed by the healthy, would be a true relief to those sick whose nerves are hypersensitive and acute to disturbances usually thought of little moment. Other benefits accruing from smooth pavements might also be adduced, but coming back to the question of cleaning them, it will at once be seen that the cost of doing this must be greatly lessened, and that there can be no excuse for any neglect of duty by those to whom this very important duty is entrusted.

Dr. Feltz[2] has shown that the virulence of tubercular bacilli mixed with dry road dust and exposed to the variations in the atmosphere lasts months, especially if also exposed to the sun; and who can doubt that the moist filth remaining for many days and weeks on the surface of streets is not also a most excellent breeding ground for the germs of many other contagious diseases? And then, when the sun dries up this filth and the wind scatters and sifts it through all our dwellings, who can tell what an assortment of maladies he may have latent within his very threshhold?

The experience of foreign cities, and even of some within our own borders, notably Washington, shows that there is no necessity for dirty streets, and our citizens should no more tolerate them, through neglect of their paid servants, than they would a like condition of their dwellings or business houses. It is too often the custom for the contractors for street cleaning to practically sub-let the whole job to Jupiter Pluvius, and the latter, not receiving any of the spoils, is apt to take things easy and to do

[1] Louis Parkes, Practical Hygiene; loc. cit.

[2] Vide Therapeutic Gazette, June, 1891, p. 410.

his work only at long intervals. Fortunately, when he does act, the work is generally well done. A grave part of the neglect is that those parts of a city which need the streets cleaned worst are the last to receive it, if at all, and that that part of the population least able to resist the depressing causes arising from street filth is the one most exposed and the part that suffers most.

The sub-soil of streets. It is proper that the condition of the soil underlying city streets and of the air which it contains should be considered in this connection. When we remember that there is almost always considerable leakage from both illuminating gas mains and sewers in their course, we realize that both the soil and soil-air of even a comparatively new street may soon become dangerously filthy. If to this leakage be added the percolations from above for many years through pavements imperfect or in need of repair, and especially in such localities as those where masses of filth lie moist and decomposing for days and weeks, (which conditions, I need not say, exist too often in tenement districts), the danger to the health of the people becomes more real and powerful. One need but pass along such a street when repairs are being made to some of its mains or drains and the soil is upturned for the time to have made patent to his senses how foul such soil can be; and city doctors know that such upturnings, if extensive, are often followed by serious outbreaks of sickness. But they rarely stop to think what a continually depressing factor this foulness is, even when street surface is unmolested and in good repair.

Owing to the extremes of atmosphereic temperature there doubtless is a continual movement of the soil air underneath the street. If, as in the crowded or closely built portions of the city, the sidewalks reach from house to curb, with no intervening grass plot, there can be practically no escape of the soil air upwards, nor ingress of fresh air from above, and whatever ventilation the sub-soil has must be through the basement walls of the buildings and dwellings on either side. This goes on throughout the year, but especially through the colder months, for when the fires are lighted and the air of the houses is thus made lighter than that without, the sub-soil air with its foul gases finds ready access through every opening in the cellar wall or floor. Even, as Prof. Dixon has pointed out, when the cellar walls and floors are well cemented to exclude the soil air, it will often be found that the space beneath the hot air furnace has been left unprotected and that there will be found a strong up-current from the underlying soil. Will not such a condition of affairs explain the existence of many cases of insidious disease, marked by the symptoms characteristically produced by "sewer gas," and which lasts during the winter months and disappears as the fires are allowed to die out in the spring? It seems to me that much may be done to improve this condition of the sub-soil and to remove the danger that is by no means imaginary. On the part of the city it should be a duty to lay all gas mains and sewers in as careful a manner as possible, that there may be a minimum of leakage from them, and where practicable, to *drain* the sub-soil by conduits *separate* and *distinct* from those carrying the house sewage. This is one of the excellent features of the Waring, or "separate" system of sewerage, and is worthy of consideration wherever new sewers are to be introduced.

On the surface there should be, if at all possible, somewhere between the curb and the house line, a strip of grass or uncovered earth, to allow of a free ventilation of the sub-soil and thus, in a measure, dilute and purify the the soil air. Enclosed spaces of grass or flowers at the intersections of convergent streets would also have a sanitary as well as an æsthetic value. On the part of the house-owner it is necessary that he should see that his cellar walls are as impervious to the entrance of soil air as he can make them, not forgetting the space underneath the furnace; and he should also take care to bring in from some *clean* place above the level of the soil an abundant supply of pure air to thoroughly ventilate the whole house. He should also keep the surface of the earth about his house at all times in as clean a condition as possible.

As to the surface of the street pavement, it should, of course, be kept smooth, in good repair and *clean*. Neither the Belgian blocks nor asphaltum will allow much, if any, ventilation of the sub-soil. I am inclined to think that the new brick pavement will, for while the bricks are called "vitrified," they are porous and allow the passage of both water and air through them. This, then, is an advantage over either of the former materials, and should lead them to to be used in narrow streets, where there can be no side ventilation. Though porous, there need be no fear of filth percolating through them, if the streets be kept decently clean as they should be; as intimated, their

very porosity helps to both dry and ventilate the sub-soil air and lessen the danger from the foul soil air.

The relationship between the curb and the house— or building—line must vary in different parts of the city somewhat as does the width of the streets. In the business and closely built portions of a city the necessity of room for traffic requires the roadway to be as wide as possible. But in localities given up to the better class of residences and where the streets are really of a good width, there is sometimes a tendency to make the improvement too broad in comparison to the space allotted to the sidewalk. This is of little importance if the buildings generally are back of the legal building line; but where they are flush with the latter, trees planted between them and the curb will interfere with ventilation and access of sunlight to the house-front, and there will also be lessened space for the soil ventilation between house and curb, especially if the sidewalks be of the regulation width. It will rarely be advisable that the roadway be over forty feet broad and in most cases where there are no street car lines thirty-five feet will be even a better width. This will allow the shade trees to be planted far enough away from the house-front to have good ventilation and light, and at the same time the general beauty of the street is enhanced.

There are certain other conditions that may arise which might influence for evil the health of the dwellers on any given street, but I believe that a study of the foregoing ones will convince the reader that they are general, and that their influence is certainly positive.

It cannot be gainsaid that with wide, *clean* streets, well-drained and well-ventilated, both above and below the surface, supplanting narrow, filthy ways and alleys with foul and reeking sub-soil, the general health of a great part of the population of any large city would be vastly improved and the city's morbidity and mortality greatly lessened. When we consider that bringing down the death-rate only one in a thousand means the ing of a thousand lives a year in a city of a million, we realize how great the responsibility is of those to whom are intrusted the sanitary duties of a great muncipality Even looking at the question from a financial standpoint alone, the gain in the earning capacity of the people would more than cover any increase in expenditure necessary to clean and well-paved highways, drained and ventilated as they should be. Is it not worth while for every tax-payer and citizen to demand that he shall have these reasonable and rightful benefits from the city in which he dwells?

CLINICAL OBSERVATIONS OF ACETANILIDE,*

BY DR. J. R. CARE,
CENTRE POINT, PA.

Acetanilide, unlike most of the more recent preparations of the chemist which scintillate with great brilliancy for a short time in the medical press, and are then relegated to oblivion, has now a permanent place, and deservedly in the list of efficiencient, and reliable antipyretics, although now, almost unnoticed by the laboratory experimentalist.

It is a lamentable fact that there are men, who after a few hurried and superficial trials of a drug during which they receive apparently brilliant results that very often are but the results of nature, hasten to bring them before the profession as fixed facts.

This being well known by the mass of the profession, is it any wonder they become skeptical? Having used acetanilide in a few cases with very satisfactory results, I determined to use it in all cases occurring in my practice with hyperpyrexia, and thus ascertain if possible its merits as well as its demerits.

I used it in a series of twenty-five cases of typhoid fever, in follicular tonsillitis and simple inflammatory fever, and the manifestations were so constant as to warrant the appended assertions.

Like the physicians of the Orient, I first took the drug myself and then administered it to my patients.

It has a slightly pungent taste, causes a sensation of warmth in the stomach by which it is well borne, first diminishes the number and force of the heart beats, followed by rapid, weak and thready pulse, if the dose has been large enough to cause a decided reduction of temperature. It produces in from fifteen minutes to an hour a profuse perspiration, with reduction of temperature of a febrile patient. If the dose has been a decided one, the extremities become cold, lips blue, yawning, somewhat quickened feeble respiration, and a sense of a profound debility in some cases amounting almost to collapse.

It attains its maximum effects in from three to four hours, gradually passing off

*Read before the Montgomery County Medical Society, September 16th, 1891.

thereafter, the temperature ascending to its former height, or nearly so.

The above is observed when the dose is large enough to reduce the temperature from three to four degrees, when the dose is smaller, there is noted the diaphoresis and reduction in the pulse beat and tension without the profound debility mentioned above.

These manifestations were seen in all cases except one in which the drug was used.

The exception was a case of scarlet fever in a boy aged 15 years, who on the sixth day, developed pneumonia with a rapid rise of temperature, and a dry hot skin that failed to yield to the ordinary medicaments.

I gave him three grains of acetanilide every four hours, with no effect on the temperature, or skin. I doubled the dose with no effect. It did produce however, profuse diuresis; the case actually passing seven measured quarts in twenty-four hours, the temperature remaining at 105° until convulsions ended the scene.

In order the more fully to illustrate the foregoing observations I will cite the history of a case in point:

Amy D——, aged 14 years, was taken with a severe chill September 3rd, 1890. We were called three days thereafter and found her in bed with a dry hot skin, tongue moist, and covered with a yellowish-brown coat, temperature 105°, pulse 120, respiration 30, stomach irritable.

I prescribed cinchonidia in capsules, and a febrile mixture.

On the following day her condition was practically the same, the stomach rejecting everything. I then prescribed bismuth and two grains of acetanilide every four hours. The following morning the skin was moist, temperature, 104°; pulse, 110; and a moderate diarrhœa. I then added five grain suppositories of quinine to the other prescriptions and found her, in the evening, with a temperature of 105°.

I had her sponged and on the following day found her the same as the day previous. I then determined to push the acetanilide, and ordered four grains at eight o'clock A. M., in connection with the suppositories, and left directions for the parents to give two grains more in four hours unless she perspired freely. I was hastily summoned at noon to see her, as they thought she was dying. I found her collapsed, extremities cold and bathed in a profuse perspiration; pulse, very feeble, beating 144 per minute; temperature, 99°; respiration, labored, and sighing; eyes turned up; lips blue.

She was very restless. The parents said she had been unconscious and that she seemed to stop breathing. Prescribed hot applications and brandy and found her resting easy in the evening. But the next morning her temperature was up to 103° and as she could retain nothing else on her stomach I ordered two grains of acetanilide, which reduced the temperature and caused profuse diaphoresis in about an hour. I saw her six hours after and found her with a temperature of 101°; mind somewhat confused. The temperature would rise every day and require one or two two-grain tablets to control it, in connection with the suppositories. She complained quite frequently of feeling cold in from two to three hours after the drug was administered. The case continued thus until the 21st day, when the temperature fell to normal.

It ran up to 103 degrees upon several occasions after that. On the 24th day she passed a small quantity of blood—but no urine. There was complete suppression for 24 hours, which was only partially overcome. Clots of blood passed per rectum; occasionally she vomited a black grumous material.

There appeared ecchymotic spots wherever she scratched herself. There was abundant sordes on her lips and teeth.

Her temperature now remained normal and the tongue was clean. Kidneys acted fairly, when on the 28th day, during the absence of the nurse, she got out of bed and walked across the room to the commode, when she sank exhausted. Her mother heard her and ran to her rescue, laid her on the bed, when she gasped and was dead.

It follows that acetanilide is a very potent drug, potent for evil as well as for good. If I have rightly interpreted the fore-going, acetanilide is a powerful cardiac depressant, apparently acting on the heart proper, also on the inhibitory apparatus.

It is a nerve depressant and a fairly certain diaphoretic, as it acted on the sudoriferous glands in all cases but one in which it was used. It seems to interfere with the oxygen-carrying functions of the blood, and consequently diminishes oxidation, which may be a factor in the reduction of the temperature. In my experience it caused profound depression of the vital parts in all cases where the dose was large enough to cause a decided fall of temperature, and the debility remained, consequently I think it is contra-indicated in all casss with marked adynamia In sthenic cases its results were most gratifying.

OBSTETRIC ANÆSTHESIA.

BY DR. J. B. CARRELL,

HATBORO, PA.

The editorial on "The Choice of an Anæsthetic in Obstetrical Practice" in the October 10th REPORTER, particularly attracted my attention and prompted me to write a few thoughts on this important subject.

Having employed chloroform extensively in my obstetrical practice I can say that my experience supports the views given in the editorial, that "chloroform is justly considered the agent *par excellence* in producing obstetrical anæsthesia.

It is my custom to administer chloroform in obstetrical cases, to relieve pain, to relieve extreme nervous irritation, and to relieve rigidity of the os and perineum. He who can calmly stand by a woman and see her suffering the excruciating pains of childbirth, and not assuage those pains, has a heart destitute of that beautiful sympathy that every physician should possess. I can not agree with the sentimentalist who argues that woman should suffer because nature has said so. That her mental faculties should not be clouded so that she can not enjoy the "caresses of her husband, the condolence of her relatives and deaden the imagination, already teeming with the joys of maternity?" That she should "not be deprived of the ineffable happiness of hearing the first cry of the new born child?" This joy I attribute more to her thankfulness in having passed safely through the perils of childbirth than the, to me, cold and cruel sentiments.

In the face of accumulated evidence which conclusively shows that the dangers of not giving this agent, in painful cases of labor, are greater than the giving, I can not see why it should not be given. It has been proven by actual experience that no ill effects result to the mother from its use. Writers are nearly unanimous on this point, and many hold that the recovery is more rapid and surer after its use. Undoubtedly there are many physicians who can trace the origin of broken nervous systems to the long and severe pains of labor. It is truly wonderful how much pain and suffering a woman can, under these conditions, endure without giving way. However, the limit can be, and is occasionally reached. Why not prevent this limit being reached and save the health of the woman? The effect upon the fœtus is *nil.* I have yet to see a child that I considered injured by giving chloroform to the mother, and such I believe to be the opinion of careful observers.

In cases where the pain is not unusually severe I do not use anæsthesia, but when they are severe, be they in whatever stage, I do not hesitate to employ it. Extreme pain produces, in most cases, severe nervous irritation, and this may lead to convulsions. When I find my patient becoming very nervous I relieve it by giving a little chloroform, thereby preventing convulsive attacks, and save the life of the child; for it is well known that convulsions in the mother mostly produce the death of the fœtus. As soon as the nervous irritation is relieved the chloroform is withdrawn.

Rigidity and spasm of the cervix uteri, and rigidity of the perineum can be, in many cases, relieved or modified by pushing the chloroform from obstetrical to surgical anæsthesia. There would be fewer ruptured perinei if the violence of the expulsive pains were modified by giving chloroform and keeping the pains in control. Cazeaux and Tarnier, in their great work, say as follows on the prevention of ruptured perinei: "The administration of ether or chloroform has received the indorsement of the best authorities. They may be given to produce relaxation and dilatation of the rigid perineum, and to increase and restore the natural glairy secretion when the parts are dry, as pointed out by Goodell. They also render the patient insensible to the acute pain which increases the contraction of the perineal muscles."

Should the pains become ineffective, the patient and uterus worn out, then a little chloroform judiciously administered will revive both the patient and uterus, and the use of the forceps will not be required to terminate the delivery. He who has used this agent in obstetrical cases has often been told by the patient that but for it she could not have had her child unaided. How often have I seen these poor worn-out and disheartened women have their drooping spirits revived by a few inhalations of chloroform, and how often have they thanked me for the relief it has given them.

It is not advisable except in urgent cases to push the agent to the extent of surgical anæsthesia, but to use only so much as will secure its analgesic effect. I would not advise its use in all cases. Use it when it is needed. Do not be afraid of it, but always keep in mind it is an agent for good or for

harm. In all obstetrical manœuvers producing severe pain and requiring quietness of the patient, and where it is necessary to produce surgical anæsthesia I would advise the use of ether. There is not the same danger in the use of chloroform in obstetrical practice as in surgical practice. Its toxic effects I have not seen, neither have I read of its having occurred when used to the extent of obstetrical anæsthesia. I have used it great many times and have only good words to say for it. It has given my patients relief from severe suffering, it has elicted thanks from many a sufferer, it has made warm friends for me. Then why not use it?

My method of using it is to put a few drops on a handkerchief twice doubled, place it over the nose and mouth and direct the patient to take a few deep inspirations and encourage her to believe in its power to relieve her suffering. This will attract her attention and when it begins to show its power to assuage pain her confidence is won. As soon as the violence of the pain has passed off the chloroform should be withdrawn. It will not be necessary to give it for every pain, but as often as may seem required. By this method the patient never loses consciousness entirely, but is relieved of her excruciating pain, and the labor passes off with satisfaction to the patient, attendants and doctor. Much more could be written on this important subject.

SUPRAPUBIC CYSTOTOMY.*

BY R. W. STEWART, M. D.,

OF PITTSBURGH, PA.

The following cases operated on by myself during the present year, and given in the order of their occurrence, will serve to show some of the conditions for which this operation is indicated and also serve as a basis for further remarks on the operation.

Case I.—This patient was under the care of Dr. Grube, who has kindly furnished me with the following notes of the case: February 10th, 1891. J. O., aged 32, furnaceman. Patient says that about six months ago he first noticed difficulty in urination, with pain in bladder and penis. This gradually passed into chronic cystitis, accompanied by pain in legs and partial paraplegia. He was treated for cystitis at Mercy Hospital. The bladder is extremely irritable, and holds scarcely an ounce, and as the slightest distension causes intense pain, it is impossible for him to sleep longer than half an hour at a time; consequently he is greatly reduced in strength. The stomach is irritable, and digestion impaired; patient living almost entirely on milk. The prostate gland is slightly enlarged, and is nodular, leading to the suspicion that it is tubercular. Patient has a brother who has pulmonary tuberculosis, and he himself has had a cough for several years, though his lungs are not perceptibly tubercular. Urine contains large quantities of muco-pus. Microscope shows pus cells, caseous flakes and debris. As patient was under Dr. Stewart's care at Mercy Hospital, I have asked him to see patient, and we have decided upon suprapubic cystotomy.

February 14. Dr. Stewart operated as above, assisted by Drs. Ward, Patterson, Emmerling and myself. As the bladder would not bear distension by fluid, the fundus was pushed up into wound by point of sound. A papillomatous growth was removed from near the entrance of left ureter—about a teaspoonful of scrapings in all. Wound closed and bladder drained by single large drainage tube; directed daily washing out of bladder with boro-salicylic acid solution.

Feb. 20. Patient has been given great relief from irritability of bladder, and is grateful accordingly. Urine still mucopurulent; general condition, bad.

March 10th. Wound has healed nicely around drainage tube, and patient manages drainage and washing out of his bladder himself.

April 1st. No improvement in character of urine, and patient losing ground steadily. There is occasional discharges of caseous-looking pus from the urethra, which evidently comes from the prostate. Tubercles have made their appearance in the cicatricial tissue about the drainage tube.

The further progress of this case was a gradual decline, until he died about the middle of May.

Case II.—Daniel R., aged 54. About eight years ago he had several attacks apparently of renal colic, occurring at intervals of two months. After this there was a period of quiescence until about eighteen months ago, when he complained of frequency in passing water, the termination of the act being associated with pain, which was referred to the end of the penis. Exertion of

* Read before the Allegheny County Medical Society, August 18th, 1891.

any sort aggravated the trouble, while on the contrary, rest in the recumbent position diminished it. So frequent had become the calls to urinate, and so difficult to restrain the desire, that it was necessary to wear a urinal. For about a year the patient was unable to pursue his vocation of machinist. He was referred to me for treatment by Dr. Ward.

Owing to the extreme sensitiveness of the patient and the irritability of the bladder, an examination without the aid of an anæsthetic was a matter of considerable difficulty, and required the utmost tact and delicacy. A diagnosis of vesical calculus was made, and the patient sent to Mercy Hospital for operation. Accordingly, on March 15th the patient being anæsthetized, a rectal bag was inserted and distended with eight ounces of water. The suprapubic operation was then performed, and three calculi lying side by side were removed. A drainage tube was inserted in the bladder and the wound partially closed with three silver sutures. A loose gauze dressing was applied over all.

The condition of the patient after operation was satisfactory, and was devoid of constitutional disturbance. He left the Hospital on the seventeenth day following the operation. A fistulous opening still communicated with the bladder, which was somewhat slow in healing, but eventually it closed, and at this date patient is in good health, has full control of his urine and is free from pain.

Case III.—Louis M., age 34, a butcher by occupation. On the evening of May 28th, he stepped on a coal-hole, the lid of which turned and he fell, the edge of the lid striking him on the perineum. He was able to walk a short distance, and then took a carriage home. On the following morning he was suffering from retention of urine, and Dr. Speer was called to see him. With a soft catheter he withdrew a quantity of bloody urine. On the evening of the same day I was called in consultation, the doctor being unable to withdraw his urine. At that time the bladder was distended, perineum tender, swollen, and much discolored, the discoloration extending to the scrotum. A diagnosis of rupture of the urethra at the triangular ligament was made, and with the assistance of Drs. Speer, Christler, and McKibben, the patient being anæsthetized, I opened the perineum freely in several places, through which a small quantity of bloody urine escaped. A complete rupture of the urethra was discovered. Owing to the extravasation, the tissues were so altered in appearance that it was impossible to distinguish the vesical end of the torn urethra, and after a patient attempt I abandoned the search for it, and ordered his removal to Mercy Hospital. He did not enter the Hospital on the following day, and as he was still suffering from retention it was necessary to asperate his bladder in the morning and evening. On the following morning he entered the Hospital, and I operated on him again. At this time the patient's temperature was 103° F., and his general condition was bad. Being again unable to find the vesical end of the urethra, I opened the distended bladder above the pubes, the incision in the bladder being just sufficient to admit a steel sound, with which I performed retrograde catheterism. The sound, after passing from within outwards through the prostatic urethra, was made to project through the perineal opening. While in this situation a stout rubber tube was fittted on the projecting conical extremity of the sound, which together with the tube was withdrawn into the bladder, and the sound disengaged from the tube. The sound was then passed from before backwards through the pendulous urethra, the extremity again presenting through the perineal opening. On this was fitted the end of the rubber tube which projected from the perineal opening, and the sound carrying with it the tube was withdrawn. By this manœuvre a tube was inserted in the whole length of the urethra, one end being in the bladder and the other projecting from the external meatus, the central portion bridging over the torn ends of the urethra, which were separated by an interval of about three-quarters of an inch. Displacement of the tube was prevented by pinning it to the prepuce. The patient's condition improved at once; his temperature was normal on the third day. The urine drained through the tube. A slight leakage escaped through the suprapubic opening. On the eighth day the tube was removed, and the patient left the Hospital on the twelfth day, since which time no urine has passed by suprapubic opening. A No. 26 French sound has been passed at intervals since that date. At present the sound is passed once every two weeks to prevent the formation of a stricture at site of injury, and except for this inconvenience the patient is as well as he ever was.

Case IV.—A. M. W., age 21. Ten years ago this patient was suddenly attacked with a desire to urinate frequently, which he attributed to holding his urine too long. This condition has persisted without intermission during the past ten years, passing water

every twenty to forty minutes, night and day, the act being associated with violent tenesmus, and, at times, excruciating pain. The constant straining has produced a marked prolapse of the rectum, which protrudes during the act to the extent of about five inches.

Three years after the onset of this attack he became subject to epileptic seizures which would occur about once a month, and in some manner seemed to be associated with an exacerbation of his vesical trouble. I may anticipate by saying that since the latter has been relieved the convulsions have ceased.

During the ten years he has suffered he has tried various forms of treatment in the hospitals, and out of them, under regulars and irregulars, besides his attempts at self-cure with the aid of patent medicines, all of which, to use his own language, did him no good, and he was waiting to die. Finally Dr. Buchanan sent him to Mercy Hospital, and he was transferred to me. The case was and still is something of a puzzle. The sound failed to shed any light on the subject. The cystoscope was also used, but nothing abnormal could be detected; external perineal urethrotomy was performed, and a digital examination of the interior of the bladder was made by Dr. Buchanan and myself, but nothing abnormal, further than a dilatation of the opening of the right ureter could be detected. Into this opening I readily inserted the beak of Thompson's searcher which passed, without obstruction, along the ureter until it must have reached the pelvis of the kidney. In this situation the searcher could be readily turned in any direction, showing that the ureter was much dilated. While the searcher was in this situation the descent of the liver in inspiration could be readily felt pressing against the extremity of the instrument. The ureter contained about an ounce of apparently healthy urine, which escaped along the hollow instrument. A drainage tube was inserted in the perineal opening, and the bladder drained by this means for ten days. During this period the patient had comparative comfort, and for the first time in ten years he was able to sleep a few hours at a time. After the tube was withdrawn on the tenth day, the perineal opening closed, and the patient relapsed into his previous miserable condition.

The results of all these examinations showed that we were no nearer the solution of the cause of this trouble. Whether the dilated ureter was the cause, or the result of the frequent urination, we are unable to determine; one thing, however, was apparent, that drainage of the bladder relieved the symptoms, and I therefore decided to establish permanent drainage.

In this operation I was again assisted by Dr. Buchanan. A specially contrived sound, having a greater curve than the ordinary sound, and a tip on it over which a tube could be readily fitted, was used. The extremity of the instrument could be felt just above the pubes. An incision was made over it, and the instrument presented itself in the wound. A tube was inserted over the tip of the instrument, which was withdrawn, leaving the tube in the bladder, and a permanent drainage was now established. The patient, in a short time, was able to manage the tube himself, taking it out twice daily, and washing the bladder with a weak bi-chloride solution, the free extremity of the tube fitting into a urinal by day, and at night connected with a long tube which carries the urine to a vessel placed at the bedside. When last seen he had gained in flesh, could sleep without interruption, and for the first time in his life he was making arrangements to earn a living for himself.

The operation of suprapubic cystotomy has, within the past few years, attracted considerable attention, and is now looked on with more favor than at any previous period. Some have gone so far as to condemn entirely the perineal route to the bladder, and assert that the suprapubic route should be used exclusively; but that this is going too far will be evident to any one who will give the subject a little attention. For temporary drainage and for digital exploration, the perineal method of opening the bladder is undoubtedly the simplest and the safest. On the other hand, the suprapubic method is, in the majority of cases, to be preferred for the removal of calculi too large to be crushed; also for the removal of tumors, with the possible exception of prostatic growths, and for the establishment of permanent drainage. This operation has been hedged around with so many precautions and imaginary dangers that what is really a very simple operation appears to the uninitiated to be one of great magnitude.

Elaborate dissections have been made to show the relationship of the vesico-parietal peritoneal reflection to the operation, and the benefits of rectal and vesical distension has been urged. The dangers of urinary extravasation and hæmorrhage have been pointed out, and the advantages of Trendelenberg's position dilated upon. Regard-

ing the much-talked-of peritoneum: In none of the cases that I have recorded was it seen during the operation, and in only one of them was a rectal bag used. While vesical distension was resorted to in none, though present as an accidental occurrence in Case III, the advantages of both of these have, in my opinion, been more than counterbalanced by the risks incurred from over-distension in their use. A longitudinal incision was used, keeping close to the upper border of the symphysis pubis, and the bladder opened on the tip of a well-curved sound, the finger being kept at the same time in the upper border of the wound to prevent displacement downwards of the peritoneum and intestines. A pair of forceps was next insinuated alongside the sound, into the bladder, and expanded so as to tear the vesical opening to the extent desired. Hæmorrhage was not troublesome in any case. No attempt was made to suture the vesical wound, nor would I recommend that it be attempted, unless the opening was very large. In three of the cases the abdominal wound was partially closed with silver sutures; but in each of these cases the wound reopened on removal of the sutures, so that in the future I will dispense with their use. I would recommend, however, that the incision, both in the abdominal wall and bladder, be limited to the smallest extent consistent with the requirements for operating within the bladder.

No constitutional disturbance was produced by the operation in any case, no extravasation of urine occurred, and the after-treatment consisted of frequent renewal of the dressings and washing out of the bladder with a mild antiseptic solution.

(For discussion see Society Reports.)

Society Reports.

ALLEGHENY COUNTY MEDICAL SOCIETY.

SCIENTIFIC MEETING, AUGUST 18TH, 1891.

T. D. DAVIS, M. D., PRESIDENT IN THE CHAIR.

A paper on SUPRAPUBIC CYSTOTOMY was read by Dr. W. R. Stewart. (See page 732.)

DR. BUCHANAN: I am very well acquainted with the history of the fourth case reported by Dr. Stewart, and I think the doctor deserves the greatest credit for the way in which he followed up the treatment. The case was a very mysterious one, and yet remains so. There was no obstruction of the urethra. There was no active cystitis. There was no disease in the kidney, or in the pelvis of the kidney, as far as could be discovered. There was nothing to give rise to the dilatation of the ureter, the enlarged outlet of which could be felt very plainly with the finger through the perineal incision and demonstrated with the sound, except the constant contraction of the bladder. The opening of the bladder for permanent drainage above the pubis was an entirely arbitrary matter, not based on anything except the fact that during the time at which the bladder was open below, the patient was relieved from pain. For this reason I think Dr. Stewart deserves the more credit for following up that hint and doing this operation without any other indication; an operation which has certainly proved very successful. The man was in a wretched condition; the contractions of the bladder were so painful as to make him cry out; he could not stand still when passing his water, and there was very extensive protrusion of the rectum.

DR. MACFARLANE: I have nothing to say except to compliment the doctor upon the manner of presenting his cases. There is one feature about the one case in which I cannot help but admire the manner in which he treated it. The case is the one in which he had rupture of the urethra. Now anybody who has ever attempted to do anything with rupture of the urethra, knows the difficulty connected with it. I have on two occasions seen men of ample experience spend two hours or more before being able to unite the urethra; on another occasion an hour and a half was spent with lack of success, the work being left to be completed at a later time, the man being, in the interval, in a precarious condition. Now, the doctor's method of treating that, I think, deserves widespread circulation, for it certainly acted very well indeed, and affords a very happy escape from the great difficulty connected with a case of rupture of the urethra.

DR. MCKENNAN: I have a specimen which may be of interest to the members of the society. It was sent to me by Dr. Ray Grayson, of Washington, Pa. It is a congenital malformation of the rectum. The rectum ends at the base of the bladder. It is interesting on account of the fact that we very seldom get a *post-mortem* in cases of this kind, and it represents a type of cases not at all uncommon. An examination of the rectum here discloses the fact that there is a peritoneum connecting the rectum with the

bladder. The rectum enters directly at the base. Some times the rectum enters the bladder at the vertex. After an examination is made, it will be seen that the peritoneum surrounds the entire lower part of the rectum running from the bladder directly to the rectum and surrounding it. This case represents one of a type of these cases of congenital malformation of the rectum which vary from occlusion of the anus to complete absence of the lower bowel. It is said that congenital malformations of the rectum and anus occur about once in every 5,000 deliveries, although some observers state that in statistics of 66,000 cases of delivery, congenital malformation of the rectum and anus occurred only three times. Other observers, however, state that congenital malformations do occur as often as one in every 5,000. To my knowledge, quite a number of cases have occurred around here. It is obvious from the malformation here that operative procedures were hazardous. An attempt in this case was made to reach the rectum but failed. The diagnosis was properly made of entrance of the rectum into the bladder by the appearance of the fæces in the urine. The operation, I believe, was made on the patient on the 17th day, and the patient lived until the 26th day.

Dr. Stevenson: I have seen three cases of imperforate anus: in one of the cases the rectum terminated in the bladder. In that case there was an attempt made to reach the rectum, but it failed and the child died. In two other cases I have seen, the rectum was reached, and the method pursued was passing up a hypodermic needle and withdrawing the fæces and cutting up alongside of the needle, and the rectum was reached and drawn down and the opening stitched. These children both recovered, and had no trouble with their bowels.

Dr. Stewart: It seems to me that in this case a suprapubic cystotomy would have been proper, and would have given relief.

Dr. Buchanan: I think a very much better way would have been to opened the sigmoid flexure of the colon; that can always be reached. It would be very much better to drain the fæces out by an abdominal fistula than through the bladder.

Dr. McKennan: I find that operations in cases of this kind have never been successful. Operations have been done, some operators opening the perinenm, cutting into the bladder and thence making a cut clear through the opening of the rectum into the bladder, making thus a large wound into the perineum. But this method of procedure either produces peritonitis or it causes a fistulous opening in the perineum, which greatly contracts. The only operation which can be done with safety is that suggested by Dr. Buchanan, and that is the operation of colotomy. I find that in malformations of the anus and rectum, that in which the rectum enters the bladder occurs in about forty per cent. of all malformations.

GENERAL DISCUSSION ON SURGICAL JOINTS.

Dr. Murdoch: I am not exactly clear as to what is meant by surgical joints. I suppose it may be joints liable to disease or injury, or that might come under the care of the surgeon, but in that case it would properly include every joint in the body, for there is no joint that might not require surgical treatment; therefore, I do not like the term wholly. I suppose, however, reference is intended to be made to those joints which more frequently come under the care of the surgeon, either for disease or injury, and as that would be so much as to include the whole subject of tuberculosis and all kinds of injuries to the joints, I am not able or willing, and if I were there would not be sufficient time, to discuss the subject as a whole. It might be said, however, that there have been great changes in the surgical treatment of joints within a comparatively few years, as you are all well aware. This has arisen in a great measure from the fact that because of the great improvements in surgery since the introduction of antiseptic treatment of wounds the joint can be invaded and dealt with with so much less risk than formerly. That is one reason. And it seems to be a sufficient reason in the minds of a great many surgeons, that simply because joints can be got into and incised or scraped out, that is a good reason for doing it, and of course this must enter into the problem of whether such an operation should be done. Another reason why the joints are more frequently treated surgically now than formerly is owing to the changed views with regard to the chief disease which attacks the joint, namely, tuberculosis. Without entering into a discussion of the pathology of that disease, we are all, I believe, convinced that the former ideas with regard to it were not correct. I think we all believe now that it is an infectious disease and is not always inherited from the parent. We believe the trouble is usually of local origin, and there is a local focus from which the disease starts, and it is in that view, I think, that a great many operations are now done by surgeons who would have formerly looked with doubt upon the idea

that the local focus of the tubercle can be taken away before it has found localities in other parts of the body. In my recent visit to Europe, both in Ireland and Scotland I saw surgeons there opening into the joints in cases where I am sure nobody here in the United States would think of operating upon, nor do I believe they would be permitted to operate. I saw the joints of young people opened where there were none of the aggravated signs which we look for here, with a view of excising this local focus, which it was believed existed either in the bone or in the joint. I saw, for instance, a surgeon, Dr. McEwen, of Glasgow, operate on a child about fourteen years old, able to walk without much limping, but afflicted with what we call the first stage of hip-joint disease. I saw him cut into the joint and remove the head of the femur. In Ireland I saw a surgeon operating by what they call there an anterior procedure. In these operations they did it in the first stage of disease, before the disease had extended and made much or any destruction of the joints, but they do this operation on an entirely different principle from what I have been in the habit of seeing. They do it with the least possible violence to the joint; the head of the bone is not thrown out of its position. In both of these operations, Dr. McEwen did his operation posteriorly, making the usual incision from the crest of the ilium down from the joint, a short incision, and then introduced his chisel through an opening not over an inch and a half long, and by its manipulation, much pressure and lateral motion, he was able in a very short time to cut off the head of the bone, and then introduce his finger, and extract the head. As I said before, I not believe this would be permitted in our country. We see so little of joint diseases here, tubercular diseases, compared with what I saw in Ireland and Scotland. This is accounted for by the fact that the patients are not so well fed there. Among the poor in Scotland, the number of young people with joint diseases is remarkable. Now, as I said before, I do not expect to be able to treat all of this subject, and I must say that I have had very little experience in the treatment of any of the joints, excepting that of the knee. I have had some experience in that, and have excised the knee some eight times, I think, and with seven successful cases. My friend, Dr. King, at the West Penn Hospital, has perhaps excised more, and has lost but one patient. I wish to speak of the difference between present practice and that in vogue when I was a young surgeon. I know of no subject which shows the great improvements that has been made in surgery more than this one of the manner in which the joints can be opened. During our late war, for gunshot injuries of the knee-joint there was fifty-seven operations performed, and of these fifty-seven, forty-four patients died. Mr. Otis, in his report of our late war, states that previous to the war there were some eighteen excisions of the knee-joint, of which sixteen were fatal. Now, the operation of excision of the knee-joint is one that is almost universally successful, that is, the patient seldom dies under the operation, and it usually results in a useful limb. In Ireland, where they do this operation a great many times, with great success, I was shown at the Richmond Hospital some twelve cases that Dr. Thompson had in the Hospital under recovery. He told me that he had done the operation forty times, with only one death, so that no doubt the operation is one recognized as proper, when formerly amputation would have been in all these cases considered the proper course. When I look back upon my practice, even as late as when I became surgeon of the West Penn Hospital, within twenty years, I can remember patients who lay there for a year or two years with white swelling, as we called it, and eventually perished. I have seen some of these cases amputated, and I have seen several of them succumb simply from the confinement and the inability of the doctors to do them any good. Now these cases would not be permitted to stay there two weeks before some surgical operation would be performed for their relief. As you know, a local focus exists in tuberculous disease; it may be necessary to incise the joint, but in other cases, when only the synovial membrane is involved, the operation of arthrotomy may be performed; opening the joint up widely and dissecting out the entire synovial membrane and scooping out with a gouge any local focus that may be found. The disease I no not believe ever commences in the cartilage. I desire, however, to state at this time, and it is probably all that is necessary for me to say to you to show the method that Dr. Thompson uses to the knee-joint, after having opened it, that this is much superior to anything that I have seen, although it is a good deal like the apparatus which I use myself. I have brought it with me and will show it to you. In operating on a knee-joint, we make what is called the horseshoe incision. This is made by commencing well back, and carrying the knife downwards and upwards across to a

corresponding point on the opposite side, the joint opened, and if it is only desired to perform arthrotomy, the whole of the membrane is scraped with a scoop and cut away with the scissors, and then the flap is replased. But if, on the other hand, it is desired to perform excision of the joint, the bones are cut off and fastened together with nails and a splint. The design of those who operate by cutting parallel with the articular surface is to leave the limb at the same relative angle. Dr. Thompson and those surgeons who have had the most experience in operating tell me that is not the proper way to make the section of the femur; he makes the section of the femur at right angles with its axis, so as to make the leg perfectly straight, as it is in the normal leg. I am inclined to believe that is the better way. I will not go into the manner of cutting the bone, as the surgeons all know that as well as I do. The best way of fixing the limb, that is the important part of the operation. I presume part of the success of this operation in recent years has been owing to this fact. Older surgeons had been in the habit of using wire and other appliances, which did not accomplish the purpose very well. I believe the idea of doing anything to keep the parts in apposition originated in Germany, by the use of steel nails driven with a mallet into the bones. I do not think that was as good a means for keeping the bones in place as the one suggested by me. In Ireland they use silver pegs about an inch and a half long, after making a hole with the brad awl. The nails which I use are four and a half inches long for an adult. They are made for me by Mr. Helmold, and according to the pattern of Mr. Wyeth. The nail should be tapered so that it binds as it proceeds. Three nails should be used. Then hold the bone in perfect apposition with the assistance of the external apparatus. The apparatus which Dr. Thompson uses, and which I think is the best way to hold the limb steady, is made from common hoop iron, an inch and a half wide. This is easily manipulated; it is simply wrapped around with a bandage over it to hold it in place, an anterior and posterior splint. The posterior splint is put down around the ankle joint and up on the foot, the anterior one leaving a space for the dressing over the knee-joint, and after the operation it is not disturbed for three weeks, unless the elevation of temperature is over 100° F. There is a drainage tube put in across the joint behind the bone, well down, and usually it is a very successful operation, I could relate some of my cases, but I will not trouble you with that; the time is passing. I will, however, mention a case that I operated upon at the West Penn Hospital, a man forty-seven years old, a miner, suffering with disease of the joint. Although in this case I feared the operation could not be very successful, the man made a remarkable recovery. He walked into the operating room four weeks after the operation with a cane, and left the Hospital in eight weeks. He had been suffering for two or three years. I received a letter from him three months after he left the Hospital. He said: "With the greatest of pleasure I let you know that I am walking without crutch or cane. It was on the 5th of February that I walked. I was very much surprised at myself when I did it. From the day that you operated on my knee until the day that I walked was four months and eighteen days. How is that for an old man? Therefore I thank you most respectfully for your skilful operation on me."

The joints in which operations are the most useful and in which the surgeons now have the most experience and have done the most benefit are the knee, the hip and the elbow. Excision of the elbow for injury is a most successful operation; so is excision of the knee. But I will say, as I said in the beginning, that there are many surgeons who think that because excision of the joint is done with such safety there is a good reason for doing it. It should always be remembered, especially by the young surgeon, that an excised joint is an admission on the part of the surgeon that he is not able to cure it. As our knowledge of tuberculosis advances, and we are able to treat tuberculosis successfully in the lung, we will be able to treat it successfully in the joint, and operative interference will not probably be essential then. It should never be forgotten, as the very first principle in the treatment of all joints, that the first consideration is rest, putting the parts at rest. If joints can be kept still even where there is a local focus of tuberculosis, if they can be kept still, and proper hygienic measures resorted to, many cases will never call for aid from the surgeon. I believe the improvement in the treatment of disease rests in an early diagnosis, and early treatment. Having said this much, with little regard for order, I leave the matter in your hands.

Dr. Davis: The term surgical joints has been used to describe joints that call for surgical interference.

Dr. Stevenson: I have never made claims to being a surgeon, but have been so

situated that I have had to do a little surgical work. I practiced for twelve years in Westmoreland county; I was medical man, surgical man, obstetrical man, and so forth. I had charge at that time of the Penn Gas Coal Company's works, which employed some seven hundred men, and I necessarily saw a good deal of injury. I think the first case I saw after I opened the office was a compound fracture of the ankle-joint, with dislocation of the tibia. After cutting, and having two or three men exert all the strength they could, I could not get the tibia returned into the joint, so I found a meat saw and sliced off about a half inch and got it reduced, and that man is walking about to-day. I saw not long after that a carpenter doing something with a foot adze, the corner of the adze striking him just over the joint, and penetrating the joint. When I saw him the synovial fluid was exuding. This being before the era of antisepsis it ended in an amputation about four inches above the knee-joint. The man got well with the loss of the limb. I have no doubt the improved methods of treatment would have saved that man's leg. I saw another case which was probably a tuberculous joint. It seemed to start without any known cause, and after continuing quite a number of months, the joint suppurated and I found it necessary to amputate above the knee. That man was not so fortunate as the other, his general health gave way and he died, although the stump had healed and done fairly well. One of the first important things is the diagnosis. What have we? Now in joints, we have a great many structures, there is bone, there is cartilage, there is synovial membrane and ligaments and the surroundings. Any or all of these may be involved, or none of them may be. We have what is called simulated disease in joints the same as we have simulated diseases of other organs. We may have a mimicry of disease in a joint, and this may simulate almost anything. It is a very important matter when a surgeon or practitioner is called to a lady, nervous, of inherited tendencies, want of stability, easily excited mentally, and finds that she is complaining of a severe pain in the knee. You look at the joint, you see it is swelled; she says she can not use it, you attempt to use it, she screams out with pain. No doubt it is very important to determine whether it is a hysterical joint.

The constitutional history of the patient may decide this, but if you have an inflammation of the knee-joint, you will have local heat. Possibly, you will have constitutional heat. If you feel this joint and it is cool or clammy, and you take the temperature of the patient, and you find there is no fever, there is strong ground for suspecting that you have no chronic trouble in the knee-joint.

Dr. Batten: In speaking of operations for joint diseases I will not go into a discussion upon surgical treatment. I believe it has been established that these diseases are of a scrofulous nature, and it was believed that that was a fact up to the time that Koch discovered his bacilli. Since that it is believed that the tubercle bacilli caused all these conditions of the joint, and that they are not hereditary. There is a question in my mind whether they are not hereditary. I believe the bacilli can be carried from the mother, a phthisical mother or a scrofulous mother, to the infant. However, that is a question. But there is one case I know in which an operation was not performed. It was a boy about ten years old, whose parents were living. He had what was called white swelling or inflammation of the knee-joint. He was placed under the care of a great many physicians or surgeons, but there were no operations performed, and he finally recovered from this condition, and is at the present time using all the joints and is an active, healthy man. I would say, however, that Dr. Murdoch is deserving of a great deal of credit for the manner in which he performs these operations, and the success that he has had in giving relief to the patients upon whom he operates.

Dr. Kœnig: In surgery, I think we all admit, cleanliness ranks superior to godliness. In view of the recommendation that Dr. Murdoch has made of a certain instrument, it seems to me that we must accord him greater godliness than cleanliness. With his well-known ingenuity he should be able to construct some appliance capable of being made aseptic, after which he would have no occasion to recommend the use of an instrument as crude as the one he has shown us.

Dr. Lange: I will relate one or two cases. A boy about eight years old while playing on the carpet screamed, said he had hurt his knee, and when his mother got it uncovered, she found on the most prominent part of the knee a single drop of blood, which was wiped away and the little fellow moved around the house, but limped. His mother instituted a search for needles and found half a needle with the thread in its eye. The accident did not seem to trouble

the little fellow much until the third day. Although there was no swelling and very little heat, there was a good deal of pain, and when called, I considered it probable a piece of the needle was in the joint or about the joint, and that it would be the proper thing to anæsthetize the boy and attempt to remove it. This was done, a careful search was made for the piece of needle for more than an hour and a half. The joint, however, was not entered. After that, the little fellow was put to bed and his limb on a straight wooden splint; he was kept in that way two weeks and then allowed to get up. He was up about a week and was again seized with pain and this time a distinct fullness of the joint. The four depressions at the four corners of the patella had disappeared and were replaced by four convexities which fluctuated.

The leg was put in plaster and all motion of the knee-joint was prohibited by the plaster for three months. Then the plaster was taken off and the boy beginning to be active, there was again a slight swelling of the joint, and the plaster was reapplied and kept on for a couple of months more, and then taken off; and finally we saw the end of that surgical joint. The needle has, in all likelihood, become encysted, and will likely do no more harm. The other case was that of a boy riding his velocipede and falling with it. He was picked up and carried home, and when his doctor saw him he concluded he had a dislocation of the femur, because the leg was fully an inch and a half or two inches longer than the other, and because it was rigid, immovable and painful. The doctor chloroformed him, and attempted to reduce the dislocation, and thought he had succeeded. He applied a bandage to the boy's thigh and pelvis, and put him to bed, and the boy complained very little for two or three days. After this the doctor took off his bandages, examined the limb, and found it was fully two inches longer than the other. It was then I saw the boy, and examined him under chloroform as the doctor had done. The curious part of the case was that when the boy was anæsthetized his limb was the same length as the other, and it was evidently not dislocated; but when the boy came from under the influence of the anæsthetic, the limb lengthened two inches. The parents sent for additional counsel, and the last medical gentleman called in concluded that the boy had hip-joint disease. We could not make a diagnosis, allowed that to go, and put the boy to bed.

He was kept there two or three days, then got up and walked, and had no pain nor deformity. On a later occasion when I saw him he complained of pain, and again his leg was apparently two inches longer. We examined him very carefully, and we found that this was a simulated disease, that, as my friend, Dr. Stevenson, has characterized it, it was an hysterical joint, and that the lengthening was not between the pelvis and the femur, but was produced by muscular tilting of the pelvis. The length from both anterior superior spinous processes, to corresponding points below, was always the same, even when the leg projected two inches beyond its fellow. On the other hand, a line from one anterior superior spinous process to the other is not at right angles with the body, but two inches lower on the side where the leg seems longer. This boy is now actively about, painless and straight; but when he is cross, wilful, or disappointed, he complains of his hip, tilts his pelvis, and lengthens his leg.

Dr. Green: Dr. Lange's case reminds me of a surgical joint with which I have had some trouble. The patient, whom I have been called to see many times, has the power of dislocating the lower jaw. She is a girl of nine years; she has always been notorious for will power. Her mother told me that from childhood, whatever she asked for had to be given her. She would say: "If you don't give it to me I'll stretch," and immediately, were the request not granted, the child would begin to "stretch," and open her mouth just as wide as she possibly could, until her jaw would slip out. About two months ago I replaced the jaw; whether she has done much stretching since that time I do not know. I have known some persons who frequently had dislocations of the lower jaw, but in no other case have I seen a person who could wilfully, maliciously, bring about this condition of affairs by stretching, and this boy of whom Dr. Lange has spoken reminded me of the spoiled child who "stretches."

Dr. Buchanan: I understand the subject of the evening to be surgical joints, and those, I presume, are joints which are subjects for surgical treatment, either from disease or accidental injury. Vast improvements have been made in the treatments of injured joints within the last ten or fifteen years. It is within my recollection when a simple puncture of the ankle-joint, and an injury requiring amputation of the anterior part of the foot, would have determined a Syme's operation, or an amputation of the

leg. So great stress was laid upon the fact that *a joint had been opened,* and I believe this to be true with very many medical men to-day, that when called to such a case, the question of amputation rises strongly in their minds. It is well known to-day by surgeons that the synovial membranes can be treated in very much the same way, and with the same impunity as the tendinous sheaths, or any other of the soft tissues of the body. The thing of importance is, when these cavities are open, to keep them aseptic. If this is done no harm can result from the opening, and in the case of the joints we have exactly the same means of keeping them aseptic as in case of the peritoneal cavity, and we can, in addition, if desired, use antiseptic solutions. Now, we are constantly called to dress injuries of joints, particularly fractures of the bones which go to form the joints; and I am satisfied that the practice will be in the future, in many cases, to open joints, wash them out, repair the soft parts, and wire the fragments of bone where the joint has been subcutaneously opened, and where the bones cannot be kept in apposition without great trouble, painfully pressing splints and firm bandaging. I am reminded of a case which Dr. Murdoch saw with me in consultation about a year ago. The patient had a simple fracture of the fibula and a fracture of the inner malleolus. I was called to the case and reduced the fracture without great difficulty, and was able to place the broken malleolus exactly in its position, and retain it there with a simple splint. Dr. Murdoch was called in consultation at the request of the patient, and, to my satisfaction, the next day, we endeavored to replace this dressing by another more permanent in character. This set up a frightful spasm of the muscles of the fibular side of the limb, and the spasms were so great that, using all our force, we had not the power to overcome them and place the limb in shape. I never saw a patient suffer more than did this patient for a few minutes. These shap-edged fragments threatened to break through the skin and form a compound fracture. I proposed at the time, although the patient refused to listen to any suggestion of the kind, to make an incision over the point of the fracture, and put in a single silver wire to retain the inner malleolus in position, and the pressure of an ounce or two ounces on that silver wire would perfectly keep the bone in position. Having to start with a simple fracture, having made the wound ourselves, we could keep it aseptic, no harm could come to the joint. I believe the time will come when that will be the ordinary treatment for such fractures in the neighborhood of joints, where the disposition to displacement is very great, where a very slight force exerted through a silver wire will hold the parts perfectly in apposition, and where we have every possible chance to keep the wound aseptic. There is another aspect of surgical joints not dealt with very often, and that is the advisability, where there is doubt, of making an exploratory opening. I see no reason in the world why exploratory openings should not be made into joints when we suspect disease, as well as into the peritoneal cavity, and as often; but such openings are, I believe, very rare. With regard to case reported this evening, of compound fracture of the inner malleolus and fibula, in which there was protrusion of the shaft of the tibia, in which the patient was etherized, and section of the tendo Achillis made, and a piece cut from the end of the tibia to facilitate reduction, I would say that I reported to this society a year ago a case exactly similar in all respects. I did not find it necessary to do a tenotomy, and the bone was returned without sawing any of it off, and I can hardly imagine a case of this nature in which the same result could not be secured, providing the opening in the soft parts is sufficiently large to let the bones slip in. Muscular action is the only thing that would prevent the return of such a bone, and it can be completely abolished by anæsthetics.

Dr. Davis: All cases of joint diseases presents certain characteristics peculiar to themselves, and require good judgment on the part of the surgeon at the time, and can scarcely be discussed in a general way, but there are joints that are difficult of diagnosis, that no doubt give rise to a great deal of distress to the patient and give rise also to a good deal of distress to the attending physician, because of the long continued suffering involved. The youngest practitioner is likely to come in contact with such joints. One of the very important questions in such joints is when a surgical operation is advisable, or whether it is advisable at all. Take, for instance, the tuberculous joints referred to. The question comes up, when to operate upon it. Will the opening of these joints remove the diseased tissue? Will it give the patient a better chance of life? It is but a few years since all cases of hip-joint disease were considered the property of the surgeon. We have heard to-night of this being carried to extremes on the other side of the water, and operations done which

would not be allowed here, and yet in looking at the statistics this operation on the hip-joint has not been satisfactory.

In the first place, quite a large percentage of those operated upon have died; perhaps not directly following the operation, but within a few days or a few weeks after it. And of those who have recovered from the direct result of the operations, over one-half have died where the diseases have been of tuberculous origin, in such a short time that it is questionable whether the operation does not hurry the general disease. I have read somewhere that out of 388 cases of hip-joint disease operated on, only 61 presented results that could be called satisfactory. Of these 61 there were about 40 that had motion in the joint. Of the 40 there were about 10 who did not have to use the artificial means, such as crutches or cane in walking. Results such as these are not flattering for the operation, and do not lead us to hurry or advise our patient to go into the hands of the surgeon and submit to the operation so liable not to be favorable in its outcome. And then in regard to operations on the knee. While we know that under aseptics it has improved wonderfully as regards immediate death, yet the cases especially where it is tuberculous have not done as well as we could wish. And so of the ankle-joint. I have in mind now a tuberculous ankle-joint where operations have been advised over and over again. I do not know but that if this young man would submit to the operation, and have all this bone removed, the confinement in the house would hasten his end. It is difficult for me to know whether to advise an operation or not. The difficulty with the general practitioner is to know whether to turn such cases over to the surgeon, and with the surgeon to know whether operation ought to be resorted to.

Dr. Murdoch: I think the surgeons who are in advance in this matter of treatment of joints are tending toward diminution of operation at the late stage, where there is great injury to bone. Patients in that condition do not recover well from an incision of a joint, and I believe the tendency of the better surgeons now-a-days, would be to recommend radical measures in joints such as Dr. Davis has described. If the bones are extensively diseased, and the joint extensively involved, the patient would be likely with an excision, to perish from general giving way of the system. I fully believe that such surgeons as McEwen, of Glasgow, and Barker, of London, and the surgeons most in advance, operate early, when the disease is local, and before it has yet attacked the synovial membrane, then is the time to operate at the earliest stage, when it is possible to remove the disease, and it can be removed through a smaller incision without disturbing the relations of the joints, and a movable articulation may then be possible. In Ireland and Scotland, where there are hundreds of these cases to one here, the people have been educated up to the necessity of not allowing this disease to go on, and are willing to submit to an early operation. I am very sure the people here will not submit to the early operation thought proper there. I believe that it will yet come to be the proper practice where a diagnosis can be made sufficiently early. I will say to Dr. Koenig that if he will come up some time to my operations, I will show him how to do the operation, and how I have been so successful in preventing infection of the wound with the washouts I use.

Selected Formulæ.

ICHTHYOL IN THE TREATMENT OF DYSPEPSIA.

Stocquart is quoted by the *Revue Internationale de Bibliographic* as having recorded seven clinical observations regarding the use of ichthyol, for the purpose of relieving vertigo and other cerebral disturbances arising from simple dyspepsia or indigestion in the gastro-intestinal canal. He found that when ichthyol was administered with the bromide of potash, the latter drug was very well borne by the stomach, and that the appetite was improved simultaneously with the increase of digestive power.

SUPERIOR LIQUID GLUE.

℞

Gelatin	ʒijss.
Glue, Russian	ʒijss.
Acetic acid, glacial	ʒij.
Alcohol	ʒijss.
Acetic acid, 20 p. c.	ʒij.
Alum	gr. ij.

Put the gelatin, glue and acetic acid over a water bath until liquid, then add the alum and alcohol. When thoroughly mixed, fill into appropriate bottles.—*B. & C. Drug.*

CREOLIN IN ERYSIPELAS AND ECZEMA.

"Dr. Rothe has used in the treatment of erysipelas a creolin ointment containing—

℞

Creolin	1½ parts.
Creta præp., axung. porc., aa	15 "
Ol. menth. pip.	gtt. 5.

This is spread in the thickness of the

blade of a knife over the diseased parts twice or three times a day, a thin layer of cotton-wool being applied as a covering. In from twelve to twenty-four hours improvement was always apparent, and the disease was cured in three or four days. The same ointment also did good service in a case of weeping eczema of the face, as also in several cases of eczema in children. A patient suffering from scabies was treated with a thorough washing with soft soap and inunction of this ointment, with such a decided effect that Dr. Rothe considers creolin to be undoubtedly a specific for the disease."
—*British and Colonial Druggist.*

FOR GONORRHŒA.

The following antiseptic injection is employed by Brindisi:

℞ Antipyrin.....gr. xlv.
Sulphate of zinc.....gr. iv.
Rose water.
Cherry-laurel water, aa.....f℥ij.
M.

—*Rev. Gen. de Clin. et de Therap.*

TREATMENT OF SYPHILIS DURING GESTATION.

Besnier insists upon a tonic and an energetic specific treatment for the above condition. Good alimentation, syrup of the iodide of iron, and preparations of cinchona bark, with the daily administration of the following pill:

℞ Bichloride of mercury.....gramme 0.01.
Thebaic extract.....grammes 0.005.
Gentian extract.....grammes 0.005.
Glycerine.....s. c.

—*Journ. de Médecine de Paris,* Sept. 13, 1891.

FOR PARASITIC DERMATOSIS.

The following ointment is recommended by the *Journal de Médezine de Paris,* for the treatment of parastic dermatosis:

℞ Acid salicylic.....grammes 5.
Creosoti..... " 2.
Saponis..... " 100.
M. et Signa. To be applied to the affected parts.

FOR CHRONIC DIARRHŒA AND DYSENTERY.

Maget advises the following combination for the treatment of the above affections:

℞ Calomel.....grammes 0.60.
Pulv. Ipecac..... " 0.40.
Ext. opii..... " 0.05.
M. et ft. Pilula vi. Sig. One pill every two hours.

—*Rev. de Therap. med. Chirurg.,* Sept. 15, 1891.

TREATMENT OF CYSTITIS.

Wyman and de Laval recommend the following formula in cases of cystitis, whether acute or chronic:

℞ Ext. pichi fl.....grammes xxxij.
Potassii nitratis..... " iv.
Syr. simplicis..... " xc.
M. Sig. A teaspoonful every three hours.

M. de Laval states that this mixture gives the best results in all varieties of cystitis, whatever the origin may be (senile, gouty, from calculus, traumatic, gonorrhœal, etc.), and finds it useful also in hæmaturia. It is, however, contra-indicated in cases of Bright's disease, in which malady pichi seems to increase the albuminuria.

Pichi (*Fabiana imbricata*) is a plant from Chili, and was brought to the notice of the profession by M. L. Boyer, in France, in 1886, for the treatment of cystitis and urinary affections. M. de. Laval advises the use of a fluid extract made from the young twigs of the plant, and not, as used by the natives, an infusion of the woody portions, which is much less active.—*La Semaine Médicale.*

ANTIPYRINE IN DERMATOSES OF CHILDREN.

In the treatment of pruriginous dermatoses of children, Blaschko employs the following:

℞ Antipyrine.....grammes v.
Simple syrup..... " xxv.
M. Sig. A tablespoonful for a dose.

—*Le Bulletin Médical,* Sept. 9, 1891.

ARISTOL FOR PULMONARY TUBERCULOSIS.

Nadaud has proposed, before the Academy of Medicine, Paris, the following for the treatment of tuberculosis, in the form of hypodermatic injections:

℞ Oil of sweet almonds.....grammes c.
Aristol..... grammes 0.01.
M. Sig. One cubic centimeter of this liquid to be injected at a time.

—*Le Bulletin Médical,* Sept. 16, 1891.

FOR HERPES GENITALIS.

After washing the parts with a weak solution of carbolized water, E. Besnier, (*L'Union Médicale*) recommends this mixture to be locally applied:

℞ Powdered tannic acid.....grammes v.
Subnitrate of bismuth.....gramme j.
Powdered starch.....grammes c.

—*Jour. de. Méd. de Paris,* Sept. 27, 1891.

PASTE FOR ACNE.

Kaposi (*L'Union Médicale*) employs the following paste in the treatment of acne. The part affected being well washed with soap, the paste is to be applied during the night, and in the morning must be replaced either by glycerine or by the common ointment of zinc:

℞
Washed precipitated sulphur..
Pure glycerine.....
Carbonate of potassium..... } grammes x, each.
Hydrolate of cherry bark.....
Alcohol.....

Jour. de Méd. de Paris, Sept. 27, 1891.—

FOR ACNE.

Payne (*Intern. ph. G.—Anz. Pharm. Post*, 1891, No. 5, p. 95) in the treatment of this disease, uses the following mixture to be applied, after washing of the parts:

℞
Sulphur.....gramme j.
Camphorated alcohol.....grammes v.
Lime water..... " lxxx.

Or this ointment:

℞
Sulphur.....gramme j.
Lard..... .....grammes xxx.
Phenic acid.....gtt. x.
Carbonate of potassium.....gramme j.

At the same time the author advises the use of purgatives.—*Jour. de Méd. de Paris*, Sept. 27, 1891.

NAPHTHALINE AS A VERMIFUGE.

According to Dr. Mirovitch (*Mecredi Médical*) naphthaline is an admirable remedy, not only for ascarides, but for tapeworm. He considers it much more certain and far less poisonous than most of the other vermifuges. For adults he prescribes a fifteen-grain powder, to be followed immediately by two ounces of castor oil. For children the following:

℞
Napthaline .....gr. jvss to vij.
Castor oil.....f℥ ss.
Essence of bergamot.....gtt. ij.

For two days before the dose the patient is directed to live on salt, acid and highly seasoned food, then the naphthaline is given fasting early the following morning.

PROLAPSUS UTERI.

℞
Tinct. cimicifugæ.....f℥ j.
Aletris cordial (rio)..... ..f℥ vij.
M. Sig. Teaspoonful four times a day.

This often cures without the aid of mechanical support.

INFANTILE CONVULSIONS,

℞
Chloral hydratis.....gr. iv.
Potassii bromidi.....gr. viij.
Aquæ.
Syrupi, aa..... .....f℥ j.
M. Sig. One dose for a child æt. two.

—*Jacobi.*

THE ADMINISTRATION OF MERCURY TO SYPHILITIC INFANTS.

Dr. Simon (*Journal des Maladies Cutanées et Syph.*) says that for an infant of five or six weeks the liquor of Van Swieten is considered preferable to other preparations, in the dose of fifteen to twenty drops per day, taken in three or four divided doses. Mercurial frictions can be applied at the same time in the arm pits.

The following formula is given:

℞
Neapolitan ointment.....grammes ij.
Lanolin..... " vj.
Mix and divide into six doses.

Each dose being wrapped separately in paraffin paper, according to Widerhofer's plan. Each day one is used for a friction in the axilla, and after from two to four days a tepid bath is given.

Widerhofer also employs the following ointment upon the sides of the nose:

℞
Red precipitate.....centigrammes 0.01.
Lanolin ..... grammes x.

This is to be applied by mild frictions in quantity equal to that of a pea. This mode of application has the advantages of diminishing the swelling of the mucous membrane of the nose, when it exists, thus permitting the infant to take the breast more readily.

Corrosive sublimate baths are useful, especially in rebellious cases which do not give way to the means above referred to. They must be repeated every three days, and, during the immersion care must be taken to prevent the infants from swallowing any of the toxic fluid.

The following is the formula for each bath:

℞
Corrosive sublimate.....grammes 0.20.
Hydrochlorate of ammonia.gramme j.
Distilled water.....grammes cxx.

If the infant is over six months of age, and is raised on the bottle, the milk can have Gilbert's syrup added to it, a third of a teaspoonful in divided doses during the twenty-four hours. The author administers a potion of which each teaspoonful contains one centigramme of mercurial salt and half a centigramme of the iodide of potassium or sodium.

The following formula can be advantageously employed:

℞
Biniodide of mercury.....grammes 0.10.
Iodide of sodium.
Distilled water, aa.....gramme j.
Syrup.....grammes x.

This is to be given according to the age of the infant, a dose of half a teaspoonful for an infant of one year, a teaspoonful for a child of two to three years, two teaspoonfuls for a child of from three to five years, and three teaspoonfuls for a child of five to eight years.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO, (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by postal note, money order or registered letter.

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount earned, received and due in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

THE VALUE OF PSYCHICAL THERAPEUTICS.

In a paper entitled "Psychical Therapeutics," Dr. William B. Sprague, the retiring president of the Detroit Academy of Medicine, has called attention to the value of mental impressions in the treatment of disease. While Dr. Sprague has only repeated what every physician of any experience knows to be true, still, his words are a timely reminder that in the hurry of a busy practice, or in the faithful performance of all the most modern means to arrive at scientific accuracy in diagnosis, we should not forget to use our personal influence for the good of the patient.

It would seem that we are only beginning to appreciate how powerfully mental states affect bodily processes. Dr. G. Bassi has demonstrated fully that in animals dying of grief are commonly found hyperæmia, capillary hæmorrhage and parenchymatous degeneration of the internal organs. Schule and others have found parenchymatous degeneration in persons dying of acute delirium. The theory held by Bassi is, that the nervous disturbance affects the nutritive processes in such a manner as to cause the formation of poisonous ptomaines, which are mainly responsible for the fatty degeneration found in the internal organs; just as certain substances, (such as phosphorus,) affect the tissues.

The mental medicines which Dr. Sprague refers to in his paper, are not the so-called "Christian Science" or "Faith Cure," or even hypnotism, but simply those which every physician can freely employ with greater or less effect, viz.: a cheerful face, kindly sympathy, and the adapting of one's self to the needs of each patient's mentality. Those doctors who have become famous for their skill in dealing with nervous diseases could, probably better than any other class of physicians, tell of the value of rightly directing the current of the patient's thoughts; and, we doubt not, largely owe their success to a *fine sympathetic mental constitution*, which

enables them to understand each patient's need and apply the proper psychical remedy, so that hope, cheerfulness, and courage may replace depression and worry.

In the treatment of "nervousness", neurasthenia, hysteria and all functional nervous troubles, the mental impression made by the doctor is perhaps most valuable, but is no less grateful in all of the little daily ailments, which often are routinely treated, when perhaps more good could be accomplished by an understanding kindliness and appropriate sympathy. By such means we would occasionally discover, that some deeply hidden grief, or great disappointment, had been the real cause of a previously unexplainable nervous affection. To deal properly with such cases requires experience and the utmost tact, and it should be the constant effort of every conscientious doctor to cultivate diligently all those qualities of mind which at times are more valuable in therapeusis than all the whole pharmacopœia.

Correspondence.

INJURIOUS EFFECTS FROM SMOKED GLASSES.

To the Editor of the Medical and Surgical Reporter:

A patient coming to my office complained that her eyes ached after wearing smoked glasses for a short time. The examination of several pairs of smoked glasses in rubber and other cheap frames revealed the fact that often the concave exceeded the convex curve sufficiently to produce a weak minus lens.

Indeed, so often is this the case that I only prescribe smoked glasses with plain surfaces and free from any inner or outer curve whatever.

It can be readily seen how the good to be derived from wearing a tinted glass would be more than neutralized by the far-sighted patient wearing a near-sighted glass.

Richard H. Satterlee,
Easton, Pa.

Book Reviews.

LECTURES ON TUMORS, FROM A CLINICAL STANDPOINT. By John B. Hamilton, M. D., L.L. D., Professor of Principles of Surgery and Clinical Surgery, Rush Medical College, Chicago. For the use of students. Detroit: Geo. S. Davis. Paper, 25 cents.

In this work are embodied eleven lectures which are intended to give the student a practical acquaintance, in a condensed form, with the general principles, clinical history and treatment of neoplasms. The colloquial form of the original lectures has been retained, and eleven atrocious wood-cuts serve as illustrations. The lectures are very readable, and the student will find this issue of the Physicians' Leisure Library well suited for the purpose for which it was prepared.

MINISTERING WOMEN.—THE STORY OF THE ROYAL NATIONAL PENSION FUND FOR NURSES. By George William Potter, M. D. London: "The Hospital" Limited. Royal, 12mo., 131 pp.

The Royal National Pension Fund, the author says, may be said to have had its origin in the misfortunes and distress of a particular nurse.

About the year 1878, a delirious sailor was admitted into the Seamen's Hospital at Greenwich, who was suffering with typhoid fever. While the nurse was attempting to move him he spat into her face, some of the saliva entering her mouth. Notwithstanding that the nurse cleansed her mouth, she became infected with the poison and an attack of typhoid fever ensued in its most virulent form. As a result of this the nurse became a permanent invalid; her friends helped her for a time, finally, her funds failed and she went to the poor house, where she died.

The object of this fund is that of a self-helping enterprise, whereby each nurse might provide for her own future wants from her past resources. As it did not seem possible to provide enough from the nurses' small earnings to entirely accomplish this, an endowment fund was raised, which in less than three years reached $250,000. $200,000 of this was invested for the benefit of those nurses who are able to qualify for pensions by the payment of their own premiums, or who may be assisted to qualify by hospitals or benevolent persons. The remaining $50,000 was set apart as a Benevolent Fund to provide for the immediate relief of destitute nurses, and for annuities for aged and disabled nurses.

The book is a record of a noble piece of work. The profits from its sale are devoted to the Benevolent Fund.

PERISCOPE.

THERAPEUTICS.

CHLORALAMID COMPARED WITH CHLORAL.

Killsbren, in an article on Chloralamid, in the *Memphis Medical Monthly*, makes a comparison between chloralamid and chloral on one hand, and sulfonal on the other. His results are as follows:

Compared with chloral:

1. It is more agreeable to the taste, and consequently easier administered.
2. Rarely causes digestive disorders.
3. Does not depress the heart or circulation.
4. Seldom produces cerebral disturbances.

As compared with sulfonal:

1. Much more prompt in its action.
2. Being more soluble, it can be administered easier.
3. Sleep nearly always passes away by morning.
4. It is only about one-half as expensive.

A NEW METHOD OF PRODUCING LOCAL ANÆSTHESIA.

Dr. Wiesendenger describes in the *Journal für Zahnheilkunde* a new method of producing anæsthesia by the application of cold, the characteristic feature of which is that it is not the cold-producing agent which touches the desired part, but a metallic tube or chamber which is cooled by carbonic acid. The cold may, according to the requirements of the case, be regulated from the temperature of cold water to one sufficiently low to cauterize. The first symptom of this artificial cold is anæmia of the cellular tissue, producing a slight sensation of burning, which is followed by anæsthesia, which lasts from one to two minutes and then disappears without any ill effects. As the instrument may be manufactured of almost any shape, it is evident that this new method may be used for a variety of purposes. The simple turning of a tap will regulate the stream of carbonic acid to any degree of temperature down to four degrees Fahrenheit. No moisture is produced. In using this cold for the purpose of cauterizing the surgeon has the advantage of producing anæsthesia at the same time. When applying it to any of the internal cavities, such as the mouth, it is necessary to have the parts carefully dried, as the tissues would otherwise adhere to the instrument. Dr. Kummel applied the method in the case of a boy in the Maria Hospital at Hamburg with such complete success that the boy looked on without moving a muscle while a deep incision of twelve centimetres in length was made in his thigh. Other gases which can be brought into a fluid state may be used in place of carbonic acid. The carbonic acid which has been used for the purposes of anæsthesia may be led into a vessel which has been tested to a pressure of three atmospheres, and is provided with a manometer and safety valve, whence it could be used as a motor agent or for preserving food. An iron bottle of fluid carbonic acid at a pressure of fifty atmospheres is sufficient for fifty operations. This can be bought for four or five shillings. The instrument for the application of cold to the tissues costs thirty shillings.—*Lancet.*

ACTION OF SUGARS IN THE ORGANISM.

Albertoni, of Bologna (*Archiv. Italiennes de Biologie*, vol. xv, p. 321), administered by the mouth to fasting dogs various kinds of sugar, varying the amount and concentration of the sugar solution, the dogs being otherwise under normal conditions. The animals were killed one hour after being fed, and a very considerable quantity of unchanged sugar was always recovered from the contents of the stomach. Of glucose, about 60 grammes (100 grammes being introduced into the stomach) were absorbed in one hour in large dogs. Maltose, and to a greater extent saccharose or cane sugar, are absorbed even more freely (70 to 80 grammes of 100 grammes introduced into the stomach). Absorption takes place, however, more slowly after the first hour. As to lactose or sugar of milk, the quantity absorbed is much less than in the case of the other sugars, being only 20 to 40 grammes in 100. In this case the sugar is found after death not only in the stomach, but also in the intestine; and moreover, especially if the solution introduced was a concentrated one, the stomach and intestine always contain more water than the amount of water introduced. This may, perhaps, explain why lactose is a purgative, and is sometimes popularly employed as such. Another important point is that weak solutions of lactose

are absorbed more readily than concentrated solutions. In dogs, the intravenous injection of sugar (glucose, saccharose, maltose) increases the frequency of the pulse from 15 to 20 beats per minute, but the increase no longer occurs if the vagi nerves be previously divided. In man, 100 grammes of cane sugar taken by the mouth increases the pulse rate 4 to 8 beats per minute, and the effect is shown from fifteen minutes to one hour thereafter. Glucose, maltose, and cane sugar increase the blood pressure in dogs from 15 to 20 mm Hg, which is not due either to excitation of the vasomotor centres, or to paralysis of the vagi, for the pressure rises equally after section of the cord and vagi. The rise of pressure is, perhaps, due to the more energetic cardiac systole. Sugar introduced into the blood causes vasodilatation of the renal vessels as measured by the oncometer; the quantity of blood flowing out of a kidney may be doubled after the absorption of sugar. Lactose and lævulose, however, produce effects not altogether identical with those resulting from the introduction of glucose, lactose and saccharose. The former two increase the blood pressure, but they diminish the number of pulse beats. The increased blood pressure depends on their action on the cardiac systole, and the diminution of the pulse beats to the intracardiac action of these two sugars on the inhibitory mechanism. All the sugars with the exception of lævulose produce polyuria. Hence it has been proposed to use lævolose in case of diabetes, and Kulz has used it in such cases. If morphine or chloral be given to the dogs, these drugs hinder the effects of the sugar on the circulation, but they have no effect on the polyuria or glycosuria.—*Brit. Med. Jour.*

SPINAL EXTENSION.

The practice of stretching the spinal column in locomotor ataxia and other affections of the spinal cord being based on not very well determined grounds, Dr. Sliunin has recently endeavored to throw some light upon the effects produced by extension of the spine by experiments on both cold and warm-blooded animals. These were carried out in Professor Tarkhanoff's physiological laboratory in St. Petersburg, and showed that when the extension force was equivalent to about three times the weight of the frog or rabbit which was the subject of the experiment, it decreased the sensibility both to touch and to pain, retarded the reaction, and increased the blood pressure. Prolonged extension led to hyperæmia of the spinal meninges, especially of those in the lumbar region. The observations on frogs gave less marked results than those on rabbits, and in a small minority of the former the results were contradictory.—*Lancet.*

TREATMENT OF LARYNGEAL TUBERCULOSIS.

Dr. Cozzolino (*Rivista de los Hospitales*, No. 29, 1891) treats it as follows:

Internal treatment is indispensable, for no lasting result can be obtained, as the larynx is continually re-inoculated by contact with the bacilliferous sputa from the lungs. The nourishment should be strong, and above all, should consist of very nutritive substances, as milk, eggs and meat. Fowler's solution given internally in doses of fifteen to twenty drops a day, according to the tolerance of the patient, and cod-liver oil, in doses of two hundred to three hundred gms. (six to ten ounces), taken during the meal, are recommended by Prof. Jaccound. Before each meal the patient should take a small dose of a mixture of phosphate of lime and two to four drops of the balsam of Peru, the efficacy of which medicine has already been demonstrated by Schnitzler, of Vienna. If this be well supported, then the dose may be increased, and to every dose of cod-liver oil one may add three to four drops of the balsam.

Local Treatment.—Four times a day one may use the following in a spray:

℞ Aq. destillat., gms. 300 (fl. ℥x).
Alcohol restificat., gms. 10-15 (fl. ℥ ijss).
Menthol, cgms. 50-80 (grs. viij-xij).
Balsam Peru, gms. 5-10 (℥j¼-ijss.

By means of an appropriate insufflator the patient himself may be told to make an endo-laryngeal insufflation of the following powder:

℞ Calc. phosphate, gms. 10 (℥ijss).
Iodoform. pulverizat., gms. 5 (℥j¼).
Acid boric, gms, 2 (grs. xxx).
Menthol cgms. 40-80 (grs. ½-j).

If there be dysphagia present, the physician will apply cocaine before each meal to the arytenoid region. In cases of vegetating or papillomatous tuberculosis, one may perform scarification and curetting of the larynx, according to Hering. This must be done under antiseptic precautions. Cicatrization of the ulcers will take place when all the morbid tissue has been removed. This operation is impossible where the disease has extended over the whole laryngeal and tracheal mucous membrane. In such cases one may

have recourse to intra-laryngeal injections of a solution of 20:100 of menthol with olive oil, Rosenberg's method. Ten grammes (two and one-half drachms) of this solution may be injected into the larynx and trachea once daily before meals. Excellent results are obtained by this method. The painful symptoms disappear, the dysphagia ceases entirely, and the general condition improves. The menthol diminishes the tuberculous infiltration and irritation. If one wishes to act directly upon the tuberculous tissue, one may use camphorated naphthol, which has given very good results in local tuberculosis. By thus treating the affection once or twice daily, a cure can be obtained in a few weeks. This remedy is infinitely less painful than lactic acid. In some cases one may advantageously apply cocaine before each local application.

SULPHONAL IN THE NIGHT-SWEATS OF PHTHISIS.

"Dr. Erede, of Genoa, calls attention to what he calls 'the marked antidiaphoretic action of sulphonal.' He says that if given in the early hours of the evening it almost invariably succeeds in suppressing or greatly diminishing the night-sweats of phthisis. A dose of half a gramme, given in the form of pastille or suspended in some gummy vehicle, generally suffices. The largest amount given was one gramme; this failed of its effect only in a very few cases in which the disease was extremely advanced. As no untoward effects were ever noticed, even in very debilitated patients, Erede thinks that with proper precautions the drug might be pushed up to 2 grammes, the usual hypnotic dose. In many cases he observed that in discontinuing the sulphonal after a time the sweating did not begin again at once, but only after some days, when it was immediately checked by repeating the medicine. This shows that the organism does not readily adapt itself to the prolonged use of the drug, as it does, for instance, to certain narcotics. Erede is inclined to think that the effect of sulphonal in checking diaphoresis is to be explained by its action on the nervous system."— *British and Colonial Druggist.*

ARISTOL IN THE TREATMENT OF TUBERCULOSIS.

Hérard has reported to the *Académie de Médicine* Nadand's method of treating tuberculosis by the subcutaneous injections of aristol. The drug has been employed with success in the following form:

℞ Aristol.....1 c. c.
Sterilized oil of sweet almonds.....100 c. c.
Dose, 1 c. c. per day, subcutaneously injected.

Of 23 patients subjected to this treatment 7 felt so well that they considered themselves cured. No accidents were observed. The duration of treatment varied from 25 to 30 days.—*La Médicine Moderne*, Sept. 17, 1891.

THE LOCAL TREATMENT OF DYSENTERY.

Dr. H. C. Wood writes in the *University Medical Magazine*, that in acute dysentery, involving the colon high up, he has found large enemata, containing two to three drachms of subnitrate of bismuth, much more efficient than the exhibition of bismuth by the mouth. When the symptoms are severe, this local treatment may often be preceded with advantage by washing out the colon with large quantities of cold water. He has never used injections of nitrate of silver in acute dysentery, although the effect of the local application of the nitrate in other inflammations of mucous membranes would justify trial of the remedy. He has seen, in one or two cases, large enemata of very hot water injected without affording relief, and believes that hot water enemata are, in their ordinary results, not at all comparable with large injections of ice-cold water.

When the lower part of the colon is affected, the local use of ice sometimes has an almost marvellous effect. He has, indeed, seen the whole aspect of a very severe and alarming case, in which the symptoms indicated that the colon was affected high up, changed in a single hour by the continuous use of *ice suppositories*. While it is not necessary to have the pieces of ice entirely regular in shape, care should be exercised that no sharp edges are left. The suppositories should be rapidly used, one being put into the rectum every three to five minutes, so as to get, for at least half an hour to an hour, the effect of the continuous application of cold.

When the tenesmus is very severe, iodoform suppositories are often much more efficient than opium in bringing relief.

A remedy which has been from time to time recommended very highly in dysentery, but has not, he thinks, been much used, is ergot; and when the passages contain large quantities of blood, or are nearly pure blood, the extract of ergot would seem to be indicated. He has never used ergot by the

mouth in these cases, but has employed suppositories containing twelve grains of extract of ergot and four grains of iodoform, used every two hours until four or five suppositories had been taken with, seemingly, great advantage.

He does not mean to advocate the local treatment of dysentery as a substitute for the use of mercurials, purgatives and ipecacuanha, etc., but as a very important adjuvant to the older forms of treatment. Nevertheless, in my experience, the effect of local remedies has been more prompt and decided than that of drugs given by the mouth; but in cases of any severity the attack upon the disease may be made from each end of the mucous tract.

MEDICINE.

THE ACTION OF ASPARAGUS ON THE KIDNEY.

During the asparagus season, when patients are constantly asking if they may partake of this favorite vegetable, and they are assured by their medical attendant that it is both wholesome and diuretic, I wish to know if this latter character assigned to it is correct and substantiated by careful observation. I am acquainted with instances where the very opposite is the effect. The urine is diminished to half the usual quantity and micturition lessened in proportional frequency. Dr. Lauder Brunton says that the odoriferous character of the secretion is due to the decomposite of asparigin, and that one of the products is supposed to be succinic acid. Has this alkaloid a stimulating or inhibiting action on the kidney?

Dr. Samuel Wilks, in the *Lancet.*

AN UNUSUAL SYMPTOM IN MIDDLE EAR DISEASE.

Dr. R. Lake, in the *Brit. Med. Jour.* writes: That sound caused by air entering the middle ear on inflation can usually only be heard by means of the diagnostic tube, induces me to put the following case on record. Grüber says, speaking on this point, "for the more distinct perception of which [sound] the otoscopic tube is employed." Politzer, "which [sound] can be perceived either by placing the auricle immediately to the concha of the person," and also "this blowing sound has various degrees of strength and distinctness."

The patient a young lady of twenty-one, was under treatment with middle ear catarrh due to Eustachian obstruction; air would not enter the cavities of the tympani either by Valsalva's or Politzer's method, and could only be driven in through a very fine catheter; the finest Eustachian bougie failed to enter the tube at all. Hearing (watch) left normal, and right four inches; after inflation eighteen inches. On February 10th, 1891, I examined the naso-pharynx under ether, and, finding some adenoids, they were removed with Daly's scraper, and a week afterwards the nose was irrigated with an alkaline solution. After this had been employed daily for some days, my patient informed me, that when she blew her nose her left ear made a noise which her sister heard "across the room." I examined the ear, and found the drum apparently normal; the hearing of the right ear was now five feet. April 6th I was sent for and told the noise was again present. On my arrival the patient used her saline solution and inflated her tympanum. I then heard the sound, and though I stood twenty feet away, I still heard it distinctly. It resembled the sudden inflation of a small bladder. Testing the Eustachian tubes, a large sized bougie entered freely.

INCOMPLETE FORMS OF DISSEMINATED SCLEROSIS.

M. Charcot, in a recent lecture on some of the difficulties of diagnosis in case of disseminated sclerosis, brought forward two cases which are worth notice. The first was that of a woman B., who had at one time or another all the chief symptoms characteristic of the disease, but who had gradually lost some of them. She had had most marked tremor on voluntary movement, attacks of vertigo, and most irregular gait; but all these symptoms had disappeared completely except the last, which had very much improved. Still there was quite enough left to show what was the nature of her disease. She had still the characteristic "scanned" speech, the lateral nystagmus, and the exaggerated pateller reflex. The loss of the other symptoms should serve as a reminder of the variability and temporary relief that sometimes occur in disseminated sclerosis, and should lead to a particularly careful study of the past history of such patients. In the other case, a woman C., æt. 41, the mode of origin was in an attack of rheumatism with hyperpyrexia (106°. F.), and the symptoms which then developed themselves were remarkable, and carefully observed by

M. Féréol. The attack was fifteen years ago, in 1876, when the patient was twenty-six, and was most acute. It was very justly called "cerebral rheumatism." After acute articular rheumatism for ten days, there was loss of pain and complete collapse; the temperature rose to 106° F; the face was pale, the hands and feet cyanotic, the pulse almost imperceptible. A cold bath was given, and after it came some revival with signs of bulbar and spinal excitement, resembling in some points tetanus, chorea and epilepsy. Seven baths were given in eighteen hours. There was frequent opisthotonos, with the *risus sardonicus* of tetanus, the loud shouting of delirium, and varied convulsions of all parts. But after about twenty-four hours the hyperpyrexia was subdued, slight articular pain returned, and there was decided improvement in strength, and a slow convalescence began. The nervous symptoms, however, did not pass off entirely. The opisthotonos and convulsions ceased, but there remained a slight choreic movement, which developed itself gradually into a jerky motion accompanying voluntary muscular action; and the speech, which was at first irregular and hesitating, became more definitely "scanned," and the gait halting and irregular after the fashion of the gait of disseminated sclerosis. This was all developed and accurately described within six weeks of the acute rheumatic crisis in July, 1876. Up to 1880 the tremor on voluntary movement was too violent to allow her to feed herself; but in 1880, under the care of Dr. Laseque, there was some improvement, and since then further improvement, so that now she is able to move quietly almost without tremor, to walk without difficulty, and the intelligence and memory are good. There is still nystagmus, "scanned" speech, and some want of balance.—*Le. Progrès Médical.*

HEREDITARY TUBERCULOSIS.

After referring to the important part played in infantile tuberculosis by the increasing habit of artificial feeding, M. Landouzy (*Revue de Médecine*, 1891) protests against looking upon all cases of tuberculosis as arising after birth; nor does he think that the question of heredity is one of suitability of the soil alone, but also of actual bacillary infection. In the transmission of variola, whooping-cough, syphilis, etc., to the fœtus, the same difficulties are not raised as in tuberculosis. The author and M. Martin proved experimentally in 1883 that inoculation from a fœtus born of a phthisical mother, and yet with no naked-eye tuberculous lesions, would produce tubercle in guinea-pigs. The recent case reported by Birch-Hirschfield and Schmorl, where tubercle bacilli were found in the placenta, and also in small numbers in the fœtal liver, is referred to. These results resemble those obtained by Johne and by Malvoz in the case of the fœtal calf. They also agree with the experimental evidence as to the transmission of the anthrax bacillus through the cow to the calf. The rarity of tuberculous lesions themselves in the fœtus is perhaps not so astonishing. The fœtus is "bacillised," but time is needed for the bacilli to grow and fructify. If this delay in their development be granted, then hereditary tubercle resembles hereditary syphilis, but it occurs late. Thus it may be understood (1) that such a fœtus can convey tuberculosis, by inoculation and (2) that the presence of the bacilli (bacillosis) in the infant gives rise to vague symptoms referred to teething, cold, etc., and later to any of the various tuberculosis lesions. The question is next considered as to whether the fœtus may be infected from the paternal germ, the mother remaining healthy. M. Landouzy refers to a remarkable case showing that this may occur. Hereditary tuberculosis should be studied under two aspects: (1) Typical forms. The fœtus is born not only capable of receiving the bacillus, but actually containing it. The development of the bacillus may be hastened or retarded by many circumstances. (2) Atypical forms. This consists really in the transmission of a veritable diathesis. It is supposed to be due to a bacillary toxæmia, the fœtus having escaped the bacillary infection. It is a condition in which not only is no immunity against tubercle conferred, but the tissues are prepared for the reception of the bacillus. The author puts out the multilethality of the offspring of the tuberculous father—how the fœtus arrives at term with difficulty, or the infant dies of so-called congenital debility at an early age, and with no special symptoms or anatomical lesions. M. Landouzy says that tuberculosis and marriage, like syphilis and marriage, is a question of social hygiene.—*Brit. Med. Jour.*

SUBCORTICAL ALEXIA.

Adler (*Berliner klin. Wochenschr.*, 1890, No. 16) records the case of a patient, aged 52. He had an attack of apoplexy, which was probably due to embolism. There was

no previous history of mental deficiency. The attack lasted two minutes, and there was no disturbance of consciousness. There were movements of the head and the left arm. After the attack he remained in an aphasic condition, which at the end of two months had improved very little, and it appeared that the particular variety was that which Wernicke has described as subcortical alexia. The symptoms were uncertainty of seeing correctly letters when he tried to copy them, although he wrote correctly from dictation; there was some color blindness; he knew objects perfectly well although he could not name them; complete right hemianopsia was present. The author supposed the following lesions to exist: destruction of the optic fibres in the left occipital lobe, interruption of the path from the right optic cortex to the left speech region, and destruction of the commissural fibres between the two occipital lobes.—*Brit. Med. Jour.*

ON ALBUMINURIA, TRANSIENT AND DIETETIC.

Dr. Henry B. Milliard, in the *N. Y. Med. Jour.*, in writing upon this subject, states: As regards albuminuria from a prognostic point of view, if the albumin is found beyond question to be true serum albumin and not caused by cystitis, elytritis, trachelitis, etc., whether it be cyclic, permanent, transient, or intermittent, whether only traces are found or it exists in a measurable percentage, it never can be safely assumed that harm can never come of it. I speak of chronic conditions. Great vigilance should be exercised in the observation of these cases. The urinary secretion should be measured, the amount of solids estimated, and the nutrition of the system as regards growth or waste, etc., ascertained, the arterial tension and cardiac condition noted, and these data not once simply but oftener if necessary, and in many cases for a continued period. "Renal inadequacy," a very suitable term, first employed, I believe, by the late Sir William Gull—that is, incapacity of the kidneys to form and excrete the proper amount of solids, and a deficient formative capacity which usually accompanies marked albuminuria—is an important factor in the prognosis. If the amount of solids fall much below what should be voided according to the diet and weight of the patient, and that persistently, there is ground for believing that serious pathological changes are being or have been developed. The average amount of solids voided by a man in health being placed at fifty-eight grammes, any great diminution for a continued length of time of solids excreted is significant. A very close approximation to the amount of solids (in grammes) voided can be obtained by Trabb's well-known simple rule—that is reducing the number of ounces voided in twenty-four hours to cubic centimetres by multiplying by thirty, then multiplying this again by the last two figures of the specific gravity multipled by two. Of course the diet, stature, weight of the subject, amount of exercise, perspiration, etc., must be considered. Forty-eight ounces being taken as the amount of urine voided in twenty-four hours and the specific gravity being 20, we should have about fifty-eight grammes of solids excreted. The aid of the microscope should always be enlisted. In slight albuminuria and in albumina minima the microscope rarely shows any of the elements of renal inflammation. Proliferation of the connective tissue, mild catarrhal nephritis, and glomerulitis may exist for a long time unaccompanied by changes in the tubules. These in time are, however, likely to become involved, and then renal epithelial casts, blood-corpuscles and pus-corpuscles, variously, may be found. It has been a not infrequent experience with me, however, that cases have been pronounced albuminuric when the albumin has been simply an accompaniment of slight catarrh of the bladder or of the prostatic portion of the urethra. I have never seen these cases, no matter how slight, where I could not recognize albumin, sometimes not more than one two-hundredth or one two-hundred-and-fiftieth of one per cent., either by Tanret's or by my own test. If the cystitis is sufficiently marked for numerous pus-corpuscles to be found under the microscope, Heller's test will probably show a sharp line at least one ninth of a line in thickness, which indicates about one ninetieth of one per cent. of albumin. The urates, too, may show this same sharp line. But if we have renal albuminuria to deal with, if persistent, no matter how favorable all physical conditions may seem, we can not assert with perfect confidence that serious lesions may not in time become manifest, and every precaution as regards dress, diet, and care in living should be observed. I should not class as intermittent albuminuria those cases produced by hard study, taking cold, etc.

After albuminuria has existed for a long time, I have known it only in a small proportion of cases to disappear permanently,

and then after a long and rigid course of treatment. Nevertheless, I have had under my observation patients in whose urine I could always find $\frac{1}{50}$ to $\frac{1}{40}$ or $\frac{1}{30}$ per cent. of albumin for several years consecutively without the occurrence of what could be considered renal symptoms. At the same time I should, however, state that the health of these patients was seldom perfectly good. Common symptoms would be a depressed condition of the strength, loss of appetite, the uric or oxalate-of-calcium diathesis. The cases without renal symptoms of some sort at some period were, however, quite exceptional.

Permanent albuminuria, even if intermittent, according to my experience, usually implies in some way impaired health or some latent pathological condition.

As to when albuminuria may be considered cured: Not until at least a long time has elapsed, the urine being examined from time to time in the most careful manner without albumin being found, arterial tension is absent, the heart is normal, and the health is good, we may hope that the albumin may not return.

Should cases of chronic albuminuria, simply from the fact of albumin being found, be rejected by life-assurance examiners? I believe they should not. I have known some albuminuric patients who enjoyed practically good health and lived to a good age. Albuminuria is not always a more threatening symptom than *other* symptoms. An albuminuric patient may occasionally be in every respect a good risk. There are cases where repeated and comprehensive examinations must be made before the examiner can decide as to the interests of his company. There can be no unvarying rule as to this point. I have known albuminuric subjects rejected whose health was good, and applicants with other affections more serious than some of these cases accepted.

What Lecorchè and Talamon say is pertinent to this subject: "It is impossible to attach any prognostic value, direct and immediate, to the presence of albumin in the urine. Albuminuria indicates an alteration of the glomerular filtering membrane; transient or permanent, abundant or minimal, it indicates nothing else; it affords us no information as to the profundity and extent, and consequently none as to the gravity, of the lesion. To form an opinion of this, other elements of appreciation and other phenomena, general or local, must be considered conjointly with the albuminuria."

Of course, if even albumina minima or intermittent albuminuria are accompanied by arterial tension and the significant signs of cirrhosis—such as headaches, disturbances of vision and debility, and insufficient excretion of solids by the kidneys—the case is perhaps more than doubtful, and the dread *sequelæ* of advanced morbus Brightii—such as atheroma of the arteries, miliary aneurisms, loss of the renal functions—are to be expected.

Finally, all persistent albumina, *maxima* or *minima*, are always to be watched.

SURGERY.

THE VALUE OF REST IN SURGICAL CASES.

Among the works which have left a deep and lasting imprint upon the medical mind, that of John Hilton, on "Rest and Pain," must be awarded a prominent place. In his address on Surgery delivered before the British Medical Association, Professor Chiene, of Edinburgh, bears testimony to the great influence which Hilton's teachings had exercised on his own success in the practice of surgery. Prof. Chiene discussed the mental and bodily aspects of rest and unrest, and called attention to the fact that it is not work, but worry—mental unrest which kills; so that a person will bear much physical discomfort to be relieved of the mental discomfort of his condition. This is well illustrated in cases of cancer, where the refusal to operate often occasions great mental depression, while an attempt to remove a tumor—even if unsuccessful—will often give the patient a feeling of mental rest in the very thought that no stone has been left unturned in the endeavor to afford relief. There is another aspect of the mental side of disease, which, in Prof. Chiene's opinion, has not received the attention which it deserves. When a patient is confined to his bed away from his work, he is often suffering as much from the worry of mental inactivity as from the physical disease for which he is under treatment. In these cases decided improvement may be effected by encouraging the patient to do some light mental work. Diagnostic incisions are also a valuable aid in avoiding psychical unrest, for they increase the patient's faith in the surgeon's ability to choose the proper method of treatment. Pain given to a patient, whether in the dressing of a wound, or in the examination necessary to make a diagnosis, is a fertile cause of unrest, and should be avoided by every means in our power. The avoidance of movement in dressing the wound will do

much to prevent pain, and for this purpose the author recommends the many tailed bandage which permits of exposure of the wound without movement of the limb. He also points out that the use of unnecessary strong antiseptics on wounds is one of the most frequent causes of local unrest. The employment of absorbable drains will obviate the necessity of a change of dressing for the removal of the drain, and therefore may be regarded as an other aspect of Hiltonism. Although pressure and careful apposition of the edges and surfaces have to a great extent done away with drainage of any sort, it is safer to employ drains for at least twenty-four hours after operation, so as to avoid accumulation of blood in the wound and consequent delay in healing. If India rubber tubes are used they should be made to project beyond the wound surface, so that the blood and serous discharge may pass into the dressing, and have no tendency to pass along the skin surface to the edge of the dressing. To steady limbs after amputations and excisions, leaden splints are employed by the author, the splint being shaped so that it can be unfolded without moving the limb. Pressure should be applied firmly, but care should always be taken to leave the distal portion of the limb exposed, so that if it swells the bandages may be loosened. Prof. Chiene thinks that extension is not sufficiently used in fractures of the upper extremity or after excision of the knee and elbow. In fractures, injuries, and diseases of the spine, in sacro-iliac disease and fractures of the pelvis, the use of double extension is of undoubted value. In all cases in which complete rest of the trunk is called for, he recommends a thick, firm mattress made in three pieces, the central portion of which can be withdrawn for the performance of the acts of defecation and urination and the examination of the body for bed sores. In injuries of the hip he has given up the use of Nelaton's line, because in order to reach the ischial tuberosities necessary for estimating the line the patient has to be moved. Its place is taken by noting the want of parallelism between the two tapes, one passing through the anterior superior spinous processes and the other through the tips of the great trochanters. In cranial surgery the curved incision suggested by Horsley, enables us to form a flap for covering and supporting the denuded brain matter or dura. In spasmodic wry-neck where the patient is in constant unrest, relief may be afforded by excision of a portion of the spinal accessory nerve, as shown by several cases in the author's hands. In rectal surgery gradual dilatation of the sphincter ani before operation gives rest after its performance, as it is followed by temporary paresis. To afford rest to the bladder the author recommends the introduction of a gum elastic catheter to which is attached a rubber tube passing into a vessel filled with water, the latter being placed at the proper level, to produce a syphon action. Rest may also be induced by perineal section or suprapubic cystotomy. In the treatment of cut-throat the immediate performance of trachetomy and accurate coaptation of the wound facilitates rapid healing, because movement of the parts is reduced to a minimum. In the application of a bandage to varicose veins or the application of a truss, the apparatus should be applied before the patient gets out of bed and taken off after he is in bed, for if the veins are allowed to fill and the hernia to come down, the good of the previous twelve hours support of the retentive apparatus is nullified by the temporary unrest.

We have quoted extensively from Prof. Chiene's address, because of the many practical suggestions of value contained in it. The doctrine of rest as a curative factor in surgical affections is certainly appreciated by all conservative surgeons and finds in Prof. Chiene an able exponent.—*Internat. Jour. Surg.*

THE TREATMENT OF COMPOUND POTT'S FRACTURE.

Hamilton (*Liverpool Medico-Chirurgical Journal*, July, 1891) writes that although compound Pott's fracture is a rare accident, it is difficult to treat successfully. From an experience of seven cases he is convinced that it is bad practice to reduce the tibia and drain, because it is impossible to drain thoroughly, as the articular surface of the tibia fits so closely the trochlear surface of the astragalus.

He, therefore, enlarges the wound, saws off the end of the tibia, and makes a longitudinal incision three inches in length behind the fibula, and if necessary removes a corresponding portion of the fibula. Two large drainage tubes are inserted on the inner side behind the bones, and out at the wound on the outer side.

The limb is put up on a "waxed splint," which prevents the discharge running up the leg, and so necessitating a frequent change of splints. The mere fact of moving the limb sends the temperature up, and may be the beginning of much trouble after-

wards. A third factor is absolute care and cleanliness when the case first comes under observation; no sponges are used, and the cases, for the most part, are dressed perfectly dry.

ATRESIA OF THE RECTUM—ARTIFICIAL ANUS.

Dr. F. de P. Bernaldez reports a case in which an artificial anus was made for complete atresia of the rectum. The patient was a male infant, 4 days old. As his bowels did not move, they tried to apply enemata, but found no anus. All the other organs were normal. The patient was very small, and had icterus. The abdomen was enlarged and tympanitic, and its veins were swollen. At the place where the anus ought to have been, a prominent cord was felt, giving rise to the hope that the rectum was not very high up. An incision, 3 centimetres (1¼ inches) long, deepening gradually to 4½ centimetres (1¾ inches), was made, without encountering the bowel. The person who presented the baby would not allow anything further done; so the wound was sutured, and the child taken home. Next day it was brought again. The wound was re-opened, but, even at 6¼ centimetres (2½ inches), no bowel could be found. The wound was closed again, and an artificial anus established in the left iliac fossa, with good results (four and one-half months after operation).—*Revista med. de Mexico*, January 15, 1891.

EXTIRPATION OF THE VESICULÆ SEMINALIS.

At the recent French Surgical Congress, Dr. Roux, of Paris, stated that in tuberculosis of the genital organs it is a mistake to remove only the testicles, since he has often observed fistulæ and abscesses extending along the spermatic cords after castration. It is therefore necessary to extirpate not only the testicle but also the corresponding vas deferens and seminal vesicle. The author reported two cases in which after removal of the testicle the vas deferens was carefully separated from the vessels of the spermatic cord, which were then tied and divided. An incision was then made in the perineum, the vesiculæ seminalis pushed into the wound by the finger introduced into the rectum and excised, and the vas deferens entirely removed. The results were excellent.—*Le Semaine Medical.*

GYNÆCOLOGY.

THE USE OF VAGINAL TAMPONS.

Sellman (*Journal of the American Medical Association*, July 11, 1891) intends to convey in this paper his impressions of the dangers attending the use of tampons, and also to prove that on many occasions when we think that we have applied them in a scientific manner, it has been improperly done, and carried out in a manner that will do much harm to our patient and perhaps develop injuries that may require months of treatment to overcome. Vaginal tampons introduced for hæmostatic purposes are seldom required, and when used are likely to be attended or followed by great injury. He makes this exception—the use of the tampon for the purpose of provoking uterine contractions and softening of the cervix—in cases where it is desired to bring on premature labor, as, for example, cases of placenta prævia. The packing of the vagina is sometimes justifiable in cases of hæmorrhage due to the presence of uterine fibroids. In hæmorrhage occurring during the progress of cancer of the cervix it is unsafe to tampon. The presence of tampons in the vagina interferes with the evacuation of the bladder and with the proper emptying of the rectum. Tampons are responsible for the production of serious inflammatory conditions of the uterine adnexa, peritoneum and cellular tissue. He advises the application of tampons only under the following conditions: In office practice, after making an application to the endometrium, if the agent employed is likely to flow down and excoriate the external genitals. This is to be removed as soon as the patient reaches home. In cases of prolapse of the uterus, where there is no uterine catarrh—used as a pessary. Also in cases of prolapse of the vaginal walls under similar conditions. After plastic operations upon the vaginal walls, where there is no danger of hæmorrhage taking place above the point where the tampon has been placed. In cases of hyperplasia, with little or scanty secretion from the endometrium.— *Univ. Med. Mag.*

ICHTHYOL IN TUBO-OVARIAN DISEASE.

At a meeting of the Turin Academy of Medicine, on June 12th, Dr. Albertoletti reported (*Riforma Medica*) the results of an extended trial of ichthyol made by him in the Maria Vittoria Hospital on a number

of women suffering from salpingo-ovaritis, endo-, peri-, and para-metritis, etc. He used almost exclusively the sulpho-ichthyolate of ammonium, which he gave internally in pills, or by inunction in the form of pomade, or by intra-uterine injection. He sums up the results obtained as follows: Resolution in a relatively short space of time of endometritis in cases which had proved refractory to the most active treatment; absorption (not always complete however) of peri- and parametritic exudations; cessation of pain in every case without exception. The remedy, according to Dr. Albertoletti, has this marked advantage over other remedies that whilst at least equally efficacious, it is perfectly well borne in all cases, and can therefore be used when other forms of medication are inadmissible. Dr. Bergesio, in discussing the paper, confirmed Dr. Albertoletti's conclusions in every particular, and said that ichthyol seemed to be destined to solve many therapeutic problems relative to utero-ovarian disease.—*Brit. Med. Jour.*

OBSTETRICS.

PUERPERAL PSYCHOSES.

R. Olshausen in the *Zeitsch f. Geb.-u. Gynæk*, Bd. 21, 91, recommends, the division of puerperal psychoses into three classes. First, one dependent on febrile affections—infection psychoses. These are principally cases of puerperal pyæmia, and ulcerative endo-carditis, more rarely cases of so-called septicæmia. When these diseases lead to psychoses the direct cause is generally a meningitic or encephalitic affection, and especially capillary embolisms. The second division is the idiopathic without general febrile disease. To this belong the greater number of the psychoses of pregnancy, lactation and childbed, in which occasionally weakening factors, such as loss of blood, are the exciting cause. The third division is that of psychoses of intoxication after eclampsia, or in exceptional cases, from anæmia without eclampsia. In 531 cases of eclampsia there were 31 psychoses, or 6 per cent. In the Berlin Klinik, in 200 consecutive cases of eclampsia in 5¼ years there were 12 cases of primapara and 5 multipara. In several cases the psychosis was preceded by unusually long-continued eclamptic sopor. They did not by any means belong to the severest cases of eclampsia. The psychoses almost always began in the early part of childbed with hallucinations of sight and hearing. There were 2 cases of melancholia, and 2 of mania. Most of the cases had the character of hallucinatory insanity, but with unusually rapid termination in recovery. It is of interest symptomatically that in a number of the cases the pulse and temperature reached an unusual height, 160° and 102-4° without any cause. Therapeutically chloral by the rectum was the best.—*Med. Press.*

PÆDIATRICS.

CHEMISTRY OF THE STOMACH IN INFANTS.

Clopatt, (*Rev. Mens. des Mal. de l' Enf.*, June, 1891) concludes as follows:

1. The gastric juice of infants has an acid reaction.

2. In children at the breast the acidity varies very little, differing not more than from three to eight-hundredths of one per cent. at the end of the first hour.

3. Gastric digestion is accomplished without the formation of free hydrochloric acid. It is only exceptionally that analyses show the presence of traces of this acid.

4. In children at the breast the fixed chlorides show a remarkable constancy.

5. In bottle-fed children, absolute acidity is often more pronounced than in the breast-fed. At the end of the first hour there is frequently more than one-tenth of one per cent. of acid.

6. In bottle-fed infants there are other acids besides hydrochloric.

7. The quantity of fixed chlorides is more subject to variations with bottle-fed than with breast-fed infants.

8. The changes in the acidity and other qualities which are determined by analysis are not exactly proportioned to the time.

ASTHMA OF CHILDREN.

R. Blache (*L'Union Medicale*) defines asthma as a bulbous disease, in which attacks are produced by impressive irritations of the vagus or peripheral nerves, particularly the trigeminus; the reflex action manifests itself by sucessive or simultaneous spasms of all the intrinsic inspiratory muscles, intercostals, scalenæ, trapezii, etc., and by a tetaniform contraction of the diaphragm.

Blache thus classifies the disease into three forms: Pneumo-bulbous asthma, essential or nervous asthma, emphysematous or alveolar asthma, catarrhal or bronchitic asthma.

Nervous asthma governs all asthmatical pathology of children. A class of asthma in infantile pathology which holds a place whose importance increases every day as the pathogeny of the affections are better known, is the class of reflex asthmas in general; these are the cases in which the bulbous irritation does not leave the broncho-pulmonary filaments of the pneumo-gastric. The bulb is then impressed by an excitement springing from all the peripheric branches of the vagus, but again from the other nerves—as the trigeminus and the cutaneous nerves—so that nasal asthma, pharyngeal asthma, amygdaline, gastric asthma, and cutaneous asthma belong to the category of dyspnœas. Nasal asthma has only been known a few years; Voltolini, in 1874, published the first facts relating to mucous polypi determining the approach of transient dyspnœa. Mucous polypi are rare in children; but, on the contrary, adenoid tumors are very frequent and a usual cause of nasal asthma. Hypertrophic rhinitis is also a frequent cause; this may be a primary disease or follow successive attacks of acute coryza, or infectious fevers, as measles and typhoid fever; it may be secondary to another nasal lesion, malformation of the nose, deviating thickness of the partition, foreign bodies, affections of the naso-pharyngeal canal, catarrh, and adenoid growth. More than this, this rhinitis is at times connected with diseases which attack the stomach (Bouchard, Ruault), the intestines (Secchi, Buck), genital apparatus (J. Mackenzie, Joul).

With such a child, predisposed to bulbous irritability, either by diathesis or heredity, and to nasal erectibility following the preceding lesions, an attack of asthma may be brought on by congestion following cold, by the action of vegetable or animal powders, by the influence of odorous matters, by the contact of a probe on the pituitary gland, by an untimely nasal irrigation, and by remote causes, stomachic, intestinal, or genital excitations.

The treatment recommended for the attack is fumigation by belladonna cigarettes, henbane, or the leaves of datura stramonium, nitre paper, inhalations of oxygen, or ioduret of ethyl, but in many cases the hypodermic exhibition of morphine will be required to produce even momentary relief. In a general way, opium ought to be very prudently used with children; belladonna is much safer and can be used longer. Bretonneau and Guersant mix one centigramme of the extract to one centigramme of the powder of belladonna, giving this each day and continuing for some time. The tincture of lobelia inflata may be given in a dose gradually raised from 20 to 100 drops. Moncorvo remarks that the endurance of children for the treatment permits him to raise the dose 10 and 12 grammes in twenty-four hours. Blache has obtained excellent results from tincture of grindelia robusta, which he gives to children in doses of from 15 to 60 drops. Inhalations of vapor of pyridine, advised by M. Sée, having helped Blache to lessen the force of the attack. According to Laborde and Daudrie, this substance lessens excito-motor force, dilates peripheral vessels, and has a paralyzing action on the vaso-constrictor nerves; hence it increases the fulness of respiration, at the same time the respiratory movements regulate themselves and diminish in frequency. The curative treatment of asthma limits itself to the almost exclusive use of iodine, particularly the iodine of potassium. The anti-dyspnœac effects of this agent on the brain, and particularly on the bulb, are certain; Binz states that it paralyzes the nervous functions and produces narcotism; in every case it moderates the exciting power of the vital centre and regulates the distribution of the nervous influx.

Asthmatics presenting hyperæmia of the nasal mucous membrane are more easily affected with iodism. In cutaneous asthmas iodine may also be contra-indicated as aggravating the skin condition. At times the emaciation and loss of strength make it necessary to interrupt the treatment. Pyridine by aspiration, tincture of grindelia, arsenic, and aërotherapy by compressed air are, then, the only means which remain at the disposition of the practitioner. The iodine treatment is applicable to non-diathetic asthma; it is contra-indicated when the disease has a telluric or hereditary origin—for example, in the arthritic or gouty—a medication favoring incomplete nutrition or modifying the morbid secretions will be indicated. Asthmatics tainted with paludalism will require quinine in combination with iodide of potassium.

Blache agrees with Simon that the value of certain health resorts cannot be overestimated; the former gives the preference to the waters of Mont-Doré, stating that their sedative and decongestive properties have produced good results, particularly in the pneumo-bulbous form; in herpetic asthma children as well as adolescents will find the

sulphorus medication good. Bigorre, Saint Honoré, and Alevard may be recommended. —*Amer. Jour. Med. Sci.*

HYGIENE.

EFFECTS OF VENTILATION ON MICRO-ORGANISMS.

Dr. Richard Stern has made experiments on this subject in a room in which he could have quiet air, or a more or less complete ventilation. The openings in the walls of the room were so arranged that he could admit the air from without either at the upper part near the ceiling and convey it off near the floor on the opposite side of the room (winter ventilation), or the air could be admitted near the floor and conducted out on the opposite side of the room near the ceiling (summer ventilation). The rapidity of the ventilation was also under complete control. The air of the room was intentionally loaded with micro-organisms. Pure cultures were mixed with the dust collected from school-rooms and factories. This was then dried and pulverized and blown about the room. The air was then examined for the number of micro-organisms, by Petri's method at various times. The conclusions arrived at were: (1) That the micro-organisms rapidly sink to the floor in quiet air. The finer the dust upon which the micro-organisms rest the slower the gravitation. (2) The usual ventilation, effecting a renewal of air from one to three times an hour, has no effect upon the removal of micro-organisms with summer ventilation, and only to a very limited extent with winter ventilation. (3) Ventilation, effecting a more rapid renewal of air (six or seven times to the hour), effects the removal of micro-organisms, but slightly without a sensible draught. (4) A rapid and complete removal of the micro-organisms from the air is only attainable with a strong draught. (5) Micro-organisms are not blown off from the floor, walls, furniture, clothing, etc., even with the stronger draughts. (6) The evolution of steam in a room is not capable of rapidly and completely precipitating the micro-organisms, although it hastens this process to an appreciable extent.—*Boston Med. Surg. Jour.*

DIMINISHED DIGESTIBILITY OF STERILIZED MILK.

In a joint paper by Professor Leeds and Dr. E. P. Davis,(*Amer. Jour. Med. Sciences*) the former describes the starch liquefying ferment in milk which renders starch paste entirely fluid and capable of passing through a filter. This ferment is coagulated and destroyed by sterilization, which also has the effect of rendering the casein less rapidly coagulable by rennet. The peptic and pancreatic digestion of sterilized milk (that is, sterilized at 100° C.) is less complete than that of raw milk. Professor Leeds believes that milk may be rendered "practically sterile" by heating to 68° C. (155° F.) for six minutes without suffering any important diminution in its digestibility; ordinary commercial milk being always more or less acid on delivery, it is necessary before sterilizing in this way to neutralize or render it slightly alkaline with carbonate of soda or lime water. A still more advantageous method is said to be sterilization and peptonization at the same time, "the proteid matter of which the micro-organisms are composed being digested away and their vitality destroyed." This is effected by maintaining the peptonizing mixture at 155° for four minutes. Dr. Davis deals with the results of observations made on infants in the Philadelphia Hospital. Acute enteritis subsided under the use of sterilized milk, and no case of cholera infantum occurred in the hospital; cases of acute diarrhœa treated as out patients by sterilized milk speedily recovered. On the other hand, it was found that though exempt from acute intestinal disorders, nutrition did not improve, and the infants died in two or three weeks of malnutrition. Infants removed to a different atmosphere and given fresh raw milk rapidly improved. The infants while in hospital were also subjected to antiseptic intestinal treatment. Koplik(*Archives of Pediatrics*) gives a summary of previous observations upon the effect of sterilization on the digestibility of milk. Hueppe recognized a change in chemical composition occurring gradually at all temperatnres between 75° C, (155° F.) and 100 C., but thought that the digestibility was scarcely diminished. Munk, Hueppe, and Chapin have all pointed out that the casein of milk suffers a change in sterilization, and is less easily coagulated by rennet. Hueppe found that milk was more rapidly and certainly sterilized and protected from subsequent acid fermentation by steam than by the boiling bath (twenty minutes in the former being equivalent to one hour in the latter.) Hirst has suggested the addition of pancreatin before sterilization "in order to digest and help the digestion of

casein made difficult of digestive solution during steaming."

MEDICAL CHEMISTRY.

AMMONIUM SELENITE AS A REAGENT FOR THE DETECTION OF THE ALKALOIDS.

Lafon (*Amer. Jour. Phar.*, 1886, p. 250) called attention to ammonium sulpho-selenite as a reagent for morphine and codeine. He prepared it by dissolving 1 gm. ammonium selenite in 20 cc. concentrated sulphuric acid. The author has studied the reagent further in its reaction with other alkaloids, placing small portions of the alkaloids in his experiments upon watch glasses set upon white paper. The following is the table he has prepared:

Atropine.—No coloration.

Aconitine.—No immediate coloration; after 20 minutes, a very slight rose-color.

Berberine.—Greenish yellow, becoming successfully very brown rose at the margins and violet in the middle; half an hour afterwards entirely vinous red, which lasts for three hours.

Brucine.—Reddish or rose color, becoming pale orange; half an hour after, an amber color, and no deposit.

Caffeine.—No distinct coloration. At end of three hours, the liquid was reddish, and there appeared a slight deposit.

Cinchonine.—Nothing.

Cinchonidine—Nothing.

Cocaine.—After half an hour, no decided coloration or precipitate. After three hours the same reaction as caffeine.

Curarine.—Slight violet coloration; after some time reddish. No red deposit at the end of three hours.

Delphine.—Slightly reddish coloration, passing into a violet red. No ppt. at the end of three hours.

Digitalin. No immediate color. Yellowish after half an hour. After three hours a reddish deposit.

Eserine. Lemon yellow color, turning to orange. Three hours afterwards the color was paler.

Morphine.—Bright greenish blue; half an hour after maroon yellow and no deposit. After three hours, the liquid maroon brown, no red deposit.

Narcotine.—Bluish color, becoming violet and then reddish. After half an hour a fine reddish color and no ppt. After three hours a small red deposit.

Narceine.—Yellow-green color, becoming brownish, and after half an hour reddish. Afterwards a red deposit, which is very distinct in two or three hours.

Papaverine.—Bluish color; the liquid becoming bottle-green, dirty yellowish green, violet blue, then red. A small bluish deposit.

Pilocarpine.—Nothing.

Solanine.—Canary yellow, and then brownish. After half an hour, a rose colored ring, and after three hours the liquid becomes violet red.

Saponin.—Yellowish, becoming slightly reddish. (Reaction not distinct.)

Senegin.—Light, dirty yellow. After three hours, liquid reddish.

Veratrine.—Indistinct yellowish color, sometimes with a green tone. After half an hour yellow. After three hours, deposit red and liquid yellowish. (Reaction indistinct.)

PREPARATION OF ABSOLUTELY PURE HYDROGEN PEROXIDE SOLUTION.

According to Crismer, absolutely pure hydrogen peroxide solution is best prepared in the following manner:

Barium peroxide is mixed with water [and made into a thin milk], then decomposed by hydrochloric acid of the specific gravity 1.100, and the solution afterwards shaken with ether. The latter dissolves out a portion of the hydrogen peroxide. It is separated and shaken with pure water, to which it yields a portion of the dioxide. The ethereal solution is now separated and again brought in contact with a fresh portion of barium solution. The same operation is repeated several times. Finally there is thus obtained a solution containing 0.5 to 0.9 per cent. of hydrogen dioxide which is absolutely neutral and free from other constituents. It contains no chlorine, but a little ether which assists in its preservation, and which may be removed, if necessary, by distillation in vacuo. The percentage of pure hydrogen dioxide diminishes very slowly by keeping.—*Bull. Soc. Chim. Paris and Chem. Centralbl.*

NEWS AND MISCELLANY.

POLYCLINIC EVENING LECTURES.

The Faculty of the Philadelphia Polyclinic deliver two evening lectures a week at 8 o'clock, during the course of 1891 and 1892. The following lectures are announced:

Oct. 27.—Dr. C. K. Mills, "Aphasias, and How to Study and Treat Them."

Oct. 30.—Dr. G. Belton Massey, "Some Everyday Experiences in Electro-Gynæcology."

Nov. 3.—Dr. Edward Jackson, "Shadow Test."

Nov. 6.—Dr. B. F. Baer, "A Plea For Early Diagnosis."

Nov. 10.—Dr. Edward Jackson, "Shadow Test."

Nov. 13.—Dr. B. F. Baer, "The Treatment of Retro-Displacements."

Nov. 17.—Dr. T. S. K. Morton, "Appendicitis."

Nov. 20.—Dr. R. W. Seiss, "Treatment of Aural Pain."

PROGRAMME OF THE SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

The following is the preliminary programme of the session of the Southern Surgical and Gynæcological Association, to be held in Richmond, Va., Nov. 10th, 11th and 12th, 1891:

PAPERS TO BE READ.

The President's Annual Address—Louis S. McMurtry, M. D., St. Louis, Mo.

Remarks on Systematic Infection from Gonorrhœa, Illustrated by Cases—Bedford Brown, M. D., Alexandria, Va.

The Rational Treatment of Peritonitis Based upon the Consideration of the Pathological Conditions Present—W. D. Haggard, M. D., Nashville, Tenn.

A Medico-Legal Aspect to Pelvic Inflammation—W. W. Potter, M. D., Buffalo, N.Y.

Complications in Pelvic Surgery, and How to Deal with Them—Joseph Price, M. D., Philadelphia, Pa.

Cholecystotomy—Report of Case—52 Gallstones and 10 Ounces of Pus Removed—Success—W. B. Rogers, M. D., Memphis, Tenn.

Some of the Complications of Psoas Abscess—J. McFadden Gaston, M. D., Atlanta, Ga.

Laparotomies Performed in the Past Year—Thomas Opie, M. D., Baltimore, Md.

Imperforation of the Rectum—Geo. Ben. Johnston, M. D., Richmond, Va.

A Case of Induced Abortion for the Relief of the Nausea and Vomiting of Pregnancy, with Remarks—Christopher Tompkins, M. D., Richmond, Va.

The Principle of Drainage as Applied to Surgery of the Deep Urethra—F. W. McRae, M. D., Atlanta, Ga.

The Neuroses of the Genito-Urinary System in the Male—Frank Lydston, M. D., Chicago, Ill.

Nephrectomy, with Report of Cases—Edwin Rickets, M. D., Cincinnati, O.

Venomous Serpents of the United States, and the Treatment of Wounds Inflicted by Them—Paul B. Barringer, M. D., University of Virginia.

A Report of Some Additional Cases of External Perineal Urethrotomy Without a Guide—J. Edwin Michael, M. D., Baltimore, Md.

Growth of Fibroid Tumors of the Uterus after the Menopause—Jos. Taber Johnson, M. D., Washington, D. C.

The Part the Shoulders Play in the Production of Laceration of the Perineum, with Suggestions for Its Prevention—W. D. Haggard, M. D., Nashville, Tenn.

The Pedicle in Hysterectomy, How Formed; Its Subsequent Behavior; Its Final Condition—I. S. Stone, M. D., Washington, D. C.

A Case of Pelvic Abscess—John Brownrigg, M. D., Columbus, Miss.

A Case of Cyst of the Mesentery, with Remarks—J. A. Goggans, M. D., Alexander City, Ala.

The Female Urethra—K. P. Moore, M. D., Macon, Ga.

Medico-Legal Aspect of Intestinal Surgery—J. D. S. Davis, M. D., Birmingham, Ala.

Albuminuria; Its Relation to Surgical Operations—J. W. Long, M. D., Randleman, N. C.

Senile Gangrene—Frank Prince, M. D., Bessemer, Ala.

Hæmorrhage *versus* Shock—W. L. Robinson, M. D., Danville, Va.

Treatment of Gallstones, with Report of Cases—W. E. B. Davis, M. D., Birmingham, Ala.

(Title of paper not determined)—Hunter McGuire, M. D., Richmond, Va.

(Title of paper not determined)—Duncan Eve, M. D., Nashville, Tenn.

(Title of paper not determined)—A. L. Brokaw, M. D., St. Louis, Mo.

(Title of paper not determined)—Chas. A. L. Reed, M. D., Cincinnati, O.

(Title of paper not determined)—W. F. Westmoreland, M. D., Atlanta, Ga.

LOUIS S. MCMURTRY, M. D., President.

MEDICAL AND SURGICAL REPORTER

No. 1811. PHILADELPHIA, NOVEMBER 14, 1891. Vol. LXV.—No. 20.

Clinical Lecture.

CONSTIPATION A PRIMARY CAUSE OF TYPHLITIS, PERITYPHLITIS AND APPENDICITIS.*

BY JULES SIMON, M. D.,
OF PARIS.

The surgical study of typhlitis, perityphlitis and appendicitis has of late been the subject of very interesting researches. The relative safety which attends at the present time the great intra-abdominal operations, renders favorable the results obtained even in the most trying cases. Thus, to-day it is possible to treat with success abscesses of the iliac fossa, perforation of the appendix vermiformis, peritoneal adhesions, peritonitis and similar disorders. The truly medical aspect, so to speak, of the diseases in question, which seems to be absolutely disregarded, deserves our closest consideration.

Before the inflammation is established, patients with few exceptions, pass through a condition more or less characterized by inactivity and engorgement of the cæcum, and I will endeavor to show you the long succession of symptoms, the interpretation of which is apt to escape the observation of the most skilful clinician.

There was admitted into the ward of our Hospital, a boy nine years of age, suffering from a very pronounced attack of peritonitis. He states that his ailment came on, the day previous to admittance, as a result of a blow received on the abdomen. On the contrary, his family history shows that he has been suffering for several months, and for the last two months he has complained of abdominal pains to such an extent that he has been unable to walk. This indicates in a clear manner that the original cause of the complaint which required his admission to the Hospital depends upon an irritated condition of the cæcum which dates some time back. In all the cases that I have studied I have met with the same symptoms and the same order of phenomena. The present instance is a self-evident example.

One of my private patients, a young girl who had suffered in her infancy from a severe constipation, exhibited at the age of six years, an obstruction of the cæcum, followed by a diarrhœa and inflammation of that part. I put her under treatment, and three weeks after all the symptoms had disappeared without a trace of induration. At this time I seriously warned the mother to pay personal attention to the danger of allowing the child to become constipated, and of the necessity of keeping the fæces in proper condition, making her understand that a relapse, which frequently occurs, would place her daughter in great danger. I insist on the fact that parents do not understand the symptoms accompanying constipation in children. They are ignorant of what these symptoms signify, and as long as the child has a passage, they pay no regard to the quantity or the quality of the stools. In spite of my timely warning my advice was disregarded and a year later the girl was taken with a typhlitis, followed by an appendicitis and a fatal perforation of the appendix. The child died in the country in such a terrible agony that I believed a perforation of the appendix had occurred. I was present at the last moments of the patient, and I could see how the physician had been dealing unsuccessfully with an uninterrupted and typical course of symptoms. It is to me apparent that if the perforation had been the ultimate cause of death, it was being prepared, as it were, for a considerable time back by the inflammation and gradual dilatation of the cæcum and appendix.

To resume, a condition of chronic constipation has produced in this girl a dilatation of the cæcum, where accumulated fæcal

*Delivered at the Hospital des Enfants.

matters gave rise to irritation of the intestinal walls followed by distension of the cæcum. Inflammation again set in, owing to impaction of fæcal matters in the cul-de-sac, and that, naturally, was followed by ulceration, perforation and the inevitable peritonitis.

In all the cases observed by me in private practice and in the wards of the Hospital I have noticed the same train of pathological phenomena, and in those instances where a special hygienic method has been observed and special treatment followed of which I will speak, the patients have always escaped the untoward symptoms mentioned.

The premonitory period of the disease is characterized by: Constipation followed by fæcal impaction which may end in resolution, but a relapse often occurs, and then it either disappears entirely or gives rise to dilatation and thickening of the intestinal walls; and finally, under various causes, depending on the character of the food ingested or the excrementitious matter formed, or under the action of cold, etc. etc., the acute inflammatory disease may come on slowly but progressively upon the walls of the intestine, or with sudden violence upon the appendix.

The beginning of the symptoms can be traced ordinarily to the age of from 4 to 6 years. This pathological state may be divided into three distinct epochs: 1. Simple constipation; 2. Engorgement of the cæcum; 3. Stercoræmia and its effects upon the general system.

Simple constipation constitutes the initial symptom. This constipation is continuous, coming on and continuing without other apparent cause than the result of taking a large amount of food without being properly masticated. It alternates with lienteric passages. The stools are nearly always glairy and bilious. The child gradually evinces a lack of energy, a sickly appearance, becomes peevish and loses his appetite. At this period palpation reveals nothing but an accumulation of fæcal matters. After evacuation there is softening of the part. Following an apparent return to the normal state, the same phenomena are reproduced.

If the constipation continues, it ends in the production of a subacute inflammation, a clammy condition of the walls of the cæcum; and then the second period sets in. Palpation then reveals no softening of the part. Reflex manifestations become marked and the child is troubled with a disturbed sleep. At times, he complains of headache, his intelligence is blunted, there is loss of memory, his disposition is soured, and his appetite becomes capricious or is entirely lost. The tongue is coated, and digestion slow and imperfect. There is then noticed a febrile reaction and a tendency to chills. Sometimes pain is felt at the iliac fossa, which may be of a dull nature. These symptoms often resemble those provoked by an attack of coxalgia. After exposure or fatigue the symptoms may take a more acute character, and the pain is frequently accompanied by vomiting.

When prolonged, the affection exercises a pernicious influence upon physical and mental development. Without producing an aggravated condition of the local symptoms, anæmia makes its appearance to an alarming degree. The aspect of the child is then that of an advanced phthisical patient. The absorption of toxic intestinal matters causes an irregular fever, and a sallow, dull, earthy pallor. This group of symptoms, together with the pains and alternating condition of constipation and engorgement of the cæcum, may convey the impression of the existence of tubercular peritonitis. The persistence of such serious symptoms endangers life directly, without surgical complications. When a patient has reached such an advanced stage of the disorder, a cure is always with difficulty and slowly obtained.

At the patient's bed the progress of the malady never takes a regular course. The disease is attended by ameliorations and relapses which make its duration and progress of an indefinite character. The reflex symptoms are worse at times than would seem to be proportionate to the affection itself, among them we may have insomnia, cephalalgia, anæmia, dyspepsia—troubles which are the first to call the attention of parents. It is then that you are called in consultation.

Inflammatory symptoms may appear at all periods of the disease. Simple constipation alone may give rise to perityphlitis without producing any disturbance of the general system; and again, as you have seen, the affection may be of a long duration, bringing about serious troubles due to stercoræmia, but without other pathological complications than a local engorgement of the cæcum. I believe such initial beginning of perityphlitis to be an exceptional one, the disease being usually preceded by a long period of simple constipation. Of late, much stress has been laid on the perforation of the appendix. Of course, it is easy to conceive how a foreign body, irregular in shape, may perforate a sound appendix; but this acci-

dent will occur more frequently when there is a stagnation of fæcal matters in the cæcum, or when there is engorgement of the intestinal walls. This engorgement is accompanied, as I have often observed in post-mortem examinations, by a true dilatation of the vermicular orifice which has facilitated the entrance of foreign bodies. In such cases, appendicitis should be looked upon, not as a primary, but as a secondary condition.

The gravity of pericæcal inflammation and suppuration is familiar to you. In the most favorable cases the pus may find its way out through the skin, but the abscess may also open into the rectum, as I have noticed in a case of private practice.

Surgical interference has given good results in the most desperate cases. While I admit the justifiability of such procedures, let me insist on the importance of an early diagnosis which will prevent those measures. If simple cæcal engorgement, even without perityphlitis, is difficult to cure, suppuration constitutes a very serious and tenacious lesion. After an operation the patient may, for the time being, be relieved of the immediate symptoms due to the local suppurating processes, but the inertia of the cæcum continues to give rise to grave reflex symptoms.

In making a diagnosis we are often misled by parents, and are at a loss to account for the symptoms exhibited by the little patients. Many children are brought here to be treated for cephalalgia, dyspepsia, anæmia, arrest of development, or similar troubles, when the true cause of the ailment is a simple constipation. An examination of the iliac fossa will reveal to us a suspicious condition of affairs. You must not confound the engorgement which results from constipation with the condition produced by perinephritic inflammations, by ovaritis, by abcesses, and by adenopathies from diverse causes. It is necessary, in order to make a correct diagnosis, to consider the malady in question as if it existed. Besides the cæcum, it is always advisable to examine the iliac fossa, when you will often find a stagnation of fæcal matter.

If the diagnosis of cæcal engorgement is comparatively easy, it is easier still to determine the degree of the lesions present. Without speaking of the period of suppuration nothing is more difficult to appreciate at first than the inflammation of the intestinal wall and of the appendix. The duration of the disease, the glairy nature of the fæces, the persisting retention, even after evacuation of the bowels by means of a purgative, all indicate the presence of the malady, and diminish, as you can understand, the chances of a definite recovery.

From an ætiological point of view, the disease starts, as I have pointed out at the beginning of this lecture, ordinarily at the age of from 4 to 6 years. Children suffering from this disorder sometimes have had severe enteritis early in life. I have often observed a true inheritance, parents showing a history of tenacious constipation. The little patients are frequently extremely nervous, and may exhibit tendencies to hysteria and epilepsy. You know also how constipation is a frequent symptom of cerebral disorders of childhood. As occasional causes, an inconvenient dietetic regimé ranks in the first place. Tough meats and imperfectly cooked or improperly masticated food constitute one of the great causes of cæcal engorgement. Castigation of children, in the form of blows or lashing, often provokes a relapse of subacute inflammation, and cold acts in the same way. The disorder often follows cold baths and indigestion, and is frequently provoked by the ingestion of cold meats.

With these facts of ætiology you can conceive what the most important therapeutic indications should be. With regard to diet you must avoid all indigestible or tough food, and at the start you can allow beef and vegetables *well-cooked*, to be taken slowly and at regular hours. Tea, coffee and wines are to be avoided. Beer, mixed with Vals or Pouges water, may be considered as the best drink. Supper must be very light.

In the treatment of neurasthenia, friction with flannel dipped in cologne water are of great service. With regard to the management of impacted of fæcal matters, you must never employ strong purgatives; you had better use, at the beginning, for this purpose, the fatty and mucilaginous substances. You can prescribe in the morning, for instance, two tablespoonfuls of the oil of sweet almonds, with the addition of a few drops of castor oil. On the following morning, a tablespoonful of macerated flaxseed together with some syrup of rhubarb. From time to time replace these laxatives with mineral water. The preparation known under the name of Ricinol can be given in half a tablespoonful doses in coffee, to young children, and double this amount to older patients. This medicament is well borne and constitutes a good way of varying medication.

In the tenacious form of the disease, belladonna and hyoscyamus are the best substances to use in combatting the dryness of the mucous membrane and atony of the mus-

cular walls of the intestine. You will order these agents in the form of pills, each containing a centigramme of the extract of belladonna and a centigramme of the extract of hyoscyamus, or a centigramme of the powdered leaves of belladonna and a centigramme of the hyoscyamus extract. To a child 4 years of age you can give from two to three pills in the course of twenty-four hours. The tolerance of these drugs is far greater than that of opium, and the doses may sometimes approach those used in adults. Nux vomica is also a good remedy to employ to provoke contractions of the intestinal walls, and its use may be alternated with that of belladonna and hyoscyamus. You can prescribe a mixture containing one part of Baume's tincture and 20 parts of tincture of rhubarb, cascarilla or aniseed, (or one drop of Baume's tincture), at the beginning of each meal.

I would also advise you to employ frictions and massage, both of which are useful in exciting contractions. Besides, you can use a liniment composed of 10 grammes of the tincture of nux vomica and 40 grammes of the oil of chamomile. In this way, an absorption of the former drug can be obtained, which has the same effect as when administered internally. Finally, electricity in the form of simple faradic or galvanic currents, intra-rectally applied, is equally good.

CHRONIC GASTRITIS TREATED BY LAVAGE.*

BY H. M. FISHER, M. D.,

PHILADELPHIA.

The man before us is 49 years of age, and was admitted to the Hospital on September 1, 1891, complaining of very severe colicky pains in the abdomen. The pain, which was evidently due to catarrh of the small intestines, was relieved by small doses of epsom salts and laudanum. He continued, however, to complain of epigastric pain, and, upon careful questioning, it became apparent that he had suffered for some months with severe attacks of pain and vomiting. The ordinary methods of treatment were tried; he was placed on bismuth and calomel in small doses; he had daily doses of Carlsbad salt (ʒj to ℥j of hot water); diet was regulated and for several days his food was restricted to peptonized milk. But, in spite of this treatment, he continued to complain of pain, and vomited about once a day. Seeing how utterly futile the above treatment was, it occurred to us that digestion was probably rendered difficult or impossible by an accumulation of mucus in the stomach, and that it would probably be necessary to cleanse the stomach of this before we could hope to obtain any marked relief.

Experience has shown that a soft rubber tube can easily be swallowed by a patient who is willing and anxious to co-operate with the physician, and who is not very nervous or irritable. This patient has already swallowed the tube two or three times, and you see, as my resident, Dr. Miller, passes the tube well back on the epiglottis and asks him to swallow it, it passes down the œsophagus naturally and without apparently causing the patient any marked discomfort. As it passes the epiglottis and compresses slightly the posterior portion of the larynx, a slight choking sensation is generally experienced, but with the descent of the tube, this sensation gradually passes off. The tube is now in the stomach, and Dr. Miller proceeds to pour directly into the stomach, through the funnel at the upper end of the tube, the alkaline solution (about half an ounce of bicarbonate of soda to one quart of water). After the stomach is full, depressing the funnel causes emptying of the stomach by siphonage. This process is gone through with every second or third day.

There is no question that the long continued use of lavage may be injurious, and may tend to impair the function of the peptic glands, but in some cases, the first effects in relieving the patient of distress and enabling him to digest food, which he for weeks has been utterly unable to do, are certainly most encouraging. The patient feels much better after this treatment. For two or three days he has had no food at all by the mouth, and was put entirely upon nutrient enemata consisting of the white of an egg, ℥j of Carnrick's beef peptonoids in powder, and ℥vj of peptonized milk. You know that in introducing food into the bowel, it is important to peptonize it, because the glands of the rectum absorb, but do not, except perhaps in a very feeble degree, peptonize food. The bowel is thoroughly washed out by an enema of soap and water, once a day, about two hours before the nutrient enema is introduced; and, to prevent excessive irritability of the rectum and secure attention

*Delivered at the Pennsylvania Hospital, Philadelphia.

of the enema, about one-sixth of a grain of morphine sulphate is added to the enema. Yesterday, he was put upon a small amount of milk. To-day, he tells us that he feels a great deal better. He complains somewhat of hunger, and I think he can now digest much larger amounts taken by the mouth. I hope he will gradually be able to live as do other people; however, it is not impossible that there may be, in this case, some obstruction at the pyloric orifice.

We may have here to deal with a case of dilatation of the stomach, brought on by long continued gastric catarrh. Further study of the case will doubtless throw light on this point, but, in any case, we must be prepared to expect a very slow recovery, as this condition is one that has probably been gradually developing for years past, and the whole nutrition of the mucous membrane of the stomach is altered, and it may take months to restore the normal conditions, if, indeed, they can ever be completely restored.

METABOLIC ELECTRIC POLARITY AND ELECTRO-THERAPEUTICS.*

BY WILLIAM JAMES MORTON, M. D.,
NEW YORK CITY, N. Y.

The main contention of this paper is, deductively, that since the normal and morbid processes of living tissues proceed by chemical exchanges (plus a directive tendency which is unknown) from the assimilation of food through excretion, viz., by metabolism, differentiated into anabolism and katabolism; and since it is probable that chemical exchanges of this nature cannot take place without the exhibition of electric polarity and electric currents and since experimentally this electric polarity is demonstrable (facts of animal electricity); and since, as claimed by the writer, this polarity must, if due to the chemical exchanges of metabolism, be initially and invariably electro-positive in its internal circuit, because katabolic and therefore initiated by the avidity of the oxygen atom (or its congeners) for the atoms of the tissue subject to combustion; and since, if, as further claimed, this polarity be admitted to be due to chemical changes, it must equally be admitted to represent, not alone a transformation into electric energy but also the transformations into heat, mechanical force and all the kinetic energies of the living organism.

Therefore, as a consequence, this initial, invariable electro-positive polarity may be regarded in the important light of being equally an invariable guide to the electro-therapeutist.

And as regards disease (and equally normal processes,) focal positivity, (corresponding to the zinc element of a voltaic cell), may be ascertained to be an invariable element of its progress and consequently may be combated by an inverse current or applied extraneous medical polarity which may augment, annul or reverse the initial focal positivity and therefore augment, annul or reverse the chemical exchanges underlying it.

To employ this guide in practice, metabolism, normal and morbid, but for the time being confining attention to morbid metabolism, may be said to consist of:

(*a*) Overactive chemical exchanges, and

(*b*) Underactive chemical exchanges.

In over-activity:

(*a*)An applied (medical) positive pole will increase the activity, *i. e.* augment the disease.

(*b*) An applied negative pole will decrease the activity, *i. e.* palliate or cure the disease.

In under-activity:

(*a*) An applied positive pole will increase the activity, *i. e.* palliate or cure.

(*b*) An applied negative pole will decrease the activity, *i. e.* augment the disease.

Two curative directions only of treatment are open, viz. the negative pole in over-activity and the positive pole in under-activity.

The above four results may be obtained experimentally by applying a voltaic battery to a single voltaic cell, as indicated.

What may be true of morbid processes is held to be equally true, on parallel lines, of normal processes.

The "current of action" or "negative oscillation" may be explained upon the supposition that unstable endothermic substances formed by protoplasmic voltaic action at the negative element during repose are decomposed (by aid, for example, of an initial neural impulse) and produce an electric current in an opposite direction.

The chemical, oxidizing, katabolic, protoplasmic foci of all the liberated energies are ascertainable by the peculiarity of one of them—the electric—that it exhibits polarity.

The polarity of metabolism, crudely speaking, may be said to be the signal flag

*Abstract of a paper read before the American Electro-Therapeutic Association, Sept. 24, 1891.

which flies at the initial chemical sources of the disease to guide the electro-therapeutist. And even if the writer's view that all morbid processes must be, initially and invariably, electro-positive, be not found to hold good in all diseases, still the suggestion to adopt polarity as a guide and to base treatment by applied currents, upon the principles outlined, will remain fixedly applicable in practice.

MALARIAL HÆMATURIA. *

BY J. B. HAMILTON, M. D.,
TRINITY, MISS.

The history of this disease seems to be veiled in obscurity. Go to our text-books, and they are almost silent. I have consulted Bartholow, Flint, Loomis and Da Costa, and lo! only a paragraph or two is to be found. Now, why is this? Is it because these men have always practiced medicine in large cities, where the morbific cause of this disease is not prevalent? I know not. But I do know that they are almost silent. It is only in the medical journals, then, that we can find any information, and even here what we seek, on some points at least, is meagre, unsatisfactory and ambiguous.

Malaria is said to prevail from 42° north latitude to the Gulf. It would seem that there is a consensus of medical opinion upon one point, to wit: That malaria, whatever that may be, germ or what not, is the etiological factor in the production of the family of diseases to which this one belongs. Probably it would be well to state here that I am fully aware that a number of cases of hæmoglobinuria, some of which are paroxysmal in character, clearly not of malarial origin, are on record. Dr. Harley, of England, in his great work on "Diseases of the Liver," reports, in substance, the following case: The subject, a blacksmith by occupation, of stout, robust build, had never been out of London, never exposed, as far as could be ascertained, to malaria. When first seen by the doctor he had a dark, sallow, careworn complexion, with evidence of hepatic trouble, and was passing paroxysmally, bloody urine, corresponding with his chilly or cold sensation. He was treated with calomel and quinine, and made a good recovery. Among other causes assigned I notice rheumatism and the syphilitic virus.

That rare disease, acute icterous hæmoglobinuria of the newly born, or Winckle's Disease, has many points of resemblance to malarial hæmaturia. Notwithstanding these exceptional cases, I don't think they militate one particle against the fact that malaria is the materies morbi in this and kindred diseases. Observe, too, that Dr. George Harley's case yielded nicely to the calomel and quinine treatment.

It seems that most writers claim this disease to be of recent origin. Can this be true? I think not, and for the following reasons: First, it seems to me that it is the literature of the subject that is modern, and not the disease. This affection is met with almost exclusively in rural and insalubrious districts. Now, it is a well-known fact that medical literature has been but little shaped by the profession of these sections—little now, and far less in the past. Second, if this morbific principle which we call malaria is generated by decaying vegetable matter, under telluric and atmospheric influences, then, I take it, that these influences have been operating from the remotest antiquity. If, as we are taught, these influences are especially active in the production of this miasm in the spring and autumn months, (more especially the latter), then it is reasonable to infer that such disease must have existed from time immemorial. It is truly gratifying to find that clear writer, fine thinker and practical physician, Dr. R. H. Day, of Baton Rouge, La., agreeing with me in the history of this disease. I know of no higher authority in this class of diseases. He has this to say: "In 1837 up to 1843, I encountered this disease every year in the bottomlands of the Wabash and White rivers in the States of Ilinois and Indiana, and from 1843 to 1846 in the White River bottom, in the State of Arkansas, and that the oldest citizens of those places at that time recognized this disease and spoke of it as their ancient and common enemy."

Its causation, or etiology, has been sufficiently given, in a general way, whilst discussing its history. It is clearly to me an hepato-renal malady, and that malarial toxæmia of considerable duration is the primary causative factor. How this subtle poison of malaria acts upon the economy bringing about this destruction of the blood we cannot learn positively, but that such destructive changes are wrought is too true, culminating at last in this form of the pernicious malarial fevers. The great Dr. Harley, in commenting on this disease, gives us this

* Read before the Lowndes Co. (Miss.) Medical Society, October 6th, 1891.

physiological and pathological speculation, which, to my mind, foreshadows a theory that gives us a rational explanation of the disorganization of the blood globules. Here is what he says: "I was particularly struck with the resemblance this urine bore to the urine I have occasionally seen dogs pass after I had injected either bile or bile acids in toxic doses under the skin of their backs. Their urine not only occasionally presented the same color, but contained lots of granular tube casts, and still further resembled this human urine in being coagulable by heat and nitric acid. All this leads me to the conclusion that the condition of the urine in cases of paroxysmal hepatic albuminuria is in great part due to the disorder of the biliary secretion brought about by the direct result of malaria acting upon the liver." Again, he says: "As bile acids have a powerful disintegrating effect on the cell-walls of the red blood-corpuscles, it has once or twice crossed my mind that this peculiar condition of the urine in paroxysmal hepatic hæmaturia may possibly be due to the abnormal quantity of bile acids in the circulation." Now, then, if it is true that the bile, in abnormal quantity in the blood is destructive, in a powerful degree, to the entirety of the red blood-globules, and if this bile and its acids are in abnormal abundance prior to and during the course of this disease, it is nothing but rational to accept this theory as explanatory of the dark, bloody urine, which alone is pathognomonic of this disease. Certain it is, in this disease, that the blood is surcharged with bile, and every tissue of every organ in the body is soddened with the same. And if this theory is not borne out by the clinical history of the disease, then our treatment, in part at least, can be naught but irrational and unscientific; for I have my first physician yet to see, or writer yet to find, who does not recommend a prompt and decided attack upon that gland by which the offending substance is both elaborated and excreted. Therefore, I accept the theory that the functions of the liver are the first to be involved by the poison of malaria. Does the pathological aspect of the disease sustain this theory? Seemingly, yes. The liver is first congested and enlarged, with cessation, more or less complete, of its functions of bile formation and elimination. Consequently, the bile and its acids come in contact with and act upon the walls of the red blood corpuscles, causing them to break down. Intense jaundice soon follows. The nervous system is profoundly affected by the bile and its acids and other poisonous products of blood disintegration, since the functions of that great depurative organ are nil or nearly so. These poisons are hourly, yea, momentarily in transit through the kidneys, causing intense congestion and grave lesions in these important organs, culminating in their break down and the attending outflow of black, bloody urine. According to Dr. Joseph Jones, of New Orleans, "the colored blood corpuscles are more uniformly and rapidly destroyed in severe cases of malarial fever than in any other disease, with the exception perhaps of pyæmia. Authors state that the more severe and malignant the case, the fewer intact red blood-globules are found in the urine. This is confirmed by the analyses of urines made by those two eminent microscopists, Drs. Sternberg, of the U. S. Army, and Tyson, of Philadelphia. This statement of clinical facts, and analyses, strengthens the hepato-renal theory of the disease.

What of the diagnosis? The physiognomy of this disease is so striking that I will only touch upon its diagnosis by differentiating it from two or three other diseases. It would be well to state here, however, that there are two types of this malady. One, assuming the form of continued or bilious remittent fever; the other, markedly intermittent in its nature. Bilious remittent fever is stated to have a sort of family resemblance to this for graver affection. Jaundice, slight in the former, and develops slowly; intense in the latter, and sudden in its onset. Nausea and vomiting, a distressing symptom of the latter; not always present in the former, and when present not nearly so distressing. The nerve centres are not as profoundly affected in the former as in the latter. The urine may be high colored in the former; in the latter, it is always very dark, sometimes black. The urine of the former, while it is high colored and scanty from the fever, yet these features come on rather gradually, and there is no suppression; in the latter, the urine is black or dark from the start, loaded with the debris of disorganized blood-discs, and with a tendency always to suppression.

Yellow fever has many symptoms in common with malarial hæmaturia. In fact, some members of the profession regard the two as different types of the same disease. I was told only a year or two since by a physician (and he was far above the average medical man in intellectual power and medical training), that he regarded yellow fever and malarial hæmaturia as one and the same disease. As he expressed it, it was simply

the yellow fever of the interior. He was a man, too, with much experience in this disease. Authors tell us that yellow fever is an acute infectious disease, occurring only south of 48° north latitude, in regions having a mean annual temperature of not less than 70° Fahr. When the germs of yellow fever are imported into a region of country, if the telluric atmospheric and sanitary conditions are suitable, it at once becomes contagious. This far from the case with the malarial disease. The former is confined mainly to the sea coast, and the denser the population the more intense and virulent the poison; the latter is found in the interior, where the land is low and marshy, and is but seldom if ever seen in populous cities. Both of these affections are ushered in by a chill. The icteroid hue of the skin is not as sudden in its onset in yellow fever as it is in the malarial affection. The dark, bloody urine of yellow fever is a rather late symptom; in malarial hæmaturia it comes on with the chill. Black vomit is characteristic of yellow fever; not very often met with in the malarial trouble. Slight cold, such as frosty mornings soon puts a stop to the ravages of yellow fever—I treated a case of hæmorrhagic malarial fever in the month of February, while the ground was covered with snow. The former attacks the robust as well as the weak; the victims of the latter are those whose systems are undermined and enfeebled by chronic malarial poisoning. It seems to me that acute malarial jaundice comes nearer wearing the habiliments of malarial hæmaturia than any other disease. And, in truth, they are closely allied, springing from the same parent stock, malaria. In both you meet the deep yellow skin and conjunctivæ. In both you meet that intense nausea and vomiting and loathing of food. Fever in both, not so high, however, in the jaundice. Enlarged and congested liver and spleen, with tenderness, and constipation and clay colored stools in both. Dark and bloody urine in the one; and dark (though not so dark) and bile stained urine in the other. This aggregation of symptoms corresponds closely to the cases of acute malarial jaundice coming under my observation. In fact, I have endeavored to portray the malady as met with in my own person. I have often thought how close I was at that time to malarial hæmaturia; for, in my mind, there is but a step from the jaundiced to the hæmaturic variety of this toxæmia. I have often thought that the difference consisted in something like this: The liver though much disordered still eliminates a sufficiency of its biliary products to prevent immediate destruction of the red blood-discs, thereby saving the kidneys from sudden shock, congestion and the overloading of their vessels and excretory ducts with these effete and poisonous products of blood disintegration, allowing them time to take upon themselves the vicarous action of excreting bile, by which they, in their turn, rescue the liver from a total suppression of its functions. In other words, the pathological steps in the two diseases are nearly the same, with the difference that the one moves with the gathered force of the destructive cyclone, while the other moves with only that of the severe gale.

Before coming to the prognosis and treatment I would like briefly to mention two peculiarities of this affection: First, writers and observers of most experience tell us that this disease is never met with in the person of the negro. Why this racial immunity I wot not, nor do these writers, as far as I have seen, venture to tell us. It is an undisputed fact that the African race is not so prone to poludal affections generally as white men, and when encountered in this people they are more benign and tractable to treatment. There is a scope of country, of considerable area, east of us, where no white man dare attempt to live; yet here the negro, the owl, the tadpole and the mosquito "flourish like the green bay tree." As the original habitat of the negro is the jungles of tropical Africa, I take it that an All Wise Creator has given him an organism that is equal to the task of withstanding the ravages of swamp miasm. However, this might more properly be called a peculiarity of this race, and not one of the disease. In the second place, how often it is that we see a man residing in a malarious section escaping the poison, or, if not escaping, having it in some of its mild or masked forms. Now let him leave for healthier climes, and he is soon stricken with this or one of the other malignant forms of this many sided disease. I have in my mind's eye now two instances of this kind that went from my own neighborhood. One of these was a youth who had had no malarial outbreak for probably a year prior to his departure for a region where malarial troubles were certainly not of common occurrence. While he had had no active manifestation of malarial poisoning, yet the unmistakable cachexia was but too plain. The other, a young man of good constitution, had suffered from one or two spells of a mild form of intermittent fever, tertian in type, just

previous to his departure for the Gulf Coast of Mississippi, where such a thing as malarial hæmaturia is unknown. Such occurrences as these are common and striking. These two cases were of the most malignant type, and death was the immediate result. How is it that these organisms of ours can hold up and succeed in throwing off the poison, though exposed to its insidious invasion each moment of our existence, and, yet, when we reach a section where malaria is not a disease producing factor, an outburst of this fearful disease is upon us? Probably it may be explained by the total change of environment, body habit, and all influences tending to depress mentally. This change may produce a lowering of the vital forces, and a depression of the functions of the organs of secretion and excretion. This lowered state may be but transitory, yet sufficiently long for the poison that is stored up in the body to gain the mastery over that equipoise of our physiological state, known as health. This view, at least, furnishes me with a rational explanation of the cause in the two cases coming under my immediate observation. While at home they had both led active lives, passing a large part of the time in the open air. After their change of residence the reverse of this was true,—one of them entering the schoolroom, and the other, a mercantile establishment.

The prognosis in this disease is, indeed, grave. The death-rate, according to different writers, ranges from twenty to as high as sixty per cent. Candor compels me to admit that the mortality in my own cases, only six in number, amounted to fifty per cent. It is some consolation to me, however, to know that my cases were of the most malignant type of the disease, with the exception of one case, and, strange as it may seem, this one is on the debit side of my experience. This case impressed me from the start as mild, if any of them are ever mild. The subject was a female, about sixty years of age. She had suffered for years from that form of malarial poisoning known to the laity as sun-pain or brow ague, and to the profession as supra-orbital neuralgia. For about a week before the hæmorrhagic spell she had suffered—something very unusual for her—with a mild form of intermittent fever. Had taken a purgative, but had taken no quinine to arrest the chills, except one or possibly two doses the day I was sent for. She had just gotten up from the dinner table, where she had eaten a large quantity of boiled cabbage, when the hæmorrhagic chill came on. Reaction had set in when I reached her, but the fever was not very high. The icteroid hue was just beginning to diffuse itself over the body, but it was not at any time, except twenty-four or thirty-six hours before her death, intense. There was nausea, but no vomiting, for the first twenty-four hours, and after that only an occasional spell of vomiting. The urine could not be called black, but it had a dark smoky appearance, and was a little more than normal in quantity at first, after which it very gradually lessened each day. The pyrexia and apyrexia were as well marked in this case as they are in any ordinary intermittent. The urine would begin to darken in color with the beginning of the pyrexia, and would continue so for six or eight hours, then, simultaneous with the apyrexia, it would begin to clear up, and in the course of six or eight hours more would be almost normal in color. Regularly each day at about twelve o'clock this exacerbation of fever and darkening of the urine would begin, and for six days, the woman dying on the morning of the seventh day—this was the picture. I think I had a right, with this group of symptoms, to regard this case as mild. One other of my fatal cases was a relapse, suppression of urine beginning shortly after the initial chill of the relapse. This patient, a woman of forty or forty-five years of age, had so far recovered from the first seizure that she could walk about her yard.

Now, as to the treatment. If you have followed me in my notion of the pathology of this disease, you know pretty well before hand, about the line of treatment adopted. I will recite the treatment pursued in the above mentioned mild case, as it was and is my general plan of treatment, varied, of course, to meet special symptoms as they may arise: I used a large blister, reaching from the liver and extending across the stomach to the spleen. Gave five grs. of calomel, with two or three grs. of bicarbonate of soda, every two hours until fifteen grs. of calomel had been given. Two hours after giving the last dose of calomel and soda I gave a large enema of warm water. Bowels acted well, large and greenish stools. Began quinine just as soon as bowels began to move, five grs. every two hours, and succeeded in getting thirty grs. in her before the twelve o'clock pyrexia. I gradually increased the quinine each day, until the fourth day she was getting as much as fifty grs. Notwithstanding this heavy dosing of quinine the

pyrexia and darkening of the urine would come on at the usual hour, or a little before. I used fomentations over the region of the kidneys, lightly sprinkled with turpentine and heavily sprinkled with tr. of digitalis, and gave the latter drug in five drop doses every three or four hours. I did not resort to quinine hypodermically in this case, because the stomach bore it very well. I know that the practice of giving morphine, and even quinine for that matter, is a mooted question in this disease. But, right here, let me say, that my patients who got no morphine have gone from hence, and those to whom it was administered are with us still. Mark me, I claim no curative power for this drug, in this disease; but I do claim that an hypodermic of one-eighth or one-sixth gr. of morphine is the most effectual treatment at our command for allaying nausea and vomiting, and for quieting that intense nervousness always met with in this disease. I further know that after using quinine for four days in the case just outlined, I then began some other plan of treatment (I do not remember the exact treatment now, though muriate tr. of iron and chlorate of potash were two of the medicines freely used), and at once my patient began to grow worse. Every time I think of that case I can but regret that I quit the quinine instead of pushing it still further; for, while it did not arrest the disease, it was evidently holding it in abeyance. This will be my general plan of treatment in the future as it has been in the past. Not that I can claim any brilliant results for it in my hands, but certainly it is rational, and others report results equal to any other plan of treatment and probably better.

UTERINE TREATMENT DURING GESTATION. *

BY J. E. GILCREEST, M. D.,

GAINESVILLE, TEXAS.

I shall notice *first*, the class of cases that we are called upon to treat, which need little or no treatment; and, *second*, the class that is needing treatment for various pathological conditions; then, I will report a few cases illustrative of each class.

I am aware that physicians differ widely on this very important subject. Some authorities say that all treatment is useless, and often hurtful; while others advocate all kinds of treatment, even for lacerated cervix, removal of ovarian tumors, fibromas and various other operations. I think much conservatism should be used in the treatment of diseases during pregnancy.

Turning now to the first class mentioned, namely, those that need little or no treatment, we find ourselves often consulted in regard to amenorrhœa, or as the patients often express it: "I have taken cold, and am suffering a great deal with my womb, and want you to do something for me to bring me all right. I know that is all the trouble." And when we suggest that the cause of the menses stopping is very likely a physiological one, they will protest and say they do not believe it possible, and insist upon something being done for them.

Of course, they are often sincere in their declarations. Some are so opposed to bearing a child, that when they think there is any chance of conception having taken place, they become almost desperate, and if they think they can get rid of it by deceiving us they will do so. Whenever we are called or consulted by a married lady who has missed her regular menstual period for one or two weeks, we should always be suspicious, and if we think there is the slightest probability of conception, then we should be very guarded in our examination, and should avoid the use of probes, sounds, and all rough manipulations.

If the patient is suffering and any treatment is indicated, give it, but cautiously. Many such cases will not want any treatment after they find you will not bring on their menses.

Case I.—I was called in May, 1886, to see Mrs. E., aged 30 years, mother of one child, four years old. She had been irregular for the past three years, suffering from backache, leucorrhœa, etc. They desired an examination, and something done. On examination I found the uterus slightly swollen, and I thought anteflexed; they told me it had been about five weeks since her menses, but assured me that was nothing unusual, as she had often gone five and six weeks.

My experience at that time had been limited almost entirely to what I had seen and examined in the Hospitals. I wanted to make a very thorough and scientific examination. Going through the different methods as laid down by Thomas for examinations for displacements, I came to the use of the sound. I then determined to see by the use of the sound to what degree the uterus was

* Read before a recent meeting of the North Texas Medical Association.

anteflexed, so I gave the sound what I thought the necessary curve and passed it. It indicated slight anteflexion; but was that all? No, I made my application and went home, but was soon called back in haste by a message that she was "flooding to death." I hurried back feeling that I had committed an unpardonable blunder, and that if my patient died I would be ruined.

I suppose she had an abortion, although I never saw any secundines or embryo. I called in an older physician, and we had much trouble in controlling the hæmorrhage. Her condition was alarming several times. I have always been very careful about passing the sound since then. This was entirely accidental on the patient's part, as well as my own. She had not intended to deceive us, nevertheless she did. I could enumerate a number of cases since that time that applied for treatment after conception had taken place, and by assuring them that it would be best to wait awhile, they would not return, but go on to full term. As I have said, I think this class of cases had better be left to nature as much as possible. We will now consider some of the conditions that do demand treatment, and I will cite a few illustrative cases.

One of the principal things calling for treatment in early pregnancy is the different displacements—and the retro-displacements stand first in importance, as they are the most common. All displacements bring about many and severe symptoms during gestation, such as vesical and rectal tenesmus, obstinate constipation, retention or incontinence of urine, often painful in various degrees; but the most frequent symptoms we are called upon to treat are nausea and vomiting. We should always look to the uterus as the cause, and endeavor to correct any pathological condition we find, as far as possible, no matter of what nature. Displacements, ulcerations, erosion, or specific diseases. Specific diseases require specific treatment. We should resort to local applications, such as are best suited to each case, with mercurial inunctions; paying attention to diet, hygienic surroundings, etc.

I will bring out the treatment I have adopted in the following cases, which have all come under my observation in the last three years.

Case II.—I was called to see Mrs. L., mother of two children. She had had no unusual trouble in her first pregnancy. She was then about the third month, had been suffering quite severely for the past month, and had been confined to her bed two weeks, and during that time had not retained anything on her stomach but a few minutes; she had not slept for a week except a few minutes when under hypodermics of morphine. She had been attended by a physicin before I was called, who had given her nearly everything in the catalogue of remedies, all of which had failed to do any good whatever, except the hypodermics which would produce a little ease. When I first saw her, she was almost in a state of collapse, pulse 140, skin clammy, trying to vomit every few minutes and begging for relief.

On vaginal examination, I found the impregnated uterus retroverted and incarcerated. The os under the pubes large and patulous to the touch. I had her take the knee-chest position and made several attempts before reducing the displacement, and finally succeeded with two fingers in the rectum. After dislodging the os and bringing it down, I introduced Sim's speculum to see the condition of the os—it was much swollen and eroded, and would bleed from the slightest touch. I made an application of argentum nitras gr. xl to ℥j, dusted the os with iodoform and used a dry tampon of wool, filling the vagina quite full. She was suffering from retention of urine, which was first relieved by soft catheter.

She rested much better for the next thirty-six hours, vomited but a few times, and would sleep two or three hours at a time. The nausea then commenced to increase, the tampon was removed and a thorough application of the argentum nitras applied, dusted the os with iodoform and tampon re-applied. She complained of a metallic taste in her mouth in a few minutes after the application. The relief was more marked. She gained strength and felt much better. The applications were kept up every second or third day for four weeks. The nausea would begin to return if the applications were left off too long. As the os became healthy she could do longer without the local treatment, till it was finally left off altogether. After the fourth month she went on to full term without any bad symptoms, and gave birth to a boy and girl, both healthy, well developed babies.

Case III.—I was called to see Mrs. B., primipara, in consultation. She had been vomiting every hour or two and suffering with continued nausea for about two weeks. She was supposed to be about in the ninth week of pregnancy; she looked thin, with eyes sunken. I was informed that she had

not slept over one hour at a time (and that was from large hypodermic doses of chloral) and that every ordinary remedy had been used without relief. She first refused to undergo any uterine examination; but the next morning she consented to have anything done that offered a hope of relief.

On examination we found the uterus prolapsed slightly, os swollen and very much eroded. We made an application of argentum nitras, and applied a wool tampon to elevate the uterus. The first application relieved her, so that she got several hours sleep without the aid of an anodyne. Her attending physician kept up these applications for two weeks, and she improved rapidly and went to full term without further trouble.

Case IV.—I was called sixteen miles from town to see Mrs. H., who was three months advanced in pregnancy. She had been suffering with severe nausea for four weeks, had not been able to retain anything on her stomach for the past ten days without suffering distressing nausea, till finally she would vomit and be partially relieved, but it would soon return and prevent her from resting or sleeping. I had been prescribing for two weeks before I saw her, and had given her nearly all the usual remedies at different times without any permanent effect. I gave her at once a hypodermic, as she was suffering very much. I made an examination and and found the os swollen, red and puffy, and the cervix very much granulated.

I thought as I could not see her again very well, I would make a thorough application, so I applied equal parts of tincture iodine and carbolic acid well up in the cervix and around it, used the wool tampon with iodoform, directed it to be worn two days, and then to use a wash of biborate of soda ʒij and tannic acid ʒss to a pint of hot water. She rested quite well that day and was better from that time on, although she suffered some for the next six weeks. I believe had I repeated the application every three or four days for awhile, she would have suffered but little more.

Case V.—I was consulted about Mrs. W., mother of five children, she had not menstruated for nearly nine weeks, but had been irregular for the past four years; youngest child five years old. She was suffering from continual nausea and vomiting. She and her husband were in doubt about her condition, as she had been suffering a great deal with her stomach the past four years, and had always suffered during her previous pregnancies. I prescribed for her over a week without any benefit. I then examined the uterus and found it considerably prolapsed, the os badly excoriated, looking very much like coxcomb ulcers. The cervix would admit the end of the finger, and this ulcerated condition extended up the cervical canal for three-fourths of an inch, and cleansing with cotton would cause blood to ooze freely from the parts. I commenced the treatment by using applications of pure carbolic acid, touching the diseased surface lightly, then dusting with a powder composed of three parts of iodoform, two of bismuth, and one of tannic acid, and placing a large tampon of wool under it to relieve the prolapsus.

There was a perceptible change after the first application, which was repeated every third day. Her stomach began to retain food and she would rest several hours with comfort. She would remove the wool the second night and use a wash night and morning. We soon noticed she would feel much worse on the third day, while going without support, so I made the application every second day for awhile, which made her much more comfortable. There was no change in the breasts or color of the vaginal surface to indicate pregnancy. The uterus was enlarged sufficient for the eighth week, so I went on with the treatment, in doubt, for three weeks. Then, by a careful comparison with the size now and when treatment was begun, I felt safe in telling her that she was pregnant. Treatment was continued for five weeks altogether. I made the application from three to four days apart toward the last. The excoriations of the os yielded nicely, and it looked quite smooth and well at the end of the five weeks. The applications, were, after the third, made with two parts tincture iodine to one of carbolic acid one time, and the next time with nitrate silver gr. xl to ʒj. She complained several times of a metallic taste in her mouth after the silver applications. She is now in her eighth month of pregnancy and has felt much better after the fourth month than she ever did in any previous pregnancy. Before, she had vomited every day, all the term; but now, has not been troubled with nausea for three months.

Antidote to Morphine.—The fatal effects of morphine may be counteracted, according to Kossa, by the joint administration of picrotoxin and paraldehyde in small doses. The paralyzing effect of picrotoxin on the respiratory muscles is obviated by the paraldehyde.

NECROSIS OF THE FEMUR, OF 29 YEARS DURATION.

(Service of De Forest Willard, M. D.)

BY HOWARD S. ANDERS, M. D.,

LATE RESIDENT PHYSICIAN, PRESBYTERIAN HOSPITAL, PHILADELPHIA.

The following case is of interest chiefly as an illustration of the wonderful reparative powers of nature, as seen in the long struggle of 29 years in an attempt to rid herself of dead material. It shows, moreover, how necessary is the surgeon's skill to assist in the removal of large masses of bone, which nature can extrude only by the tedious process of liquefaction.

W. S. H., aged 45, white, single, without vocation, able to walk with a cane—not easily, however—was admitted into the men's surgical ward. The following history was elicited: In 1862, without known injury or prior disease, the patient first noticed a small swelling, purplish in tint and very painful, on the outer middle aspect of the left thigh. Extensive osteitis resulted, with burrowing of pus in all directions, so that small discharging sinuses opened in "twenty-five or thirty" places on the leg, above and below the knee. He was prostrated in bed for one year, in consequence. At various times pus was liberated from the thigh by frequent incisions. In 1863, the left knee became painful, red and swollen; the pain growing worse at night. Contraction of the "ham-string" tendons followed, and impeded motion in the joint progressively increased until admission into the Presbyterian Hospital, when only very slight flexion and extension was possible.

Upon examination, there were observed old linear cicatrices about the middle of both the inner and outer aspects of the diseased thigh; several discharging sinuses on the inner, and one on the outer side, in the scar-lines. The probe gave undoubted signs of loose sequestra in the lower portion of the femur. Although the man was rather thin and somewhat pale and weak, his general health was—in spite of the inveteracy of his necrosis—quite fair; his physical characteristics were those of the motive temperament.

Three days after patient's admission, Dr. Willard performed sequestrotomy. The incision was about four inches long, a little external to the line of the femoral vessels, in the lower third of the thigh. A cloaca was enlarged, with a chisel, sufficiently to admit the blades of a Liston's forceps, and a very large sequestrum discovered. The thick, dense involucrum was partially chiselled away, and six inches of the condyles and lower portions of the shaft were found entirely dead,—and were removed; the sequestrum consisted of the entire lower portion of the bone. The bone cavity and the sinuses were curetted, douched and packed with aristolized gauze; a large calibered drainage-tube was inserted from within to an external counter-opening. The knee-joint was not involved by the necrotic process.

The patient rallied well from the immediate effects of the operation; but, about six hours afterward, inspection of the dressings showed that considerable bloody oozing had saturated them. Recurrent hæmorrhage having been suspected, the resident removed the dressings and applied fresh antiseptic gauze with close packing and firm pressure. No pain was complained of; but the pulse was very weak, small and rapid. Faintness, pallor and nausea lasted for awhile, but passed off under active stimulation and the frequent administration of nourishment.

Drainage was effectual; and the wound did well and was kept packed and made to close by granulation. Convalescence was entirely satisfactory.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

SEVENTEENTH ANNUAL MEETING, HELD IN ST. LOUIS, MISSOURI, OCTOBER 14TH, 15TH, AND 16TH, 1891.

FIRST DAY—MORNING SESSION.

The Association convened in the Pickwick Theatre, and was called to order at 10:30 A. M., by Dr. I. N. Love, Chairman of the Committee of Arrangements.

Prayer was offered by Bishop D. S. Tuttle.

The Address of Welcome was delivered by Hon. E. A. Noonan, Mayor of St. Louis, which was followed by addresses on the part of the State Medical Association, by Dr. W. B. Outten; the St. Louis Medical Society, by Dr. Ludwig Bremer, its President, and remarks by Drs. Harold N. Moyer and J. C. Culbertson, of Chicago.

After the report of the Chairman of the

Committee of Arrangements, which was an interesting and attractive one, Dr. C. H. Hughes, of St. Louis, took the chair and declared the Association ready for the transaction of its scientific work.

The first paper read was by Dr. W. Carroll Chapman, of Louisville, on "The Toxic Effect of Tobacco Vapor, With Report of Cases." (This paper was published in the REPORTER of October 24th, p. 653.)

FIRST DAY—AFTERNOON SESSION.

"The Treatment of Typhoid Fever." This was the title of a paper read by Dr. Robert C. Kenner, of Louisville, Ky., in which he directed particular attention to the cold bath treatment.

Dr. William Warren Potter, of Buffalo, followed with a paper entitled "Pelvic Inflammation in Women; a Pathological Study." The author affirmed that pelvic inflammations and their residues constitute about one-third of the diseases that gynæcologists treated, hence the importance of frequent discussions of all mooted questions relating to the subject. He briefly reviewed the anatomical relations of the pelvic organs, calling attention to their enormous blood and nerve supply, which became both their weakness and their strength. He contrasted the pathology of Bennet (1843) with that of Emmet (1873), and the latter with the teachings of Price, Tait, Hegar, and McMurtry of the present age. He referred to the pathological studies of Bermutz and Goupil of thirty years ago, and affirmed that the observations of the present had served to confirm the correctness of those pioneers.

He next asserted that the pathology of to-day had been established by operative surgery, which had shown that pelvic inflammation begins in the tubes or ovaries and extends to adjacent structures through absorption or by contiguity; that it almost never begins in the cellular tissue, but may be carried there through the tubes and ovaries by infections, either specific, puerperal, or traumatic. He affirmed that the inflammation was in most cases a peritonitis, intra-pelvic or local in character, and not a cellulitis; that para- and perimetritis were misleading and confusing terms, hence should be dropped; and that the so-called pelvic abscess was a sequence of salpingitis, ovaritis, or peritonitis, not a primitive accumulation in the areolar tissue itself.

The tentative management in these cases —rest, counter-irritation, hot sitz baths, vaginal douches, and attention to the digestive organs and general health—resulted in only temporary improvement, or in cure in a very small percentage. Those reported cured were generally, if the history could be known, subject to repeated relapses; and a frequently recurring pelvic peritonitis usually indicated leaky tubes. Electricity, too, had disappointed even its most sanguine advocate, and need not be considered.

In conclusion he asserted that if the views be accepted the logical deduction was to watch the early manifestations of the disease carefully, that competent surgical skill be invoked before the damage to important structures becomes too great to justify the expectation of successful operation.

Dr. Geo. F. Hulbert, of St. Louis, read a paper on "The Nervous Equation of Pelvic Inflammation."

Dr. L. T. Riesmeyer of the same city, contributed a paper entitled "Pathology and Surgical Treatment of the So-called Strumous Inguinal Lymphadenitis.

SECOND DAY—MORNING SESSION.

The Association was called to order by President Hughes at 10 A. M.

Prayer was offered by Rev. S. J. Niccols, of St. Louis.

Dr. Rufus B. Hall, of Cincinnati, Ohio, read a paper on "Complications During and Following Abdominal Operations."

Dr. Arch Dixon, of Henderson, Kentucky, followed with a paper entitled "Gastrostomy for Impermeable Stricture of the Cardiac End of the Oesophagus; Recovery; Subsequent Dilatation of the Stricture." On July 14th, of the present year, Dr. Thomas W. Taylor consulted him in regard to a patient who was unable to swallow anything save liquid. The patient, Captain S., aged 54, weight previous to difficulty in swallowing, 230 pounds, at the time of examination 156 pounds. Examination by means of œsophageal bougie (smallest size) revealed the fact that complete stenosis of the œsophagus existed at the cardiac end. Repeated trials failed to pass the stricture and the patient was informed that only an operation, the nature of which was explained to him, could prevent his death from starvation. Operation was declined. Again on July 29th, the patient consulted him and after persistent effort he failed to pass the stricture with the smallest bougie. He was requested by the author to go before the Henderson County Medical Society, which held a meeting that afternoon and be examined. To this the patient consented and

again an attempt was made to pass the stricture by a number of physicians present, without success. A statement of the case was made by Dr. Dixon and the unanimous opinion was expressed to the patient that only an operation could save his life. The patient had by this time grown much weaker and was reduced in flesh to 140 pounds. The operation was now consented to and on August 4th, at the Home Mission Sanitarium, assisted by Drs. John Young Brown, W. M. Hanna, W. S. Stone, A. J. Lieber, and T. W. Taylor, Dr. Dixon did a gastrostomy after Hacker's method, as follows:

The patient was prepared in the usual way, the field of operation being made as nearly aseptic as possible. Chloroform was administered by Dr. T. W. Taylor. The incision was made four inches long, beginning one inch below the ensiform cartilage and an inch and a half to the left of the median line; the peritoneum was reached, caught up between forceps and divided the full length of the incision. The index and the middle fingers were inserted, the transverse colon pushed downward and the stomach reached without difficulty; a fold was caught between the fingers and partially drawn through the wound, where it was held by Dr. Brown, while a careful search was made for the cardiac end and to detect, if possible, any tumor or enlargement which might be the cause of the stricture; none could be discovered. A silver pin was now passed through the fold of the stomach, which was drawn through the wound, a little above the level of the skin, care being taken that the pin pierced the mucous membrane, as suggested by Weir, thus forming a support for the stomach in the wound and serving as a guide when the opening should be made into it to show that the cavity was reached. The pin was about three inches long and rested on the skin on either side of the wound; the peritoneal coat of the stomach was now stitched to the peritoneum by a continuous suture which on either side of the wound included the skin. The peritoneum above and below was brought together by interrupted sutures, which embraced muscle, fascia and skin as well.

The wound was now covered with iodoform collodion over which iodoform gauze was placed, confined by adhesive strips. The opening into the stomach was purposely deferred until adhesions should have formed. The patient recovered from the effects of the anæsthetic well. There was some pain of a darting character, which was relieved by hypodermic injection of morphia ¼ gr., and atropia $\frac{1}{150}$. The operation was finished at 11 A. M. At 6 P. M. temperature was 99°; pulse 78. August 5th, temperature 98½°; pulse 72. Temperature and pulse remained normal until the morning of August 7th, when the dressing was removed.

A few drops of cocaine were injected into the fold of the stomach which protruded through the wound and the gastrostomy was completed by cutting down upon the pin with a tenotome. As in Weir's case, the presence of the pin was a valuable guide in showing beyond question that the cavity of the stomach had been entered. There was no hæmorrhage of moment. The adhesions being firm, the pin was withdrawn and the mucous membrane was drawn up and stitched to the skin. A rubber tube was now passed into the stomach through the opening fitting it snugly. Iodoform collodion was liberally used around the tube and over the abdominal wound. Iodoform gauze folded several times, through which a hole was cut for the tube, came next, covered by a piece of rubber sheeting. Borated cotton held in place by adhesive strips completed the dressing. The tube was kept *in situ* by a thread passed through it above and below, and the thread held in place by adhesive strips. Peptonized milk, ½ pint with a teaspoonful of Mosquera's beef-meal was now injected through the tube into the stomach by means of a large syringe. An ordinary spring clothes pin was used as a clamp for the tube. Six hours later another one-half pint of milk with the beef-meal was thrown into the stomach, the patient experiencing a satisfaction which had not been experienced previously from the use of nutritive enemas. Temperature at 8 P. M. reached 101°. At 10 A. M., August 8th, it had again fallen to normal. The feeding was continued at intervals of six hours, the food being varied in character; chopped meat, eggs, bread, etc., the patient having an aversion to brandy, and would take no stimulant of any character. Improvement was steady and in ten days the patient was out of bed. In two weeks he was walking about the house, and in three weeks was down in the city, a distance of one-half mile from the Sanitarium.

On the 28th day of August, twenty-four days after the primary operation, and twenty-one days after the stomach was opened, Dr. Dixon determined to try dilatation, and was agreeably suprised to find that the smallest size, olive-pointed bougie entered the stomach, passing the stricture without difficulty;

a size larger was now used and it passed also without force.

The following day a large stomach tube was passed down the œsophagus and with little difficulty entered the stomach. Dilatation was continued at intervals of a few days. From liquid food the patient soon essayed some solid food, and on September 10th took his first square meal, which consisted of oysters, broiled beefsteak, coffee, eggs and bread. The patient left the Sanitarium, and he was thinking seriously of closing the abdominal opening, or allowing it to close. On September 23rd, the patient, who made daily visits to his office, complained again of difficulty in swallowing solid food; especially was there difficulty in swallowing bread. The bougies passed the stricture easily on entrance, but on withdrawal there was a decided hitch; even the smallest bougie was caught slightly when withdrawn. Dr. Dixon at first attributed this to spasmodic action, but the difficulty grew greater and greater, until finally he could no longer enter the stomach by way of the œsophagus with a bougie. Liquids could still be allowed and found their way into the stomach. He now determined to try retrograde dilatation, and on September 30th, assisted by Dr. John Young Brown, he succeeded in finding the cardiac end of the œsophagus and entering it with a very small *bougie-a-boule.* The opening was about the size of a very small shirt buttonhole and felt much like the meatus urinarius in a girl; it was surrounded by a hard tissue, feeling much like a fibroid. A uterine sound was next properly bent and with the finger as a guide, passed into the œsophagus; this was followed by a uterine dilator; slight pressure on the handles opened the blades almost half an inch, but the patient experienced so much pain that it was deemed best to desist. The following day chloroform was administered and retrograde dilatation was accomplished, first by means of G. Wylie's uterine dilator, the use of which enabled him to enter the orifice with a large size bougie (rectal).

Up to this time he had not been able to determine whether the stricture was due to malignant trouble or not, but on passing the finger into the non-dilated œsophagus, a friable irregular growth was detected, which easily broke down and bled rather freely. A piece of this growth was twisted off by forceps and was sent to Formad, of Philadelphia, for examination. Since the dilatation the patient has been able to swallow solid food without much difficulty and has notably improved in flesh and strength, and is able to attend to some business.

The author wished to acknowledge his indebtedness to Dr. Robert F. Weir, of New York, for many valuable suggestions, both in the performance of the operation and in the management of the case afterward, gleaned from his report of a similar case published in the *Medical Record,* July 25, 1891.

Dr. Dixon also exhibited the patient to the Association.

Dr. L. Ch. Boisliniere, of St. Louis, exhibited a new obstetric forceps of his own design.

SECOND DAY—AFTERNOON SESSION.

Dr. J. W. Carhart, of Lampasas, Texas, contributed a paper on "The Influence of Grave-Yards on Public Health," in which he drew the following conclusions:

1. From whatever standpoint this subject is approached it must be with care and gentleness, since the grave-yard, though a constant menace to public health has a pseudo-sacredness fostered by the profoundest sentiments of our natures.

2. The method of the disposal of the dead should be founded on reason and not on custom or sentiment.

3. The interment of the dead in the earth was never enforced by a statue, Jewish or Christian, and was merely incidental to both dispensations.

4. No law, human or divine, requires us to dispose of the dead in a manner prejudicial to the health and comfort of the living.

5. Whilst it may be an open question as to the right of the state to decide as to the manner of the disposal of the dead, except in exceptional cases, it is clearly the province and duty of the state to prevent such disposal as will in any wise jeopardize the interests of the living.

6. From all the facts at our command, we are led to the conclusion that the grave-yard should become a thing of the past, and that incineration is the method most in accordance with science, sanitation, anæsthetics, reason and religion.

7. We would add, as a corollary to these several conclusions, that since the intelligent, broad-minded physician is the almost exclusive guardian of public health in seeking to prevent the development and spread of disease, it is plainly his duty, when cemeteries are being located, to use his best endeavors to have them so placed as to jeopardize as little as possible the public health; and for its moral effect he should encourage

efforts to beautify existing cemeteries; and that he should seek, as fast as possible, without too much violence to the tender sensibilities of the masses, to encourage incineration of the dead, or some other method more in harmony with sanitary science than the common modes now practiced.

Dr. J. T. Jelks, of Hot Springs, Ark., read a paper on "Blenorrhœa."

Dr. Landon Carter Gray, of New York, followed with a paper on "The Present Aspect of Cerebral Surgery," in which he epitomized the work of Horsley, Ferrier, Keen and others.

Dr. John A. Larrabee, of Louisville, Ky., read a paper entitled: "The Importance of Recognizing a Temporary Rachitic Condition in Infants."

Dr. F. C. Hoyt, of St. Joseph, Missouri, read a paper entitled "Pachymeningitis Hæmorrhagica Interna, with report of a case and Presentation of a Pathological Specimen," and suggested the following deductions, offering them as a practical and rational view of the subject:

1. That the disease known as pachymeningitis hæmorrhagica interna chronica, is not a disease of the dura mater primarily, and not necessarily at all. The name is, therefore, a misnomer, and the simpler term, sub-dural hæmatoma, should be substituted.

2. That the condition is due primarily to paralysis or loss of the normal vaso-motor tonus, associated with structural changes in the cerebral vessels, particularly those of the pia mater.

3. That hæmorrhage may, and often does, take place in the substance of the dura from the causes stated in the paper, but that its vascular supply and anatomical structure render it improbable that these hæmorrhages play any part in the formation of a sub-dural hæmatoma.

4. That the hæmorrhage occurs from the vessels of the pia mater primarily, forces its way without difficulty through the upper web-like layer formerly called the arachnoid, escaping into the sub-dural space. The extravasated blood becomes organized, new vessels are formed, and these assist in furnishing the recurrent hæmorrhages.

5. That the inflammation of the internal surface of the dura mater is secondary and due to the irritation of the extravasation, and then is not general, but occurs only in patches where organic union has taken place.

Dr. Seth S. Bishop, of Chicago, in a paper entitled "Camphor-Menthol in Catarrhal Diseases," reported a large number of cases of naso-pharyngeal catarrh, hay fever and diseases of the ear as having been treated with camphor-menthol with much better results than menthol alone produces. The presence of the camphor appears to intensify the action of menthol.

A number of hay fever sufferers, among them the President of the U. S. Hay Fever Association, have obtained greater relief from this inhalent than from any other they have ever tried. The effect of the camphor-menthol in reducing turgescence and consequent tumefaction of the turbinated bodies has rendered a contemplated operation for stenosis unnecessary in several cases cited.

Injections of a ten per cent. solution of lanolin into constricted Eustachian tubes have caused them to become patulous. The improved ventilation of the middle ear thus effected, together with inflation with a five or ten per cent. spray of the same liquid in hypertrophic tympanic catarrh increased the hearing and produced a sense of clearness and comfort in the head.

Cases of laryngitis with the voices reduced to a whisper were treated with inhalations varying from five to twenty per cent. in strength with the result of restoring the voices completely in from twenty-four to forty-eight hours.

No ill results have followed the use of this remedy in the nose, throat, larynx or middle ear. The ordinary strength of inhalations recommended by Dr. Bishop was three or five per cent. for very susceptible or sensitive individuals like hay fever patients, and ten per cent. for less nervous persons with hypertrophic catarrh, etc. In order to reduce great swelling of the turbinates and relieve stenosis, the solution should consist of twenty or twenty-five per cent. of the camphor-menthol.. The full strength of camphor-menthol applied to eczematous eruptions relieved the itching and dissipated the redness and swelling. Similar results followed its application to herpetic eruptions.

Finally, camphor-menthol contracts the capillary blood vessels of the mucous membrane, reduces swelling, relieves pain and fulness of the head, or stenosis, arrests sneezing, checks excessive discharges and corrects perverted secretions.

Dr. F. King, of New York, read a paper in which he advocated the poro-plastic felt jacket in the treatment of spinal troubles.

SECOND DAY—EVENING SESSION.

The Association was called to order at 8 P. M., by the Second Vice President, Dr. S. S. Thorn, of Toledo, Ohio, after which Pres-

ident Hughes delivered his address on "Medical Progress."

He reviewed the history and progress of medicine and surgery. He said it was gratifying to the humanitarian student of scientific medicine to note the amazing progress lately made in the knowledge of the human organism and in resources for its regulated control in health and disease. He referred to the wondrous laparotomies of Tait; the brilliant craniotomies of Victor Horsley; and the abdominal sections of Senn.

He also said the memory of Harvey, Jenner, Jackson, McDowell, and a host of others, is not yet fully appreciated by the world at large. But their deeds will shine brighter and brighter as the world comes to know them and fully realize as we do their incomparable benefactions, their unsurpassed greatness, and their unequalled heroism.

Dr. J. B. Hamilton, of Chicago, followed with an address on "The Drainage of Chicago," in which he principally dwelt upon its topography.

Dr. Joseph M. Mathews, of Louisville, delivered a timely, entertaining and remarkably humorous address on the "Lights and Shadows of a Doctor's Life." The address was punctuated throughout with great applause, and was a relief to the laity after listening to the profound, scientific, scholarly addresses of the preceding speakers.

At the close of the session the members repaired to the Lindell Hotel, where a banquet was given with all the manifestations of true St. Louis hospitality. Dr. I. N. Love acted as Toastmaster.

THIRD DAY—MORNING SESSION.

Mr. Charles Truax, of Chicago, read a paper (by invitation) entitled "Are Conservative Amputations always in the Interest of the Patient?" He said that during the past quarter of a century the development of prosthetical science has advanced with a rapidity unprecedented in the history of the art. The first of the two great causes which stimulated this development may be found in the dreadful carnage and mutilation observed in the late civil war, which left thousands of veterans maimed by the loss of one or more limbs, for whom it was necessary to provide artificial substitutes. Experience and investigation had convinced him that the percentage of favorable cases can be largely increased, provided surgeons will familiarize themselves with the necessary mechanism of ordinary artificial legs and the relations existing between them and the stumps on which they are to be worn and select their point of amputation accordingly.

From a statistical point of view he finds that out of 2,135 tibial amputations reported to him as being performed between the years 1885 and 1891, 90.7 per cent. resulted in healthy stumps; 3.1 per cent. of stumps upon which compensative appliances could not be worn. Of these tibial cases, 962 were seen by the surgeons after they were wearing, or had attempted to wear, an artificial limb, 86.9 per cent. of which walked with an easy movement and a comparatively graceful step. Of 658 tarsal and tibic-tarsal amputations reported at the same time, 62.7 per cent. resulted in sound, healthy stumps; 8.3 per cent. underwent re-amputation; while 3.2 per cent. died, leaving 14 per cent, including re-amputation upon which prosthetical apparatus could be worn. Of this class of cases, 169 seen after attempting the use of compensative appliances, 54.4 per cent. of which could walk well.

If we can judge from the foregoing statistics, in over 100 cases of each of these classes of operations, we may reasonably expect the death loss to be in favor of tarsal operations as 30 to 3.2 per cent.; while the ratio of re-amputations necessary will be in favor of tibial amputations, as 8.3 is to 3.1.

He recommended surgeons to avoid amputating within three inches of the knee-joint. Do not amputate between the metatarsal bones and the junction of the lower and middle thirds of the tibia. At all other points they should save all they could, and then they will have done, in every case, the best for their patients.

"Intestinal Obstruction."—This was the title of a paper read by Dr. Henry H. Mudd, of St. Louis, in which he advised early operation.

Dr. C. H. Dalton, of St. Louis, read a paper entitled "Temperature no Guide in Peritonitis." So skeptical had he become on the subject that in considering the advisability of an operation in abdominal cases, he was no longer guided by the thermometer. He takes the temperature in all cases, but does not let the lack of fever influence him against operation, when other symptoms, upon which he had learned to place far more reliance, would move him in the opposite direction. Surgeons found it difficult to convince the average physician that a violent peritonitis may exist without a normal or even subnormal temperature, for the teaching by some has heretofore been that sepsis is always accompanied by an elevated temperature.

Several weeks since he was called in con-

sultation in a case of intestinal obstruction in which peritonitis was in full blast. He advised operation and was met with the objection that there could not be much peritonitis with a temperature of 99.50. He pointed in vain to the patient's anxious countenance, to the great tenderness on pressure, a distended belly, the vomiting, the pulse, as well as to the fact that purgatives had been tried without avail. The doctor in attendance insisted upon one more dose of salts. It was given, it did not move the bowels, but it did move the patient to that place from whence no traveler returns. Time and again he had seen cases of intestinal obstruction with stercoraceous vomiting, rapid pulse, anxious countenance (facies abdominalis), in which the temperature was about normal or even subnormal.

In his earlier experience the lack of fever in abdominal cases puzzled him very much and led him astray in a number of instances. While it is well to remember that fever when present in belly cases indicates peritonitis, its absence does not warrant us in saying that peritonitis is not present, and should not blind us as to the actual condition.

"Sarcoma of the Dorso-Scapular Region." —Dr. Geo. N. Lowe, of Randall, Kansas, read a paper on this subject. He reported a case upon which he had operated, the patient, a man, aged 18 years, with no history of tuberculosis, carcinoma or sarcoma, recovering. The object of the paper was to show:

1. The necessity of an early operation in all cases of a malignant growth.

2. That some species of sarcoma are more rapid and destructive in their course than carcinoma, especially the spindle and giant-celled variety.

3. The necessity of having a law to enforce patients so afflicted, as soon as a correct diagnosis can be made, to an early operation, thereby preventing great suffering and prolonging life.

4. That in a sarcoma which has grown to an emormous extent, infiltrating the surround ing tissues at any considerable extent from the main growth with cell proliferation, an operation is almost useless as regards a permanent cure.

Dr. W. H. Linke, of Petersburg, Indiana, read a paper on "Appendicitis," and offered the following conclusions: In the commencement of the attack, give salines often and liberally till the gut is completely emptied. Advise perfect rest in bed. Forbid any but liquid nourishment. If pain is severe apply counter-irritation and dry heat till salines act. If patient improves, wait. If pulse grows worse, if temperature rises, if pain increases, if tumefaction becomes larger, if tenderness becomes more marked, operate. At no time, give morphine, but consider an increase of pain sufficient to demand relief by opium an imperative, unequivocal and emphatic indication for surgical interference.

"Rheumatism and Gout as Factors in the Causation of Eczema, and the Management of Those Conditions," was the title of a paper contributed by Dr. A. H. Ohmann-Dumesnil, of St. Louis. He did not purpose speaking of the etiology of eczema. The only phase which he desired to take under consideration was, in how far rheumatism and gout were concerned in the causation and prolongation of eczema, and what was the proper management of those conditions in order to derive the greatest benefit, so far as the cutaneous involvement is concerned. Naturally this implied that he was about to sustain the position that the conditions named were etiological factors, and such was probably the case. If we took the trouble to examine critically the history, condition, treatment and results in patients, a mass of evidence would be found, which, if it did not constitute absolute proof, bore so much weight with it that the probabilities would all tend to confirm and strengthen the position that rheumatism and gout prolong, intensify, and even cause eczema. He had found it to be quite frequent also to note the fact that an acid condition was present in eczematous patients. It occurred too frequently to be regarded as a coincidence. Moreover, a correction of this acid condition finds its good effects reflected in the ease with which the cutaneous trouble gave way to proper medication. Whether such cases were inclined to rheumatism or gout it was difficult to say; but that an excess of acid was found in all of these conditions there was no opportunity of denying. For, if eczematous patients were interrogated in this respect a large proportion of them would speak of acid eructations, pyrosis, and other evidences of the condition.

In regard to the management of gout and rheumatism, volumes had been written and equally good results had been claimed for different methods of treatment. The most powerful alkali to effect the solubility of uric acid was, beyond all doubt, lithia. The urates of the alkali are the most soluble known, and, on that account, a better elimination can be secured. Potash salts rank

next in value in regard to their solvent value upon uric acid. The soda salts, while exercising a good influence, are not as valuable in this respect as either of the others; and the magnesia salts are the least effective.

A question of no mean importance was that concerning the solubility of the various alkaline salts. Chemical investigation has clearly demonstrated that the bicarbonates of lithia, potash, and soda are not only the most soluble, but the most easily assimilated by the animal organism. To prevent any decomposition it is only necessary to dissolve them in carbonated water, which not only keeps them in a soluble state but also adds to their palatability.

Dr. Enno Sanders, of St. Louis, has prepared a well known lithia potash water, which fills all the indications required, and which acts not only as an anti-rheumatic, anti-lithic, and anti-gouty mixture, but constitutes a grateful table water as well. It not only acts as a curative remedy, but, what is of still greater importance, it is a reliable prophylactic. Its composition is as follows:

℞

Lithium bicarbonate	gr. xiij.
Magnesium bicarbonate	gr. x.
Potassium bicarbonate	gr. xvj.
Sodium chloride	gr. x.
Carbonated water	℥ xvj.

M. This quantity, one pint, should be taken daily, or the amount increased if deemed necessary.

Conditions occasionally arise in which it will be found that a mixture of salicylate of soda and bicarbonate of soda will effect the happiest results in rheumatism, and occasionally in gout. Given in carbonated water the administration is made pleasant, and the mixture has an effect upon the patient which is refreshing at the time it is taken, and which effects beneficial results in a very short time. When eczema is present the proper local remedies should be made, and it is astonishing how their action will be accentuated by the internal use of the alkalies as indicated above.

Dr. C. A. L. Reed, of Cincinnati, Ohio, read a paper entitled "Observations on the Management of Uterine Tumors", in which he said that there are certain solid tumors of the uterus that require no operation. They are for the most part comparatively small neoplosms, either interstitial or subserous; they are indolent in growth, and they do not produce alarming symptoms from either pressure or hæmorrhage. There are certain other myomata of the uterus that are uniformly recognized as demanding operation. They are for the most part rapidly growing tumors in young subjects, removable fibrocystic tumors; soft œdematous tumors; large bleeding fibroids, and those growths which give rise to ascitic accumulations.

Dr. Reed offered the following conclusions:

1. That all persistently hæmorrhagic uterine myomata of whatever variety should be advised to early operation.

2. In young subjects, with multi-nodular tumors giving rise to alarming hæmorrhage, the appendages should be removed when practicable as an alterative for extirpation. But the latter operation should be done whenever the character of the growth will permit of its removal by dangers less than those which would be involved by its continued existence.

3. To those tumors already recognized as demanding operation should be added those of uterine development that are liable to dangerous constriction by the uterine walls and in which their destruction by this means might induce sepsis.

4. All cases of subserous growth, indolent, yet progressive in character in which the tumor has become a menace to neighboring organs, should, whether hæmorrhagic or not, be advised to exploratory incision with reference (1) to removal of the appendages, or (2) of the neoplastic organ.

5. All growing tumors, in women beyond the menopause, should be removed, if possible, by vaginal total extirpation, or, if that be impracticable, by abdominal section.

6. All distinctly operable cases demanding interference should be advised to submit to operation at the earliest practicable moment.

"The Etiology and Treatment of Granular Conjunctivitis". This was the title of a paper contributed by Dr. Francis Dowling, of Cincinnati, Ohio.

Dr. Dowling stated that the great *role* which the disease plays in the causation of blindness, renders its successful treatment one of the great desiderata of our day. Its great hot-beds are in some of the countries of the Orient, owing to the prevalence of whirlwinds of sand, and the intense heat and glare of the sun. The malady attacks by preference the poorer classes; the rich and well fed enjoy a comparative immunity from the disease. It is most frequent in persons between the ages of 15 and 45; children under six rarely have the disease. It does not become epidemic at a height of over 250 metres above the sea level, and it loses its contagious character at this height. Low regions and swamps favor its spread. It is highly contagious; probably three-fifths of the blindness throughout the world are di-

rectly or indirectly due to this disease. There is often some special liability on the part of certain individuals to the contraction of the disease, owing to the presence of a special diathesis, or otherwise.

Treatment.—Personally he had more success by touching the lids with the mitigated stick of argentum nitras, and then immediately washing it off, than with any other remedy. He applies the treatment usually twice a week, and on the intervening days he rubs in an ointment composed of yellow oxide of mercury and atropine. He also corrects any trouble of refraction that may exist, for unless this is attended to, the disease will persist under all kinds of treatment.

The disease is now treated in Paris, France, by completely everting the lid, and scarifying the granular tissue, then rubbing in with a stiff brush a 1–500 solution of bichloride of mercury. Cases are cured in this way in four to six weeks, that formerly took several years to cure with the old treatment. In outbreaks of the disease in orphan asylums, barracks, etc., the afflicted should be completely isolated from the healthy inmates, and their apartments should be kept absolutely clean, and fumigated with burning sulphur at least once a week.

Dr. John Bartlet, of Chicago, presented a paper in the form of a review of an obstetrical work, published in Paris in 1682 by Paul Portal. He said the older members of the profession had for years rested in the opinion that it was Paul Portal to whom obstetrical science was indebted for the discovery of the fact, that in placenta prævia the after-burden was attached to the womb, and had not simply fallen down over it, as was taught by writers before his day.

Dr. G. Frank Lydston, of Chicago, followed with a paper entitled "Observations on Urethral Stricture," in which there were many striking original points. The author opposed the general impression prevalent among surgeons that the long duration rather than the severity of a virulent urethritis determined the development of organic stricture. He claimed that this view has been due to fallacious reasoning from the standard of *post hoc ergo propter hoc.* It is not the long continued urethritis that produces a deposition of the adventitious tissue constituting organic stricture. On the contrary, a chronic localized urethritis exists because the stricture, or the foundation of it has been determined at some portion of the urethra by the primary virulent inflammation. He claimed that the liability to the formation of organic stricture is directly proportionate to the severity of the primary inflammation. The localization of stricture, the author claimed, was not due as Sir Henry Thompson and his school assert, to an obstruction to drainage and the retention of the products of virulent inflammation, but to deficient elasticity or distensibility of the canal at certain points. The conditions determining stricture he compared to those prevailing in a rubber tube about which cords are tied in such a manner that while some actually constrict the tube, others simply prevent its distension. If fluid be pumped through a rubber tube thus constricted or restricted, as the case may be, at a certain degree hydrostatic pressure, and at certain intervals friction, occurs at these points and produces a continual unrest. The epithelium is rapidly removed, its vitality being impaired by the virulent poison of urethritis. By and by rapid removal and reformation of epithelium becomes a cell habit, the resulting formation of cells being of a low grade of inherent vitality. In addition to this change upon the surface of the mucous membrane there is deposited young connective tissue cells in and about the affected point as an evidence of an attempt on the part of nature to secure rest and prevent strain. These cells the author likened to sandbags thrown up to strengthen or prevent a breach, as the case may be, in a fortification.

The doctor called attention to a number of interesting reflex phenomena incidental to stricture of the urethra. He also went inexhaustively into the various toxæmic conditions incidental to renal disturbance secondary to stricture, and to that peculiar form of toxæmia incident to the absorption of ptomaines from the site of the urethral lesion. He went into the subject of electrolysis and absolutely denied the possibility within the limits of safety of using it in the treatment of organic stricture. Galvanism, he claimed, instead of electrolysis is what is really accomplished. He condemned the routine and extreme claims of Newman, and also the other extreme as represented by Dr. Keys, who asserts that galvanism, i. e., so-called electrolysis has absolutely no effect. Dr. Lydston claimed that the effect of galvanism upon organic stricture of the urethra was the same in its physiological character as upon healthy or morbid tissue in any other situation. The author described what he terms *plus* conditions of organic stricture. Thus we have engrafted upon the organic foundation varying degrees of hyperæmia, spasms, and œdema, one or all. These *plus* conditions the author claimed, galvanism, properly

applied, would subtract from the organic condition in certain cases, and in so far as this effect was marked the stricture would be benefited. The author denied the possibility of the galvanic current producing absorption of fibro-connective tissue after it had arrived at the acme of differentiation by any current which will not destroy the mucous membrane itself; in other words, we cannot control the galvanic current so that it will exert a selective action and remove the abnormal tissue while sparing the normal tissue.

The following officers were elected:

President—Dr. C. A. L. Reed, Cincinnati, Ohio.

First Vice-President—Dr. C. S. Bond, Richmond, Indiana.

Second Vice-President—Dr. Thomas Hunt Stucky, Louisville, Kentucky.

Secretary—Dr. E. S. McKee, Cincinnati, Ohio.

Chairman of the Committee of Arrangements—Dr. Joseph Ranshoff, Cincinnati, Ohio.

Place of next meeting, Cincinnati, October, 1892.

Selected Formulæ.

COCAINE AND ANTIPYRINE COMBINED AS A LOCAL ANÆSTHETIC.

Dr. D. Stuver (*Hygiea*, No. 3, 1891) praises a solution of five parts of cocaine and fifteen parts of antipyrine in one hundred parts of water as a very efficacious local anæsthetic for minor surgical operations. The action of this mixture he states to be more intense and longer lasting than that of cocaine alone. It has also been successfully employed in cases of obstinate vomiting.

FERRO-IODIZED CODLIVER OIL.

Ch. Diete gives the following in the *Chemische Zeitung:*

℞
Porphyrized iron..... grammes iv.
Iodine..... " 8.20.
Ether..... " lxx.

Mix and agitate until all the iron is converted into iodide. Then heat in a water-bath 200 gm. of codliver oil; add the etheric solution of iodide of iron and continue the heat until the ether is driven off. Let cool, and filter. This preparation should be preserved in small containers only.

THIERSCH'S ANTISEPTIC SOLUTION.

The extensive use of Thiersch's solution (named after a German surgeon) in many modern abnormal, intestinal and bladder operations, conducted in hospitals and frequently at the patient's residence, and in urethral and uterine irrigations performed at the surgeon's office, has induced Adolph Levy to recommend the combination of this solution (consisting of salicylic acid 3 parts, boracic acid 12 parts, in 1.000 parts of water), in form of compressed tablets each containing:

℞
Salicylic acid, resublimed.....gr. xiv.
Boracic acid (boric) resublimed.....gr. lxxxiv.
Compressed in form of tablets.

To each tablet is measured sufficient distilled hot water to measure one pint. The solution may be prepared as needed.

TYPHOID FEVER.

In an interesting article on this disease, I Burney Yeo quotes the following two prescriptions. Both have been thoroughly tested and highly recommended. The first is by Dr. Wilks:

℞
Sulphurous acid.....m xx.
Water.....f℥ j.
Syr. aurant. cort.....f℥ ij.
Sig. At a dose every four hours.

The following is given by Dr. H. C. Wood:

℞
Ol. caryophyli.....gtt. vj.
Ol. terebinthinæ.....f℥ jss.
Glycerini.
Mucil. acaciæ, aa .....f℥ ss.
Syr. et. aq. ad.....f℥ iij.
Sig. Dessertspoonful every two hours during the day, patient being allowed to rest at night.

Yeo has tested chlorine water and obtains excellent results. His prescription is as follows:

℞
Potas. chloratis.....gr. xxx.
Ac. hydrochlor. fort.....m xl.

Place in a 12-ounce bottle and cork. When filled with gas add water gradually and shake. Then add—

℞
Quin. sulph.....gr. xxiv--xxxvj.
Syr. aurant. cort.....℥j.
Sig. One ounce every two, three or four hours, according to the severity of the case.

—*Lancet*, April 11, 1891.

LOCAL ANÆSTHESIA MIXTURE FOR SMALL OPERATIONS.

Dobisch, (*La Rassegna di Scienze Mediche*, No. 2, 1891) used the following mixture as a spray to produce local anæsthesia for minor operations:

℞
Menthol.....parts 1.
Sulphuric ether..... " 15.
Chloroform..... " 100.

Anæsthesia is complete, profound, and lasts two to six minutes.

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO., (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

THE ETIOLOGY AND TREATMENT OF PUERPERAL ECLAMPSIA.

There is no acute disease which should demand greater consideration, as regards pathology and treatment, than puerperal eclampsia. In support of this assertion it is only necessary to refer to the high mortality (both to mother and child), the alarming suddenness of its onset very frequently, and the fact that the mind of the profession is by no means made up regarding the causation of this grave affection and the best means with which to combat it.

In 1842 Lever discovered that in the great majority of cases of puerperal eclampsia, albumin is present in the urine, and since that time the condition of the kidneys has been considered one of the most important factors in its etiology.

At the annual meeting of the British Medical Association, a most interesting discussion was held upon this subject by several prominent English obstetricians, and it may be of interest to briefly review some of the opinions expressed, since, from the high professional status of the assemblage, their utterances must be regarded as more or less authoritative. The causation of puerperal convulsions has been a rich field for discussion, and, with the increasing number of theories advanced during late years, it would seem that in the present state of our knowledge, definite conclusions are as far away as ever. This difficulty is, however, more apparent than real, for a careful study of the whole subject seems convincing that much light has been thrown upon both pathology and treatment by the carefully recorded clinical observations and experimental studies which have been made. A great deal of valuable negative knowledge is available, and also much that is positive, confirmed by repeated bedside experiences.

At the meeting already referred to (Annual Meeting Brit. Med. Ass'n., Section of Obstetric Medicine, Bournmouth, July,

1891), the etiology of puerperal eclampsia was discussed in three divisions, as follows:

I. The causation of that form of albuminuria which is associated with eclampsia.

II. The relation between the albuminuria and the convulsions.

III. The explanation of those cases in which the urine is at first free from albumin, and the albuminuria only appears after the convulsions; also of the exceptional cases in which albuminuria is absent throughout.

Regarding the first question, or the causeation of the albuminuria so frequently present in such cases, Dr. Galabin referred to the theory of Dr. Blane, of Lyons, who has isolated a specific bacillus from the urine of patients having puerperal eclampsia, which he regards as the primary cause of both the convulsive phenomena and the kidney lesion. In support of this theory Dr. Blane found that the injection of pure cultures of his bacillus into pregnant rabbits was followed by eclampsia, dyspnœa, and death; while in non-pregnant rabbits only local inflammation was produced at the point of injection. Therefore, Dr. Blane has reasoned, the bacillus is the primary cause, and that a poison is developed within the body which produces convulsions and nephritis by direct action upon the nervous centres and the kidneys. Dr. Galabin rejects this theory from lack of proof and because it would render puerperal convulsions a zymotic affection to which only pregnant women and rabbits are liable, and he prefers to believe in the uræmic origin of the eclampsia, even if the production of the nephritis cannot at present be satisfactorily explained. As powerful predisposing causes of albuminuria in primiparæ, he mentioned the increased intra-abdominal pressure of pregnancy which interferes with the renal circulation, and also the depressed state of the nervous system so often attendant upon a first confinement. Dr. John W. Byers, referred to the paper of Leyden, (*Deutsch. Med. Wochenschrift* March 4th, 1886), who considers the kidney lesion, associated with puerperal eclampsia, as a *special form* of nephritis, due to prolonged arterial anæmia, the primary causes of which, he thinks, is the altered intra-abdominal pressure.

Another interesting theory regarding the cause of albuminuria is that proposed by Stumpf, which is that a toxic nitrogenous product, probably acetone, is developed in the blood, and this in its elimination gives rise to nephritis. Other theories as to the origin of the kidney lesion of puerperal eclampsia are not wanting, and Dr. Braxton Hicks has advanced the view that the convulsions themselves cause the albuminuria. Santos attributes it to the strain and consequent irritation of the uterine nerves during the enlargement of the uterus, and that this acts reflexly upon the sympathetic and renal nerves, producing the convulsions and the albuminuria. Winckel conjectures the existence of several poisons which develop and act with varying intensity. Pagot considers the fits reflex, the nervous discharge occurring from the cerebro-spinal centre close to the albuminuric centre. The Traube–Rosenstein view is that the convulsions depend upon cerebral anæmia due to œdema of the brain which is caused by the hypertrophied heart of pregnancy pumping watery blood under high pressure.

Enough has been said to prove that there is complete want of agreement among the highest authorities concerning the importance of, and the cause producing, the albuminuria of puerperal eclampsia, and Byers undoubtedly states it truly when he says "I do not think we are yet in a position to give a dogmatic answer to such a question."

There is far more unanimity of opinion concerning the second part of discussion, viz: "The relation between the albuminuria and the convulsions." The weight of opinion seems to be, that when albuminuria is present it is usually associated with a diminution of the amount of urine, or the solids of the urine, and that the convulsions are due to the retention in the blood of certain toxic substances; while in those cases in which albuminuria is absent, the convulsions are simply epileptic, or are due to reflex irritation from the uterus, acting upon an excitable nervous organization.

Those cases in which albuminuria only appears after the occurrence of one or more convulsions have been explained by the theory that the kidney lesion in such cases is a pre-albuminuric nephritis—in other words, that the portion of the kidney which has to do with the transudation of albumen becomes affected last, and to this fact the late appearance of albumen in the urine is due.

Dr. Auvard, of Paris, has made a special study of eclampsia, and has formulated what he terms the "pathogenic theory," which is that puerperal convulsions result from a poisoned condition of the blood, due to diminished elimination by the liver and kidneys. His own words are,—"to sum up: the pathogenic theory views eclampsia as the result of a 'strike' on the part of the organs of elimination, giving rise to intoxication of the organism."

The treatment of puerperal eclampsia is of far greater importance in the present state of our knowledge than speculations regarding the multitude of theories which have been brought forward to account for the disease. This, of course, is modified largely by the severity of the attack, and the time at which it occurs. It is now well known that the mortality is higher when the convulsions appear during pregnancy than when they begin during labor, and that the prognosis is more favorable still if the convulsions begin after labor. Those cases in which the convulsive seizures begin early in labor are more fatal than when they begin in the last stages of labor. Statistics also show that the convulsions cease in one-third of all cases when the uterus is emptied, so it is not surprising that the induction of permature labor occupies such a prominent place in the treatment of cases occurring during pregnancy, and that rapid delivery is of so much importance when convulsions appear early in labor. Auvard, whose theory of the pathogenesis of puerperal eclampsia has already been stated, also sums up its treatment as follows: "The therapeusis of eclampsia comprises the three-fold indication to favor elimination by means of purgatives, durietics, and diaphoretics; and the three-fold indication of sedation by means of anæsthetics, venesection, and by emptying the uterus." Winckel, in his recently published text-book says: "Whenever the patient becomes restless, and the approach of an attack is thereby recognized, or as soon as the first contractions commence, chloroform is to be given, and the inhalation to be continued until the attack disappears. The chloroform acts, therefore, as a preliminary calmative until the chloral can be given (1 to 2 grammes=15–30 grs.), which is at once to be administered per enema, after each attack, and we are not afraid of giving as much as 12 grammes (=3 drachms) of the drug per day, and even more." Winckel's record is 92 cases with 7 deaths. Dr. Byers' treatment is chloroform and chloral, with rapid delivery if the case does not yield to these remedies. Another set of equally prominent clinicians rely upon venesection first, followed if necessary by chloroform anæsthesia and chloral, and thirdly delivery if indicated. Other remedies in common use are morphine, pilocarpine, nitroglycerine, amyl nitrite, veratrum veride hypodermically, the bromides, and brisk purgatives when the patient can swallow. Since every grade of severity of the convulsions occurs, it is impossible that any one treatment is applicable to all cases, and the time at which eclampsia appears, the condition and habit of the patient, the state of the urine, and the amount of albumin present should guide us in deciding the treatment of each case.

A CORRECTION.

On page 643, first column, 25th line from the bottom, the word "contraction" should read "combination."

CORRESPONDENCE.

PROMISCUOUS SPAYING OF WOMEN.

ED. MEDICAL AND SURGICAL REPORTER:

The operation of spaying or removing the ovaries of the female, has become such a

rage, with a certain class of ambitious young surgeons, each striving to count the greatest number of abdominal sections, that the woman who consults them for any gynæcological disease, is lucky if she escapes without being unsexed.

This subject has been forced to my notice, from the fact of several of my patients being induced to have the operation performed, without a due knowledge of its consequences, or the serious risk of life to which they were exposed. Of four cases that have recently come to my knowledge, in which the ovaries were removed, one died within twenty-four hours after the operation, the other three recovered from its immediate effects. One of the latter was a young married woman, married less than a year; she had consulted me for irritability of the bladder with a frequent desire to urinate. This I attributed to her changed condition of life and a somewhat nervous temperament. She was soon relieved by appropriate remedies and certain advice as to the marriage relation.

After a time the same state of affairs occurred again, when a lady friend advised her to visit a certain institution *that shall be nameless.* She was there informed that an operation would be required, to which she ultimately consented. (She positively asserts that she had not the slightest idea of the nature of the operation, or that her life was placed in the slightest danger.) Both ovaries were removed, and she recovered from the effects of the operation. In a few weeks after I was again sent for, and found her in great distress, her symptoms she declared were exactly the same, and she suffered even worse than before the operation, which was done ostensibly for her relief. And now she began to realize her deplorable condition, which to a young married woman, can be more easily imagined than described.

Wm. C. Todd, M. D.,
Roxborough, Pa.

THE APOTHECARY AND THE PRESCRIPTION.

To the Editor of the Medical and Surgical Reporter:—There have recently appeared a number of articles in our medical journals on the subject of the physician's prescription and its final retention by the druggist. It may be interesting to your readers to know the views of a writer of the 16th century and probably the first mention of the apothecary's prescription file.

"In the reigns of Edward VI, Mary and Elizabeth no one ranked higher than William Bulleyn, as botanist and physician." Among some of his rules for "The apoticarye" I find the following: "That he neither increase nor diminish the physician's bill (i. e. prescription) *and kepe it for his own discharge.*' These quotations are from the interesting book entitled "A book about Doctors" by J. Cordy Jeaffreyson.

Very truly yours,
G. Granville Faught.
October 24th, 1891.

Book Reviews.

ON PAINFUL MENSTRUATION—THE HARVEIN LECTURES, 1890. By Francis Henry Champneys, M. A., M. D. Oxon., F. R. C. P., Physician-Accoucher and Lecturer on Obstetric Medicine at St. Bartholomew's Hospital, etc., London: H. K. Lewis, 1891, 8vo., 88 pp.

Dr. Champneys is a man of such broad culture, a physician of such extensive experience, and a writer of such conscientiousness, that anything coming from his pen is stamped with a guarantee of value. We, therefore, opened this book with the assurance that we would find its pages full of valuable thoughts, and we were not disappointed.

Dr. Champneys has endeavored to collect here the truth, as far as ascertainable, into an easily accessible form. In doing this he has performed his task so acceptably that he has placed in the hands of the physician some invaluable information on a subject which is not only one of difficulty but of frequent occurrence in the every day work of the general practitioner.

In the first lecture he treats of menstruation, the changes in the uterus, the changes during the monthly cycle, the question of uterine contraction, the condition of the pelvic organs during the cyle, dysmenorrhœa, and the classification of dysmenorrhœa. The second lecture is devoted to the study of membranous dysmenorrhœa—its history, pathology, clinical history, causation of pain, differential diagnosis and treatment. The third lecture is a discourse on spasmotic dysmenorrhœa—its natural history, pathology, treatment, etc.

The work throughout is excellently done; and the last lecture will be a revelation to those who look upon dysmenorrhœa, as being of mechanical origin.

In the treatment of spasmodic dysmenorrhœa he has found that cases treated unsuccessfully by most, if not quite all of the usual drugs got well suddenly as soon as castoreum was given. He uses it in the form of a tinc-

ture, from twenty to thirty drops being given three or four times a day during the pain, with or without a few drops of the tincture of nux vomica.

No gynæcologist or general practitioner should be without this work.

PERISCOPE.

THERAPEUTICS.

ANTIPYRIN IN CHOREA.

Leroux (*Rev. Mens. des Mal. de l'Enf.*, August, 1891) concludes that antipyrin exercises a favorable action on Sydenham's chorea, quickly diminishing its intensity and shortening its duration. Of sixty cases treated, forty-one resulted favorably and nineteen unfavorably. Of the forty-one favorable cases, in nineteen the average duration of the disease was thirty-three days, and the treatment twenty-one days; in seven others the average duration was fifty-five days, and the treatment forty-three days; in seven the average duration was sixty-eight days and the treatment forty-nine days.

In nineteen cases the results were unfavorable for the following reasons:

1. The condition proved refractory to antipyrin.
2. The medicine could not be tolerated, vomiting, diarrhœa, etc., being caused by it.
3. Cutaneous eruptions were produced when intolerance existed.
4. Treatment was irregularly carried out or interrupted by an intercurrent affection.
5. In some cases the disease was prolonged in the form of convulsive tic, which was refractory to antipyrin, or post-choreic tic, which was usually cured in a few months.

HYPODERMIC INJECTIONS OF ARISTOL IN PHTHISIS.

At a meeting of the Paris Académie de Médecine on September 15th (*Sem. Méd.*, September 16th, 1891), M. Hérard read a communication from Dr. Nadaud, of La Rochefoucauld, giving the results which he had obtained by the hypodermic use of aristol in phthisis. Having observed the good effects of that substance on tuberculous ulcers, and having satisfied himself as to its harmlessness when given internally, Dr. Nadaud proceeded to use it hypodermically in the form of a solution of 1 cubic centimetre of aristol in 100 cubic centimetres of sterilized oil of sweet almonds. The first case in which he tried it was a child, aged 7, in whom hip-joint disease had left numerous discharging sinuses. One cubic centimetre of aristol was injected daily, and after twenty-five days there was no trace of suppuration. The injections were next tried in 23 cases of pulmonary phthisis, no other medication being employed. In 7 of these, after from twenty-five to thirty days of treatment, a complete cure seemed to be effected, and this was maintained up to the date of the report (from three to four months after the conclusion of this treatment). In 5 others, after rapid improvement, a relapse occurred within a month after the treatment had been brought to a close. After a second series of injections the symptoms again disappeared. In none of them was a third course of treatment required. In 3 cases in which large cavities existed in the lungs the effect of the injection was *nil*. Two patients died during treatment—one of diphtheria, the other of tuberculous peritonitis. The 6 who are still under treatment "for the most part show distinct improvement." Dr. Nadaud draws the following conclusions:—(1) Aristol given hypodermically is perfectly innocuous; (2) It is in a large measure eliminated by the lungs; (3) It acts as an antiseptic and as a modifier of nutrition; (4) It acts very quickly, the effects beginning to show themselves on the sixth or seventh day by diminution of cough and suppression of night sweats; (5) After from twenty to twenty-five days of treatment it is generally found that the patient had gained weight; (6) The injections are useful in the first and second stages of pulmonary tuberculosis; when cavities exist and the expectoration is purulent they have no effect, or a very slight one; (7) The injections cause no inflammation of the skin at the seat of puncture, nor are they followed by abscess, eschar, or induration; the pain is trifling. In commenting on Dr. Nadaud's paper, M. Hérard said that *a priori* the treatment was rational, inasmuch as aristol was composed of powerfully antiseptic substances. Dr. Nadaud's facts, however, in his opinion, were insufficient to form the basis of any practical conclusion. The cases must be numerous, and must be kept under observation for years before the therapeutic effects of aristol could be compared with those of creasote and guaiacol, which seemed to be really valuable agents.—*Brit. Med. Jour.*

HYDROCHLORIC ACID IN DIPHTHERIA.

Starting from the fact established by Roux and Yersin (*Bulletin Médical*, 1889), that the virulence of diphtherial toxines can be considerably diminished by slight acidulation of the bacterial products—especially with some mineral acid—Dr. S. H. Kraszewski, of Ivyë, resolved (*Gazeta Lekarska*, No. 28, 1891, p. 555) to try hydrochloric acid in six typical cases of croup in children, aged from six months to three years, and in five cases of faucial diphtheria in two children and three adults. The following formula was used: ℞ Liq. ferri perchloridi, *Ph. Roes.* (that is, equal parts of the iron salt and distilled water), 4 grammes; acidi hydrochlorici, 1.0 gm., aq. destillatæ, 200.0 gm. M. D.S.: A teaspoonful every fifteen minutes for one hour; then every thirty minutes for three or four hours; later on every hour. In faucial diphtheria the remedy was applied locally as follows: ℞. Liq. ferri perchloridi, *Ph. Ross.*, 8.0 gm.; acidi hydrochlorici, 1.0 gm.; aq. destill., 30.0 gm. M. D.S.: To be painted over the affected area with cotton-wool every two hours, a fresh piece being used on each occasion. The treatment lasted from two to five days, the only adjuvants employed being frequent gargling with a four per cent. solution of boracic acid in faucial diphtheria, and the internal administration of a 1.5 per cent. solution of sulphate of copper, in croup (as an emetic when symptoms of laryngeal obstruction were present.) Every one of the patients made an excellent recovery. In four out of five faucial cases the diphtheritic deposits vanished completely and permanently in from twenty-four to forty-eight hours, the throat becoming normal within three or four days. The fifth patient recovered in a week. The laryngeal cases (of which two had been apparently hopeless) were cured in from three to five days. In none were any unpleasant accessory effects observed.—*Medical Record.*

BICHLORIDE OF GOLD TREATMENT FOR INEBRIETY.

The so-called bichloride of gold treatment for inebriety, for which so much has been claimed, and to which the newspaper press has given such prominence, proves to be a rank humbug. Bichloride of gold, though a chemical possibility, is impossible therapeutically, as the preparation reduces and becomes inert the moment the chemical bichloride transformation is effected.

It is stated that the remedies employed by the manager of the institution, which has been chiefly identified with this treatment at Dwight, Illinois, are the hypodermatic use of cocaine and administration by mouth of the so-called bichloride of gold, which a recent analysis reveals to be a weak solution of aloin in water combined with comp. tr. cinchona. The only gold used in the treatment is that supplied by the dupes in the form of fees.

The favorable effects of this treatment are in part due to the action of cocaine, but chiefly to the mental effect on the patients who, emotionally stimulated by faith in the promised cure, are enabled to gain temporary control of their habit. The lay and religious press have given the chief quack and his humbug an amount of free advertising beyond computation.

The Secretary of the State Board of Health of Illinois is authority for the statement that the manager of this institution at Dwight was refused a license to practice medicine in Illinois.—*Med. Age.*

THE TREATMENT OF SMALL CYSTIC TUMORS BY MEANS OF INJECTIONS OF CHLORIDE OF ZINC.

This method which was recommended some time ago by Landerer has been used with success by Schilling. A one-tenth per cent. solution was employed, of which 0.2 to 1.5 c. cm. were injected into the cyst. In cases of extensive tumors of the sheaths of the tendons, as for example on the back of the hand, several injections were made at the most prominent places. The procedure is almost painless. The cysts after injection become at first hard and then softer; they disappear almost completely in four or five weeks. Sometimes the injection must be repeated. The operation is sometimes followed by œdema and slight hyperæmia of the surrounding skin, which are best treated by wet compresses. The author has treated in this manner three cases of simple ganglia at the back of the hand, one hygroma over the patella, and one hydrocele in a man fifty-six years old.—*Wiener Medizin Presse*, No. 32, 1891.

HYPODERMIC INJECTIONS OF CARBOLIC ACID IN TETANUS.

MM. Fancel and Frache report (*Arch. de Méd. et de Pharm. Milit.*, September, 1891) a case of traumatic tetanus in which a cure was effected by means of hypodermic injections of carbolic acid. The patient was a

man, aged 32, who had received a superficial wound of the left forearm from the bursting of a gun. The man, who was a bricklayer, continued to work at his trade without having had the wound dressed, and on the third day he was suddenly seized with rigidity of the limb, which was quickly followed by lock-jaw, opisthotonos, and other symptoms of tetanus. On examination of the wound it presented a healthy appearance, but some fragments of lead were found in it and removed. Treatment by chloral, bromide of potassium, subcutaneous injections of hydrochlorate of quinine, etc., having proved futile, injections of carbolic acid were tried, 1 centigramme being given every two hours, and all other medication being discontinued. The effect was almost immediate, the spasms becoming much less violent and less painful, and the patient's general condition showing marked improvement. The injections were continued for seventeen days, and the patient was finally discharged completely cured, fifty days after his admission to the Hospital. The authors refer to the introduction of this mode of treating tetanus by Baccelli, who reported a case in which he had employed it successfully to the first Italian Congress of Medicine in 1888. They do not, however, agree with him in attributing the efficacy of the treatment to the sedative action of the carbolic acid on the spinal centres, but regard it as due to the parasiticide power of the remedy.—*Brit. Med. Jour.*

MEDICINE.

DIGESTION ACTIVITY IN MENTAL DISEASES.

An article on this subject appeared (*St. Petersburg Med. Woch.*) by Dr. E. Grabe, in which he attempts to elucidate the question of nervous dyspepsia as he considers it the most important, because the most frequent, of the neurasthenic indigestions due to functional disease of the nervous system.

In examinations of the stomach contents in a number of psychoses, over a given time, it was found that the mental condition had much influence on the general economy. Leyden's conclusions on this subject after making observations during health and disease, were that the functions of the stomach and appetite and digestion were under the influence of the central nervous system and that stimulation or depression resulted in alteration of function. It must then be accepted, that in a high grade of psychical disease, the stomach functions cannot be normal and that the resulting dyspepsia is therefore a neurosis. Notwithstanding some new views to the contrary, recent examination of the stomach juices in fourteen cases of melancholia, the patients being otherwise in general good health, showed hyperacidity, due to free hydrochloric acid and decrease of peptic formations. Hypersecretion was not, however, constant. Under such circumstances it is not surprising that appetite is lost in melancholia and allied diseases. Krafft-Ebing, in his text-book on Psychiatry, says that the explanation of the loss of appetite in dyspepsia, melancholia and hypochondria is due to the lessening in the quantity of, or chemical alteration in, the digestive fluids. In the twelve cases of mental disease, examined by the author as to the condition of the stomach secretions, all were found to contain free hydrochloric acid and lessened peptonoid products.

The irritated state of the nervous apparatus in the various forms of mental diseases seems then to be responsible for the secretion activity of the stomach resulting in the production of hydrochloric acid. It is the author's intention to make further investigation as to the constancy of the functional alterations in psychoses.

INFECTIOUS ORIGIN OF RICKETS.

Dr. Stephano Mercoli alleges as the result of certain bacteriological researches, that pyogenic microbes are present in the nerve tissues of persons suffering from sciatica, chorea, and hydrocephalus, and the most common of those found are the staphylococcus and streptococcus. He has also been examining most minutely children who have died from hydrocephalus and rickets, and from the bony tissue of the latter, ribs, forearms, and so forth, he has been able to obtain, so he affirms, pure cultures of pyogenic microbes. According to this authority rickets is a parasitic disease; he believes that in adults the microbic activity is not enough to cause more than a local manifestation of the disease, whereas in children the infection becomes general, but it is chiefly in the nervous and osseous tissues in which its effects are most manifest. It would be convenient if we were made a little more acquainted with the details of these bacteriological investigations before being asked to accept the results to which they are presumed to point.

ACUTE YELLOW ATROPHY OF THE LIVER.

Burckhardt (*Corresp.-bl. für. Schweizer Aerzte*, August 15, 1891) reports the case of a widow, thirty-two years old, who, after profound emotional depression, developed jaundice, followed in turn by delirium, with but slight elevation of temperature, death taking place in coma. The autopsy confirmed the diagnosis of acute yellow atrophy of the liver. Burckhardt takes occasion to controvert the view that acute yellow atrophy is always the result of phosphorus-poisoning. In the former, the primary enlargement of the liver and the colicky pains of the latter are wanting, while the maniacal manifestations of acute atrophy are absent in phosphorus-poisoning. Examination has thus far failed to find phosphorus in the organism in acute yellow atrophy. From the absence of fever in, and the sporadic appearance of, acute atrophy, Burckhardt is unwilling to place it in the category of infectious diseases. He would rather ascribe the symptoms to the absorption of abnormal products developed in the course of parenchymatous inflammation of the liver induced by an unrecognized noxa.

PERIPHERAL NEURITIS IN DIABETES.

In a communication by Auché, of which a summary is given in the *Neurologische Centralblatt*, the author refers to the fact that although there is strong clinical evidence of the existence of peripheral neuritis among diabetics, no absolute proof that the condition giving rise to symptoms of neuritis is really one of inflammation of the peripheral nerves has as yet been brought forward. This, however, is the view which the writer adopts, and which he proceeds to prove by means of his own observations and those of others, embracing almost every form of disturbance of the nervous system occurring in diabetics. He also cites his histological observations, showing widespread inflammatory processes in the peripheral nerves. In the summary of his views of the subject the author states that the upper extremities are attacked with less frequency than the lower, that the affection is mostly bilateral, but may be one-sided, that the functions of the bladder and rectum are unimpaired, and that atrophy and the reaction of degeneration are present in the affected muscles. Sensory disturbances, consisting of pains, hyperæsthesia, paræsthesia, or anæsthesia, frequently precede motor troubles, but may accompany them, or may occur alone. Vaso-motor troubles, such as hyperidrosis, œdema, shiny skin, and ecchymosis, may also be present as well as trophic disturbances, such as perforating abscesses, local atrophy of skin, falling off of nails, &c. The loss of knee-jerk which occurs in some cases of diabetes is to be ascribed to neuritis. The author in conclusion refers to the generally accepted opinion that the nervous symptoms are not at all proportional to the quantity of sugar in the urine. Some researches which he made as to the effect of injections of saccharine solution in the vicinity of the sciatic nerve led him to conclude that sugar was not the active agent in setting up changes in nerves; but that such changes are more probably to be ascribed to the presence in the blood of acetone or of some as yet undescribed chemical substance. —*Lancet.*

MORPHOLOGICAL CHANGES IN THE BLOOD CAUSED BY INJECTIONS OF TUBERCULIN.

Recent investigations, carried on by Dr. N. W. Uskoff, have shown that the injection of Koch's fluid causes a temporary increase in the number of leucocytes, such increase affecting mainly the proportion of multinucleated cells. Dr. N. Tschistowitsch (*Berlin klin. Wochensch.*, August 24th, 1891) publishes five further cases in which the leucocytes were counted while under treatment by Koch's injections. Considerable variation was noted in the five cases. On the whole, however, he, like Uskoff, found that an increase in the number of white corpuscles occurred, this leucocytosis consisting mainly in a multiplication of the multinucleated elements and often, also of the uninucleated elements with lobulated nucleus. An increase in the other forms of leucocytes also occurred in severe cases, but was less constant. This form of leucocytosis, induced by the injection of Koch's fluid, sets in very rapidly, before any other signs of reaction have appeared. It disappears again equally quickly, to be followed by a diminution in the number of white corpuscles. In harmony with this observation of the power that Koch's fluid has to cause a multiplication of leucocytes, and especially to promote the development of immature into mature forms, is the fact that the presence of tubercle bacilli in a tissue (whether these have entered spontaneously or been artificially inoculated) provokes a rapid aggregation of leucocytes in such tissue.—*Brit. Med. Jour.*

ACTION OF PRODUCTS OF BACILLUS PYOCYANEUS.

MM. Morat and M. Doyon (*Lyon Medical*, May 31st, 1891, p. 143), using the filtered products of the bacillus pyocyaneus, found that after the injection of from 10 to 20 cubic centimetres into the veins of a rabbit the pneumogastric soon lost its inhibitory action on the heart; the vasodilators of the sympathetic trunk were paralyzed, whilst the vaso-constrictors remained unaffected, even under considerable irritation; the iridodilator nerves of the sympathetic, however, still remained active; but the chorda tympani lost its vaso-dilating power. These results they found, however, could not be obtained in the case of the dog; nor were they able to obtain any evidence of any action of this poison on the sympathetic trunks in the cat. —*Brit. Med. Jour.*

MORVAN'S DISEASE.

Church (*Journal of the Amer. Med. Association*, 1891, No. 10) reports a case of so-called Morvan's disease, with a brief review of what is known on the subject, the literature of which is scanty. The affection is characterized by a destructive process, progressively and symmetrically involving the digits, ulceration with exfoliation of the bone taking place, and resulting in deformity, sometimes preceded by pain and attended with anæsthesia. In the only case of the disease in which an autopsy has been reported, an excess of connective tissue was found in the posterior horns, posterior columns, and gray matter of the cervical cord and in the peripheral nerves. Nothing is known as to its etiology. The disease is to he distinguished from scleroderma, anæsthetic lepra, symmetrical gangrene, and syringomyelia. The treatment is symptomatic.

THE RETURN OF THE KNEE-JERK IN A TABETIC.

Dr. J. Hughlings Jackson, in the *British Medical Journal* for July 11th, reports a very interesting case of return of the knee-jerk, after hemiplegia, in an old case of tabes. The patient, a man of forty-nine years of age, had contracted syphilis some twenty-three years previous to the report of the case. At the time that he came under observation, in February, 1888, the symptoms of tabes were typical. There were also some evidence of hemiplegia, the patient having suffered from two attacks a short time before his admission to the author's service. About forty-seven days after the second attack of hemiplegia the return of the right knee-jerk was noticed, and subsequently the left was obtainable by re-enforcement. It was presumed that the return of the patellar reflex was contemporaneous with the establishment of sclerosis of fibers of the pyramidal tract in the bundle of deep fibers of the lateral column. It is well known that in many cases of uncomplicated hemiplegia there is exaggeration of both knee-jerks. It has been shown by various authors that at least in some cases of lesion of one internal capsule there has followed degeneration of fibers in both lateral columns.

SURGERY.

EXTIRPATION OF THE LARYNX.

Tauber (*Archiv. f. klin. Chir.*, Bd. xli., Heft. 3) has tabulated 163 cases of extirpation of the larynx, and has analyzed his tables with typical German minuteness. As a general result he finds that the operation is followed by death in 69.9 per cent. of all cases. Permanent cure—that is, failure of the disease to return for three years after operation—is noted in 7.9 per cent., of the cured cases. It is a well-known fact that in Spencer Wells' hands ovariotomy gave a mortality of 70 per cent., and that by improvement in technique this mortality has fallen to less than 4 per cent. There is little hope held out by Tauber that a similar improvement in the results of laryngectomy may be expected, since the percentage of death is the same now as it was ten years ago.

It would seem from this study that laryngectomy is an operation which should not be performed, since even when from mechanical interference a tumor of the larynx threatens to produce a fatal result, tracheotomy, will afford immediate relief, and there is about as much assurance against recidivity as is afforded by complete extirpation of the larynx, at least in such cases as are far advanced.

Bardenheuer (*Ibid.*) takes quite an opposite view of this operation. He believes that he has so improved the technique that the mortality will be greatly lowered, and instances, in proof of this fact, that while his first four patients died immediately following the operation, the last four, treated by a different method, all recovered. He found that the patients died not immediately after the removal of the tumor, but in from four

to eight days, and that the mortality was due to septic inflammation, usually beginning in the deepest portion of the wound, in the space between the trachea and the surrounding muscular tissues. From this position inflammation extended along the loose cellular tissue of the neck into the mediastinum, and death usually resulted from septicæmia and pneumonia. The cause of infection was usually penetration of the liquid food and of the secretions of the mouth into the deeper portions of the wound. Bardenheuer modified his laryngectomies by attempting to sterilize the mouth for several days before operation.

The teeth were subjected to repeated frictions with antiseptic solutions, and the mucous membrane was dried with salicylic cotton. His next modification consisted in so placing the patient after operation that secretions of the mouth could not drain into the wound. The mattress was so arranged that the head was extended backward, and the pharynx was on a lower level than the cavity made by extirpating the diseased trachea; hence fluids gravitated to the mouth, and not away from it. His final modification consisted in carefully respecting the anterior wall of the œsophagus and the mucous membrane of the trachea immediately below the epiglottis, so far as it was healthy. After removal of all the diseased portions, the anterior wall of the œsophagus was brought forward and stitched to the mucous membrane of the trachea, thus forming a septum between the mouth and the wound cavity. Further, the free edge of the epiglottis was freshened and stitched back to the anterior wall of the œsophagus. The cavity of the wound was then firmly packed with sterilized gauze, and the dressing was changed in from two to eight days, depending upon the length of time the stitches held. Frequently the patient was able to swallow, thus relieving the operator of the necessity of passing an œsophageal tube. The sutures shutting the mouth from the wound cavity need not be left longer than fourteen days, since this is a sufficient time to allow of protective granulations being formed.—*Amer. Jour. Med. Sci.*

CASES OF BRAIN SURGERY.

Dr. Minossi reports (*Gazzetta degli Ospitali*, March 15, 1891) two cases of brain surgery, in which Professor P. Postempski, of Rome, was the operator. One was a case of cerebral tumor in a woman, aged 58. She had suffered from pain in the right arm for some ten years, which had gradually increased in frequency and severity, till it became continuous; the movements of the limb had also become somewhat difficult. On November 21, 1890, she was seized with clonic convulsions in the limb, with clonic contraction of the eye-lids, and of all the muscles supplied by the right facial nerve. She did not lose consciousness. Other attacks of a similar kind followed at varying intervals, and aphasia, with transient verbal amnesia and paresis of the right facial and hypoglossal nerves, came on. The right arm, when left to itself, lay semiflexed, the thumb being in the same plane as the fingers, which were also semiflexed. Sensibility in the limb was unimpaired. Professor Ezio Sciamanna, under whose care she was, sent her to Professor Postempski, with the diagnosis of tumor in the left motor area. On February 23, Postempski removed a subcortical tumor (probably a glioma) of the size of a large chestnut, which occupied the region of the left ascending parietal convolution in its middle part. The operation was immediately followed by right hemiplegia, due to plugging of the wound, and the next day the urine was found to contain a moderate amount of sugar, with traces of albumen. The wound healed by first intention, and the symptoms rapidly disappeared. The patient was shown at a meeting of the Royal Medical Academy at Rome, on May 24th (*Riforma Medica*, June 4, 1891), when the mental condition was absolutely normal, and there was no disorder of speech; she felt well, and was cheerful; there was no impairment of mobility, either in the right arm or in the regions of distribution of the facial and hypoglossal nerves. The right hand could be closed, but the fingers could not be fully extended. There was a certain amount of thinning of the skin on the dorsal surface of the ends of the fingers, and some thickening on the palmar, especially in the thumb. In the other case the patient was a man, aged 37, who had been struck with a hammer on the left side of the head. There was a compound stellate fracture of the skull over the region of the Rolandic fissure. When seen soon after the injury the patient was aphasic, and there was complete hemiplegia and hemianæsthesia of the right side. The head was shaved and disinfected, the wound enlarged, the depressed bone removed over an area of 3 square centimetres, and a light dressing applied. Three hours afterwards the hemiplegia had almost disappeared, but there were zones of anæsthesia on the outer

aspects of the thigh and arm. Six days later these also disappeared, and nineteen days after the injury the patient had completely recovered.—*Brit. Med. Jour.*

NOTES ON PYOKTANIN.

Pyoktanin, the trade-marked name of certain aniline colors (methyl-violet or "blue pyoktanin," and aurin [?] or "yellow pyoktanin"), has so far found many supporters, but also many opponents. Its supporters use it because it has been found to be, under certain circumstances, the most efficient antiseptic and bactericide at our disposal. And its opponents base their chief objection upon its disagreeable and extraordinary tinctorial powers. Moreover, some who used it without prejudice have reported it to have failed in their hands.

Regarding the latter it may be said that there may have been various causes for the failure, not due to the agent itself. One of these may have been the age of the solution. It has been found that the bactericidal power of the solutions of these aniline colors is rapidly lost by keeping. Solutions of pyoktanin should be freshly made when wanted for use, or, if to be kept for some days, should be preserved in bottles made of non-actinic glass.

Concerning the bactericidal power of pyoktanin, the experiments of Jaenicke may be quoted. The latter found that the development (but not the life) of the following bacteria was arrested by solutions of the dilution quoted in each case:

	Strength of Solution.
Bacillus of Cholera	1:62,500
Coccus of Pneumonia	1:1,000,000

To destroy their life or vitality, solutions of a higher strength were required, varying from 1 in 1,000 to 1 in 5,000 for the same period of time (one-half minute). In some cases more dilute solutions will accomplish the same purpose, but they require more time.

Pohl, who has recently published a dissertation on this subject, points out that the objection against pyoktanin, based upon its tinctorial power, is perhaps due to the use of this agent in cases where it is not at all wanted. It is not claimed that it has advantages over corrosive sublimate and similar antiseptics, when the object is to prevent a wound from becoming septic. Our present methods—application of dressings, bandages, sprays, etc., containing sublimate, etc., or sterilized by heat—are ample for this purpose. But pyoktanin comes especially into use and fills a real gap when the object is *to disinfect a wound which has become infected or septic*, for which purpose we had heretofore no efficacious agent.—*Amer. Druggist.*

BASSINI'S RADICAL CURE OF HERNIA.

At the recent Congress of German Surgeons, Dr. Escher, of Trieste, reported his results from this method of operation. It consists in laying open the inguinal canal over its entire extent and somewhat beyond; the spermatic cord and hernial sac is then lifted up, and the latter incised up to its neck, and then ligated, excised and the remaining portion replaced. The layers of the internal oblique and transversalis muscles are then carefully isolated, as well as the internal portion of Poupart's ligament, and the edges of these structures are accurately united by suture. The spermatic cord is sutured in this gutter, and the fascia, muscles and skin united. The author has employed this method in the treatment of 53 herniæ. The results were as follows: Of the 35 cases of reducible herniæ 25 per cent. healed by first intention, 10 with suppuration; of the 9 cases of incarcerated hernia 5 healed by first intention, 3 with suppuration, and 1 terminated fatally; of the 9 cases of irreducible hernia 4 healed by primary union, 4 by suppuration and one died. As regards the permanence of the cure, in 24 cases which can be utilized for this purpose, there have been no recurrences during a period of observation varying from three months to two years.—*Deutsche Medicinische Wochenschr.*

NEPHRECTOMY FOR CARCINOMA.

Krönlein (*Corresp. bl. für Schweizer Ærzte*, August 15, 1891) presented to the Society of Physicians of Zurich, a kidney obtained from a woman, forty-four years old, who for a considerable time had presented symptoms of floating kidney. Subsequently hematuria manifested itself, and a large tumor was detected in the right side of the abdomen. Operation having been decided upon, a lumbar incision was made and the kidney separated from the peritonoum without injury to the latter. In isolating the pedicle the renal vein was torn. The vessel was speedily caught and ligated. Drainage provided for, the wound was sutured. The case pursued an even and afebrile course. There were no uræmic symptoms. The tumor had not invaded the con-

nective-tissue capsule of the kidney, so that the prognosis was favorable. Five weeks after the operation, the patient was dismissed, cured. Microscopical sections showed the tumor to be a papillary carcinoma. Krönlein stated that he removed the kidney in three cases for carcinoma.

GYNÆCOLOGY.

OFFENSIVE LEUCORRHŒA ASSOCIATED WITH ACUTE ANTEFLEXION.

Dr. Graily Hewitt reports the following case (*Brit. Med. Jour.*) which is of great interest both from a theoretical and from a practical point of view. A. B., single, aged 27, was brought to me for consultation on Oct. 8th, 1890. She is a servant, and has worked extremely hard. She is very conscientious, and during the last year she has frequently sat up at night to do extra work; namely, washing. During the last two years her health has been failing. The symptom which is the most distressing is the presence of a terribly offensive odor and discharge from the vagina. This has existed for nearly two years, being always very much worse during the week following menstruation. She is now obliged to have repeated change of linen, and the greatest difficulty is experienced in getting rid of the offensive smell from the rooms used by the patient. She looks ill and pale, there is pain at the epigastrium, also pain in the pelvic region, and she can only sit on the edge of a chair. On examination it is found that the uterus is large and broad, and anteflexed. The body of the uterus forms a retort-shaped mass, which lies low down behind and below the symphysis pubis. By means of the sound the uterus can be straightened, but doing this occasions much pain. The size of the uterus is that of a small orange.

The diagnosis formulated was: retention of menstrual *débris* with decomposition of same due to a pouched anteflexed uterus.

Treatment: Insertion of a cradle pessary and plenteous carbolic injections of hot water. Diet: Milk in large quantity.

October 15th. Much better as regards pain and offensive leucorrhœa. October 31st. Very much better. Wearing cradle, which controls the position of the uterus satisfactorily. The last period more as it should be. Has now begun to do a little. April, 1891. The offensive discharge has now ceased, the position of the uterus good. Local treatment continued. Takes food well, and in all other respects material improvement.

Whatever view may be taken of the above case it is the fact that the reposition of the uterus at once produced an alteration in the vaginal discharge. The patient had previously been treated by injections, etc., unavailingly. By elevation of the body of the uterus the contents of the organ (retained menstrual products) more easily escaped, and their decomposition was prevented. The intensity of the anteflexion in this case was very noticeable, and Dr. Hewitt says he has never seen such acute anteflexion except in cases where very unusual exertion, or a violent shock from an accident has been experienced. It is his belief that retention of menstrual products in cases of acute anteflexion is common. The rarity of the case above related is the long continued putrescent character of the discharge.

The explanation of the putrescence is probably the detention of menstrual shreds in the cervical canal in contact with air passing into the vagina, or even possibly passing into the uterus. As regards the presence of air in the vagina, some years ago he saw a case in which, whenever the patient sat down to table, flatus was expelled from the vagina in a most annoying manner. It was found that the uterus was large and heavy, and markedly anteflexed. The vagina was distended like a ball. The opinion formed was that the air entered the vagina consequent upon exaggeration of the displacement, and a sort of suction action was set up thereby. At all events the reductionof the anteflexion put an end to this disagreeble symptom. There was no such escape of flatus in the case above related, but the putresence implies rather free admission of air into the vagina, which admission was probably favored by the anteflexion.

OBSTETRICS.

PUERPERAL MANIA.

In a recent essay, Olshausen, of Berlin, quotes the following language, used by Donkin, in 1863, with the comment that to-day it is approximately true. "There is certainly no subject connected with obstetrical science in a more crude and unsatisfactory condition than the pathology of puerperal mania." The ætiology especially needs illumination. It cannot be denied, with our present knowledge, that bodily causes connected with the parturient pro-

cess associated with those acting on the mind, especially when an hereditary predisposition is present are adequate to the production of a puerperal psychosis. But there is not a shadow of doubt in our mind from careful study of a number of cases that Olshausen is entirely correct when he asserts that there are numerous cases in which the puerperal psychosis is connected very closely with severe infectious disease of the puerperal woman and can only be explained by this association. Not long since Hansen in an admirable paper published in the *Zeitschrift für Geburtshülfe u. Gyn.* insisted upon this connection and illustrated his views by appropriate examples. It is to be regretted that so few writers of text books on Obstetrics have given sufficient prominence to this relation. Clinical investigators have now the important problem to solve, as to what forms of infectious diseases are likely to give rise to psychoses, and further as to the anatomical basis of the psychoses. Olshausen is of the view from his experience, that cases of puerperal pyæmia as likewise cases of endocarditis ulcerosa are readily associated with acute psychoses. It is rarer, on the contrary, to find cases of pure septicæmia so associated. When the pyæmic form of puerperal fever leads to the psychoses it is very probable that meningitic and encephalitic processes have taken place, especially capillary emboli, which are the anatomical cause of the psychosis and in the autopsy have been overlooked. In life the phenomena observed are often only those pertaining to a pure psychosis with a considerable degree of fever.

When there is no peritonitis the diagnosis of an infection may escape the physician, the more readily, as regular measurements of the temperature may not be possible on account of the restlessness or wild delirium of the patient and no demonstrable localizations may be found in the joints or other organs. Besides the psychoses due to infection and the puerperal mental diseases originating from pure physical causes, there is a third group, the psychoses after eclampsia. This class of cases has heretofore not received the attention its importance deserves. With regard to the time of appearance, the form and the course of the psychoses after eclampsia Olshausen instructs us as follows. Almost always the disease begins in the first days of the puerperal period, consequently only seldom as early as in other psychoses.

The third day of the puerperium is the one by preference for the outbreak. More rarely it is the second or fourth. In the majority of cases an interval of a day elapsed after the recovery of the patient from the eclamptic coma and the return of consciousness, before the phenomena of the psychosis developed. In one or two cases, however, hallucinations followed immediately the awakening from coma, so that a condition of lucidity of consciousness could not be predictated. The psychoses appeared in every case with hallucinations. In the majority of cases the illusions related to the sense of hearing, in others to that of sight. Not infrequently the patients believed themselves to be objects of pursuit. Great restlessness is a frequent symptom, the patients wish to get out of bed, yet, as a rule, they can be easily restrained, occasionally the psychosis bears the character of melancholia.

Furious delirium is rare—suicidal attempt is very uncommon. The disease runs a speedy course and for this reason cases rarely come under the care of Alienists in Insane Asylums. With regard to symptomatology it should be noticed that in a number of cases the temperature and pulse attained to an unusual height during birth with no sort of local disease. Without doubt in these cases of psychosis after eclampsia the morbid condition is one of empoisonment in close connection with uræmic change of the blood conformably to the psychosis observed occasionally in chronic disease of the kidneys.

Olshausen recommends accordingly the following classification, with reference to puerperal psychosis.

1. Psychoses that are directly dependent upon febrile infectious puerperal disease, infection-psychoses.

2. Idiopathic psychoses (without corporeal, febrile disease.) Here belongs the great majority of the psychoses of pregnancy and lactation and a portion of the psychoses of the puerperal period.

3. Intoxication-psychoses after eclampsia, or exceptionally in uræmia without eclampsia.—*Gaillard's Med. Jour.*

PÆDIATRICS.

PSYCHOSES IN CHILDHOOD.

Dr. E. Doernberger reports a case (*Münch. Med. Wochenschr.*, July 7th, 1891) of insanity, complicated with chronic morphinism, occurring in a child. The patient was healthy until 2 years of age, when she was violently thrown down in a wagon by the horses bolting. Greatly terrified at the time, she fell into a delirous and feverish

state, lasting about ten days. Several months later paroxysms of screaming and outbursts of maniacal laughter and incoherent singing occurred. Some years later she suffered acute headache for several weeks. In the course of a year or two, nocturnal terrors, with visual hallucinations of thieves and fire, developed, and her disposition became intensely excitable and violent. To quiet her the parents commenced to inject her at night with 0.016 g. of morphine; they gradually increased the amount to 0.008 g. six or seven times daily without noteworthy improvement. Severe cephalalgia and palpitation ensued, together with frequent emesis, thirst, epistaxis, and deranged intestinal action. When placed under Dr. Doernberger's care the patient's age was 11 years; she was emaciated, weak, and languid, excitable, nervous, and vicious; her memory and power of learning were impaired; the pupils were contracted and sluggish. The morphine injections were immediately discontinued; decreasing doses of the alkaloid in potassium bromide solution were substituted, in addition to special hygienic measures. Phenomena of abstinence at once appeared; excitement increased; auditory and visual hallucinations were vivid; the patient craved for an injection. At the end of three months of this treatment the symptoms of morphinism subsided, leaving the original mental anomalies practically unchanged. Within a few months the patient relapsed into morphinomania, her mother having recommenced the injections to assuage the head pain. Notwithstanding that the patient's father was of deficient intellect, her mother extremely nervous and addicted to the morphine habit, and that other neuroses abounded in the nearest relatives, Dr. Doernberger considers that the heredity in this case is not sufficiently established; he would rather attribute the insanity to cerebral abscess or meningitis produced by the accident.—*Brit. Med. Jour.*

PERITYPHLITIS IN CHILDREN.

Beynes (*Gaz. Méd.*, May 23, 1891) writes that the cæcum is fixed at the lower border of the large intestine, and is connected with the appendix by its mesentery. In children fæcal matter readily penetrates it, and the anatomical condition may be said to predispose to appendicitis and to perityphlitis, with perforation. In almost all cases of perityphlitis in children it is the appendix which is perforated. The general causes which give rise to the condition are the same in children as in adults. But additional and not infrequent causes are tuberculosis of the mesenteric glands, abscesses following congestion and perinephritic abscess, with or without pyelonephritis. Among the local causes may be mentioned stagnation of undigested material, calculi of stercoraceous matter, biliary calculi, foreign bodies, gangrenous perforating appendicitis, and typhoid ulcerations of the closed follicles of the large intestine. The lesions of perityphlitis in children are those of pericæcal peritonitis, which may be sero-fibrinous with adhesions, and curable, but liable to be followed by recurrence; or it may be suppurative and with a tendency to result in general peritonitis. Perityphlitis may result without perforation of the appendix.

The symptoms at the beginning are vague; there may be a coated tongue, pain in the abdomen, vomiting, and fever. Suppuration, as was shown by Grisolle, does not usually take place before the tenth or fifteenth day. The principal indications of such an occurrence are an exaggeration of the local and general symptoms and a tumor in the iliac fossa, which may show fluctuation. Percussion may give a note indicating the presence of fluid and gas. The abscess may open externally or into the cæcum, these two terminations including almost all cases. But the opening may take place in the peritoneal cavity, in the rectum, in the internal iliac artery, or the termination may be chronic peritonitis or pyæmia.

The most favorable termination is that in which the opening is exterior. The prognosis of this disease is more grave in children than in adults. In forty-six cases the mortality was thirty-nine, while in adults the mortality is about thirty per cent. General peritonitis frequently results, and if the patient recovers there frequently remains a deposit in the iliac fossa which predisposes to recurrences. If abdominal section is to be performed it should be done early in the disease.

HYGIENE.

THE USE OF THE FLESH OF POISONED ANIMALS.

This subject has been studied by Schmidt-Mulheim with a view to determine whether if eaten by men such flesh would be injurious. As reported in the *Revista Internazionale d' Igiene* of Naples, for June, 1891, it may be used without any danger whatever. Many

savage races constantly use the flesh of the animals that have been killed with poisoned weapons and have never been injured by that means.

Harms has proved that the flesh of animals that have been poisoned with nux vomica and with tartarized antimony is not at all hurtful; Feser has demonstrated the same fact in regard to strychnine and eserine; Spallanzani, Zappi and Sonnenschein have done the same for arsenic.

Froehner and Knudson have made some experiments for this purpose with strychnine and with eserine. They fed dogs with large quantities of mutton poisoned with strychnine and eserine, and they found that no injury whatever was done to the animals. Besides, they themselves ate some of the poisoned meat and drank soup made from it, and found that the flavor was good and had no injurious effects whatever on the system.

In regard to the alleged injurious effects caused by the meat of animals poisoned with hellebore, and which had eaten belladonna leaves, the authors have shown that the accounts published in this regard have not been proved and require further tests.

The *Revista* says that in the interest of meat inspection, it is desirable that experiments should be made with other poisons.—*Univ. Med. Mag.*

THE INFLUENCE OF REST ON THE SENSIBILITY OF THE RETINA TO LIGHT AND COLOR.

Basevi (*Ann. di ottalm.*, vol. xviii, 6, p. 475) has made careful investigations upon himself and others as to the adaptability of the retina for white and colored light. His results are very similar to those of Aubert, Peschel, and Treitel. The eyes of the person upon whom the experiments were about to be performed were rested in a partially darkened room for about fifteen or twenty minutes. The room was darkened with heavy curtains. The author found that after this period of rest the visual acuity had been increased threefold as measured by Snellen's types. The sense of light, measured by Treitel's tests, was found to be increased eighteenfold. After the eyes had been rested and light was gradually admitted, the colors were recognized in the following order: red, yellow, green, and lastly blue. When color fatigue for any particular color was produced with a glass of that color, it took a position last in the series. The visual field, both for light and colors, was found to be enlarged, but the period of rest required to be longer and the darkness greater. The author concludes, from his experiments, that night blindness is a disturbance in the adaptability of the eye.

PHYSIOLOGICAL EXPERIMENTS ON THE EFFECT OF ALCOHOL.

It has been well established in late years that under certain circumstances the continued use of alcohol produces a form of inflammation of the nerves known as multiple neuritis, or clinically, as alcoholic paralysis. These cases are rare and often occur in those whose indulgence in alcohol has not been excessive, so that it has seemed as if some element besides alcohol alone was necessary to cause the nervous disorder. Experiments with alcohol upon the lower animals have not heretofore shown that its continued use produces any such condition as multiple neuritis in man.

In a recent essay, however, by Dr. P. F. Spaink, of Baarn, Holland, to which was awarded the Mason Prize, some facts are given which seem to show that alcohol does have a directly degenerating influence upon the peripheral nerves. Only an abstract of Dr. Spaink's work has as yet appeared (*Journal of Inebriety*), and many details are lacking. But we learn that Dr. Spaink fed several series of rabbits with pure alcohol, giving them from 2.3 to 8 cubic centimetres daily (℥ ss., ℥ ss.). The animals were finally killed and the peripheral nerves examined microscopically, control animals being used. In the great majority of cases degenerative changes were noted. They consisted essentially in a splitting or fissuring of the nerve, with the appearance of elongated, usually large, collections of myeline, thickened or thinned parts of nerve fibres, myeline drops, or simply neurilemma sheaths. Very rarely could any increase of nuclei be observed.

Besides this a large number of specimens showed, in addition to the above-described degeneration, a further peculiarity. This was a twisting or looping, after a corkscrew fashion, of the axis cylinders. These corkscrews recurred at varying distances on the same or neighboring fibres. At these twisted spots the axis cylinders appeared thicker, broader, and more diffuse than when their course was direct. Sometimes in badly-stained preparations these corkscrews were all that could be seen of the axis cylinder.

Since a splitting of the nerve fibres and

corkscrewing of axis cylinders are changes unknown to human nerves in alcoholic neuritis, the correctness of Dr. Spaink's findings is likely to be questioned.

A corkscrew appearance of the nerves in alcoholism is, however, very suggestive, since that interesting and useful spiral instrument plays so large a part etiologically in the disease. Is it possible that Dr. Spaink is a grim joker who has been trifling with the pundits of the American Association for the Study and Cure of Inebriety? One must not forget Dr. Dujardin-Beaumetz and the pigs to which he gave alcohol for two and a-half years without causing serious structural changes anywhere. There were no corkscrews in the pigs.—*Med. Rec.*

MEDICAL CHEMISTRY.

PURE PHOSPHORIC ACID.

M. Nicholas, in *Comtes Rendus*, describes a method of preparation of pure phosphoric acid, in which a known quantity of pure calcium phosphate is gradually added to a slight excess of pure dilute hydrofluoric acid contained in a leaden or platinum vessel, the mixture being well stirred after each addition. An energetic action takes place, and considerable heat is evolved. When all the calcium phosphate has been added, the high temperature of the mixture must be maintained for some time in order to complete the reaction. After the removal by filtration of the calcium fluoride which is formed, the solution of phosphoric acid is evaporated. At the point when the solution commences to become viscid the excess of hydrofluoric acid used is volatilized. The evaporation is continued until a thick syrup, containing 60 to 70 per cent. of phosphoric anhydride, is obtained. Meta and pyro-phosphoric acids may be prepared by further continuing the evaporation and heating. The various calcium salts of phosphoric acid, described by Erlenmeyer, may be readily prepared by adding hydrofluoric acid to a large excess of calcium phosphate, and, after mixing well, dissolving out with warm water the acid salts produced. Impure phosphate, such as bone ash, may be used for the preparation of phosphoric acid, provided that the resultant acid, after being evaporated to carbonize the organic matters present, is diluted with water, filtered, and again evaporated.

HYPNAL.

Hypnal, or monochloral-antipyrine, is prepared, according to Dermandre, as follows:

To a solution of 47 Gm. of chloral in 50 C.c. of distilled water add a solution of 53 Gm. of antipyrine in 50 C.c. of water, and transfer the mixture into a funnel provided with a stopcock (separating funnel). When the mixture has separated into two layers, an upper, aqueous one and a lower, oily one; draw off the two layers separately. After about twenty-four hours the oily layer, will have been converted, almost entirely, into a mass of transparent, rhombic prisms, and a few small crystals will be found in the aqueous portion. The mother liquids having been poured off in both cases, the crystals are collected together and dried, first between blotting paper and afterwards over sulphuric acid.—*Petit Mon. de la Pharm.*

NAPHTHALIN CAMPHOR.

If, says the *Journal de Pharmacie*, naphthalin and a champhor of the laurinaceæ be brought together at a temperature of 35° C., a liquid compound will be formed. This body seems to be a combination of 10 molecules of camphor with 7 molecules of naphthalin. It can be obtained either by melting together in a water-bath 10 ($C_{10}H_{16}O$) with 7 ($C_{10}H_8$), or by melting together an indefinite quantity of the substances, letting the resultant liquid cool to about 30° C., and pouring off the portion that remains liquid at this temperature. This new compound melts at 32.6° C., and remains fluid down to 23°. It sublimes with partial decomposition, and boils at about 207° C. It distills over at this temperature, but decomposes in distillation, the distillate containing less naphthalin than the body submitted to distillation. Exposed to the air the camphor volatilizes little by little, leaving the naphthalin as a residue. It is soluble in those liquids which dissolve the two components, and itself is a good solvent for iodine and gun cotton.

CITRIC ACID AS A NORMAL CONSTITUENT OF MILK.

Th. Henkel has found that citric acid is a normal constituent of cow's milk. Sterilized condensed milk regularly deposits a sediment consisting almost entirely of calcium citrate. In a factory of milk products to which Hendel had access, fresh cow's milk is first "purified" by centrifugal machines, then evaporated to one-third in vacuo, and the condensed product heated in hermetically

sealed tin boxes so as to sterilize it. Upon standing during several days, there are found in the cans concretions or voluminous precipitates which, when the milk is diluted, fall to the bottom. They consist chiefly of calcium citrate mixed with a little casein.—*Zeitsch f. angew. Chem.*, 1891, 503.

Concerning the occurrence of citric acid in milk, A. Scheible has contributed a detailed account in *Landwirthsch Vers.*, 39, 153 (abstracted in *Zeitsch. f. angew. Chem.*, 1891, 503.) This investigator found that cow's milk contains between 1.7 and 2 Gm. in a liter, goat's milk 1 to 1.5 Gm., and human milk about 0.6 Gm. The occurrence of citric acid in milk has heretofore been overlooked. Its isolation is quite a task, the process given by Scheible being quite tedious and circumstantial. It depends in the main upon the fact that a mixture of alcohol and ether in definite proportions will dissolve the citric acid, while it will leave undissolved the other constituents of the serum of milk.

HASTENING THE REACTION BETWEEN HYDROGEN PEROXIDE AND PERMANGANATE.

When a solution of potassium permanganate acidulated with sulphuric acid is made to act upon hydrogen peroxide (dioxide), the reaction is sometimes quite sluggish, though when more permanganate is afterwards added the latter is at once rendered colorless. If, however, the hydrogen peroxide was previously mixed with a little manganous sulphate, the reaction with permanganate will take place fully and at once, at the first contact. It seems that the presence of manganous sulphate—itself one of the first products of the reaction between hydrogen dioxide and permanganate—is necessary for the continuance (or rather commencement) of the reaction. R. Engel, who makes this communication in the *Bulletin de la Soc. chimique*, vol. vi., 17 (*Chem. Centralbl.*, 1891, ii., 338), assumes that permanganate of potassium, when first encountering the manganous sulphate, oxidizes this to manganic sulphate. The latter salt is then decomposed again to manganous sulphate by the hydrogen dioxide.

If the hydrogen dioxide is very pure, and if the sulphuric acid contains neither sulphurous acid nor any nitrose, the reaction permanganate and the dioxide is very slow. Yet, as these conditions of extreme purity are seldom present together, the tardiness of the reaction under those circumstances has not been noticed or understood up to the present time.

News and Miscellany.

THE SOCIETY FOR THE ABOLITION OF THE TITLE OF DOCTOR.

The Society receives help in the following annotation from the *Medical Press and Circular:* "The titular appellation which medical practitioners rejoice in is a relic of antiquity akin to that of the legal wig, and it is curious in that it has survived the levelling tendencies of the present generation. A correspondent raises the question as to whether the practice is an unmixed advantage. It serves to distinguish the doctor from his fellow-men, and although from an advertisement point of view this may not be altogether a drawback, it certainly entails inconveniences of its own. It never occurs to an outsider to start a conversation with a doctor on any but a medical topic, and it is quite open to discussion, a contemporary suggests, whether, if medical men did not differentiate themselves so much, and were content to be like other educated members of the community in title, manners, and personal appearance, it would not be better for themselves both in public and private life." —*Med. Record.*

MALFORMATION OF THE NOSE IN IDIOTS.

M. Revillet (of Cannes): In idiots deviations of the nose to the left has been observed in more than half the cases. The nasal passages are almost always the seat of chronic catarrh. Hypertrophy of the mucous membrane of the septum and that of the turbinated bones is of great frequency, and more remarkable since these affections are relatively rare in men of sound mind. Deviation of the septum from the fact of the narrowing which it produces in one of the nasal fossæ is a very efficient pathogenic cause of hypertrophy of the septum and of the turbinated bones.—*La France Medicale.*

A PIN SWALLOWED PASSES PER URETHRAM.

The following case is reported by Tuttle (*N. Y. Med. Jour.*): K. D., aged five years, while playing with a bent pin in her mouth, suddenly caught her breath and drew the pin into her throat. It lodged in the fauces, but, upon her mother attempting to remove

it, was dislodged and swallowed. This occurred on December 12. Fearing too great peristaltic action with a sharp-pointed foreign body in the alimentary canal, I gave no cathartics, but had the patient fed on food containing a large proportion of excrementitious matter and the stools constantly examined to find the pin if it should pass. Ten days elapsed and, nothing having been seen of it, I had about concluded it had imbedded itself in some of the intestinal folds or been overlooked in the dejections, when the father called to tell me that the child had passed the pin upon urinating that morning. She complained of sharp pain upon making her water, and, looking in the vessel, found the pin somewhat corroded but otherwise just as when she swallowed it.

The passage of the pin through the intestinal wall is not so remarkable as its passage from the bladder after it had once fairly entered that organ. Of course, it is possible the pin may have passed from the rectum through the vagina and not entered the bladder at all, but the child's symptoms indicated irritation of the latter organ.

MEDICAL ALLIANCE TRANSACTIONS.

The transactions of the first annual meeting of the U. S. Medical Practitioners' Protective Alliance have been published and are now ready for distribution to the profession. The volume contains the addresses in full, delivered at the Baltimore meeting, together with the constitution and by-laws and other information. A copy will be mailed to any physician interested who will send stamp to the Secretary, Dr. J. F. Davidson, Glendola, New Jersey.

FIRST SEMI-ANNUAL REPORT OF THE NEW YORK PASTEUR INSTITUTE.

Dr. Paul Gibier, Director of the New York Pasteur Institute, reports the following results of the preventive inoculations against hydrophobia performed at this Institute during the first six months of the second year of its existence (February 18th, 1891, to August 18th, 1891). During this time 415 persons having been bitten by dogs, cats and other animals applied for treatment. These patients may be divided in two categories:

1st. In the case of 345 of these persons it was demonstrated that the animals attacking them were not mad. Consequently the patients were sent back after having had their wounds attended to during the proper length of time.

2. In 70 cases the anti-hydrophobic treatment was applied, hydrophobia of the animals inflicting bites having been evidenced clinically, or by inoculation at the laboratory, and in many cases by the death of some other persons or animals bitten by the same dogs.

Indigents have been treated free of charge.

The persons treated were:

17 from New York.
16 from New Jersey.
11 from Massachusetts.
5 from South Carolina.
5 from Texas.
3 from Connecticut.
2 from Maryland.
2 from Missouri.
1 from Ohio.
1 from North Carolina.
1 from Michigan.
1 from Pennsylvania.
1 from Rhode Island.
1 from Arkansas.
1 from Virginia.
1 from Mexico.
1 from West Indies. (Curaçoa).

DEATHS BY HYDROPHOBIA AFTER TREATMENT:

Miram Adams, 5 years old, of Framingham, Mass, badly bitten July 14th last, in 19 places by a dog, recognized to be mad. Treated from July 15th to August 1st. Symptoms of hydrophobia appeared six days later, (August 6th). Died August 9th.

Three other persons (two, sisters of the patient) and a man, bitten by the same dog, who received the same course of treatment, are now enjoying good health.

This so far, is the only death by hydrophobia out of 255 cases treated at this Institute to date.

BEER-DRINKING AND HEART DISEASE.

It is said (Blätter f. Klin. Hydrotherapie, 1891, No. 4) that disease of the heart is very prevalent in Munich, where the consumption of beer amounts, on the average, to 565 litres per head annually; and in the same place the duration of life among the brewing trade is shorter than that of the general population. Whereas the average age attained among the latter is 53.5 years, that of ale-house keepers is 51.33 years, and of brewers 42.33 years. The same note adds that for the whole of Germany the annual consumption of beer per head amounts to 88 litres, but for Bavaria it is 209 litres.

Clinical Lecture.

LATENT NEPHRITIS, WITH SUPPRESSION OF URINE, IN CHILDREN.

BY ALEXIS M. LÉON, M. D.,
NEW YORK CITY.

Gentlemen: The case which forms the text for these remarks is unhappily incomplete by reason of the failure to secure its post-mortem aspects. On this account, it has been deemed proper to present our subject, Latent Nephritis, with Suppression of Urine, in Children, in its clinical bearings alone.

The pathological divisions of the different forms of kidney disease are not as clearly defined nor their classification as universally agreed upon as, no doubt, will hereafter be the case. On the one hand, necroscopists hold that no kidney is found healthy in the person of one dying from any acute or chronic disease. On the other, those who denying this broad assertion claim that nephritis is by no means always present in the post-mortem room. Again some authorities speak of but two forms of the acute and two of chronic kidney disease, whereas others sub-divide this classification two or three fold.

This being the status of the subject, it is simply impossible to properly arrange and classify the few cases that are included in this writing or to base any conclusions upon their pathology. The confusion in this regard relating to the most frequent cause of nephritis in children, that complicating scarlatina, makes this strikingly manifest. Almost without exception, writers speak of scarlatinal nephritis as a simple entity whereas there are certainly two forms of the disease. Niemeyer[1] states that acute croupous nephritis and parenchymatous degeneration of the kidneys both complicate scarlet fever. Delafield[1] says "most cases of scarlatina are complicated either by acute parenchymatous or diffuse nephritis," and so others distinctly assert the existence of more than one form of kidney complication in scarlet fever.

In connection with the recitation of the subjoined case it might be well to glance at the distinctive features of nephritis in children and in this way, perhaps, demonstrate certain of the peculiarities of the latent affection in these subjects.

What, then, are the differences, if any, between nephritis in adults and in children? They exist, it is believed: 1st, in the relations of the etiology to the disease; 2nd, in the relations of the distinct character of the group of symptoms to the disease; 3rd, in the relations of the prognosis to the disease; and 4th, in the relations of the acute and chronic forms of the disease. With regard to the etiology of the first, in adults, nephritis is due in the vast majority of cases to direct exposure to cold, damp or wet; less frequently it complicates certain infectious diseases, and in other instances it is caused by pregnancy.

According to Niemeyer[2] croupous nephritis, the form that is companion to the zymotic diseases, etc., is the one most frequently observed in children. Of the parenchymatous nephritis he observes: "chief among the pre-disposing causes is the temporary, and in a still greater degree, the continual exposure of the skin to the effect of cold and moisture." And of this form he speaks of its frequency of occurrence "far less in childhood than in more advanced life." In childhood, kidney disease is the result, almost always, of some zymotic disease, in the great majority of cases, scarlet fever; and is very rarely of idiopathic origin—so rarely, indeed, that in many of the text books on Children's Diseases no special mention is made of nephritis except as complicating

[1] Practice of Medicine.

[1] Pepper's System of Medicine.

[2] Loco citato.

one or another zymotic diseases. West[1] says that three-fourths of the cases of nephritis in children occurs after scarlet fever[2].

Tanner & Meadows[3] declare that probably nine-tenths of the cases of nephritis are due to scarlet fever, and further states that "acute idiopathic inflammation of the kidneys is undoubtedly a very rare affection in childhood . . . . . We cannot call to mind a single instance within our own observation." Day[4] quotes from Dickinson (at Children's Hospital) a series of 103 cases in which 75 were due to scarlet fever and but 5 to exposure to cold[5].

Rilliet & Bartley[6] cite 416 cases of nephritis in children, 364 of which were secondary and 56 primary or 13.4 per cent. Of these 13 per cent. some were caused by poison, copaiba, cubebs, turpentine, squills, iodine and above all cantharides.

Bonchut (Maladies de Noveau Nés) also states of nephritis of childhood, that it is "very rarely it occurs primarily, but I have seen examples." Thus we infer that nephritis in adults in most cases being due to exposure, it differs in this respect from this disease in children which is seen, in the great majority of instances, to occur as a complication to some zymotic disease.

The symptoms of nephritis in children are more pronounced and less variable than those of the nephritis of adults. In fully one-half the cases in adults the access of the disease is insidious or disguised so that it sometimes is not recognized until coma or a convulsion makes its appearance.

Mahomed[1] in discussing 100 cases of granular kidneys says that "only 26 per cent. of these cases presented the ordinary symptoms of Bright's disease, such as would have led to their disguises during life." William Carson[2] cites several cases of latent kidney disease in persons of advantages and education (one a physician) whose symptoms were so slight that they did not merit attention until suppression or uræmia set in. M. Debore[3] reports three cases of sudden death in old people aged respectively 70, 77 and 66 years, the subjects of interstitial nephritis (and cardiac hypertrophy) who, during life, exhibited no symptoms whatever, and with the exception of a slight dyspnœa for a few hours in the third case, gave no pressage of impending dissolution.

McBride[4] goes further and lays down a combination of symptoms, which when in sufficient accord announce the existence of renal disease before the more diagnostic signs or the urinary changes appear[5]. In corroboration he gives the histories of six such cases (adults) and adds that he has at least six more "now under observation and in which although the symptoms and signs usually considered as diagnostic of the small kidney have not thus far declared themselves, yet I feel very positive that before long they will be found to be present."

In the nephritis of children œdema or anasarca is almost always present (at least in those cases where the disease is severe enough to run a more than transitory course) together with fever, at the outset, vomiting anorexia and the changes in the urine.

Every practitioner can testify to the proportionate frequency of such a case as this in persons of middle life and beyond. He is called to see a patient who can give no distinct history of previous illness, though perhaps has complained of odd pains and bad feelings for some months before. The patient after an exposure has been attacked by an acute pleurisy or bronchitis. After treatment for a week, the fever has disap-

[5] These are: (*a*) Persistent high Sp. Gr. of urine.
(*b*) Frequent presence of large crystals of uric acid and more occasionally Oxalate of Lime.
(*c*) Persistent high arterial tension.
(*d*) Beginning hypertrophy of Left Ventricle.
(*e*) Murmurs due to high arterial tension, or arteritis deformans.
(*f*) Endarteritis Chronica.

peared, the pain in the side or cough subsided but still the patient is worse instead of better than he was the first day of his sickness. There is, no doubt, headache, complete anorexia, perhaps vomiting, perhaps diarrhœa, he cannot sleep and feels feeble and confused. His pulse is probably slow and hard, his temperature but little elevated. At once the doctor's attention is called to the urine which, as expected, might be found scanty and containing albumen and casts.

But such a picture is an unusual one in children. In the chronic forms of the diseases, the nephritis, if not a continuation of an acute attack is almost always associated with and dependent upon an hypertrophied heart[1]. And as these cases often remain dormant for months and perhaps years, the renal affection may be supposed to be not yet fully established; but when once established, the characteristic complexion, the pale mucous membranes, the bad health, and the œdema (which will probably be found, to a greater or less extent) make the disease sufficiently manifest to avoid confounding it with any other malady.

In the acute forms in children—in the great body of cases that follow or accompany scarlatina or diphtheria, it is not of infrequent occurrence, where even from day to day the urine is examined, to note the access or exacerbation of fever and even puffiness of the eyelids and face before the albumen is manifest in the urine. (And, indeed, in some cases the œdema and other symptoms may exist without any changes in the urine being appreciable).

The converse of this state of things is also true, and is of more frequent occurrence, namely, the presence of albumen in the urine without any general symptoms of nephritis. There are those who claim it may be thus found from the altered character of the blood, without renal disease and others, that it is due to a mild form of parenchymatous degeneration (or inflammation) of the kidney.

In childhood's nephritis when of sufficient severity to produce marked and characteristic symptoms in the patient, almost all authorities agree in the statement that dropsy is a symptom rarely absent. "The beginning of kidney complications (in scarlatina)," says Dr. Eustace Smith[2], "is generally announced by vomiting, headache, loss of appetite, a dry skin and pallid complexion, an irregular pulse and a rise in temperature." Then œdema, etc., "in a certain proportion of cases, uræmic symptoms occur." He makes no mention of latent cases with severe terminations.

Bartels[1] states that dropsy is "a symptom which is scarcely ever absent in the severer cases of acute parenchymatous nephritis, although very often absent in the milder cases."

Henoch[2] says that in the majority of cases there occurs œdema, more or less. Vogel[3] declares the rule to be that "in nephritis after scarlet fever, anasarca and effusion of serum into serous cavities take place."

J. H. Ripley[4] places himself in accord with the above statements and says that "dropsy is one of the earliest and most constant symptoms of scarlatinal nephritis." And these conclusions are further established by the fact that the current medical literature while attesting to the frequent occurrence of kidney disease with latent symptoms in adults most positively attests to the infrequency of this condition in children.

3rd. With regard to the prognosis the gravity of which in nephritis of adults and its favorable character in children is a subject of such frequent observation that the reference to the following collection of cases of death from kidney disease may dismiss the question. Roberts[5] gives the total number of deaths from kidney disease during one year in England as 3342—of these but 143 (4.2 per cent.) were under 5 years of age and 294 (8.7 per cent.) were under 15 years of age.

4th. The infrequency of chronic nephritis in children and its corresponding frequency in adults is also of daily clinical observation. Flint[6] says that chronic Bright's disease "occurs very rarely in infancy and childhood" and gives a table of 52 cases, not one under the age of 10 years. All authorities are necessarily of accord on this subject and further quotation is superfluous.

The bearings of the etiology, the distinctness of symptoms, the prognosis and the acute or chronic character of the disease on nephritis in children, in reality, seem to depend on the very fact that this disease occurs in the young almost always as a complication to a zymotic disease. It is, therefore, acute; and it presents, very

[6] loc. cit. p. 772.

generally, distinct signs at its access and can be accorded a favorable prognosis.

With this view accepted, the conclusion at once appears that latent nephritis with suppression of urine is a rare occurrence in children.

Our own experience, the authority of the text books and the clinical records prove the truth of this proposition. And perhaps the truest means of proof is the knowledge of the fact that so few cases have been reported in medical literature during the past few years; whereas, less interesting and unusual cases of fondroyant symptoms in adults, the subjects of a nephritis which did not previously manifest itself, and cases of sudden suppression of urine due to different causes are of frequent citation in the journals. This is clearly shown, and as well the comparative infrequency of suppression in children in the very elaborate monograph of Dr. E. P. Fowler,[1] in which he describes 93 cases of complete anuria of long duration. Of these, 15 altogether were under the age of 20 years. And of these, 2 were due to valvular occlusion of ureter; they were marked by distinct symptoms. Three cases occurred with corrosive sublimate poisoning. One followed measles and gave no symptoms, and recovered. Six were the result of scarlet fever; the oldest of these was 15 years of age. In the reports, three of these cases mentioned no symptoms. In one there was but headache; in another but vomiting; and the other presented vomiting, headache, coma, etc. Three were due to uncertain causes; one, with distinct symptoms; one, not stated; even the termination of the case not given; and the other gave no symptoms at all. Hence, in these 93 cases of suppression of urine collected through the journals (issued during a period of 100 years), but seven were possibly instances of latent nephritis in children.

Now, in speaking of latent nephritis, it should be borne in mind that these cases do not constitute a separate form or variety of kidney inflammation, they simply present an aspect of the disease. An aspect which will be found to be identified by a certain constant symptomatic group, the gravity of these symptoms and the often fatal termination of the case. But, it is indeed a fact, that one of several pathological conditions may be the cause.

Latent nephritis, with suppression of urine might be defined as an existing nephritis giving no symptoms, or none that are distinctive of kidney disease until partial or complete suppression of urine sets in.

Flint[1] refers to these cases when he says "coma and convulsions may occur as sequels of scarlatina, due to uræmia taking place, without either albuminuria or dropsy" —and speaks of such cases in which even the scarlatinous rash is wanting. Henoch[2] calls attention to the fact that these cases often deceive the attending physician, for without warning, in many instances, "the scene is opened by complete anuria."

The cases found to have been reported or referred to during the past ten years and my own case may form the ground for further conclusions; be these of greater or less importance, there is still no doubt that the recitation of these cases may prove instructive in many ways.

William G——, U. S., aged 4 years, and 6 months. Family history: father and mother both alive and healthy. Patient an only child.

Previous history: had always been healthy and was particularly bright and intelligent for his age. Had never any sickness, or any of childhood's diseases. Condition: fair complexion, well nourished and stout. Present history: saw the patient August 15, 1887. Three to four weeks previously he had complained of ill-feeling and slight sore throat, and was noticed to have some fever, which symptoms subsiding next day, no physician was called at this time. Recovery was apparently complete; the child played about and seemed as well as ever. About two weeks after, or a little over a week before the patient came under my observation he scratched his hand posteriorly at a situation between the metacarpal bones of thumb and forefinger, near the margin of the web, with a tin toy; and the following day while sailing a toy boat in the bath tub, had washed off some of the red paint from the boat on to his hand. He complained of pain and smarting in the scratch. The mother took the boy to a druggist, who gave a carbolic acid wash of fair strength, to be used as a lotion. The following day the pain grew worse, and about the scratch the skin looked red and swollen, and the dorsum of the hand beginning to swell, a physician was consulted. A mild lotion was ordered. But from day to

[1] "Suppression of Urine, etc."—a paper presented to N. Y. Medico-Chirurgical Soc., Dec. 14, 1881.—W. Wood & Co., N. Y.

[1] loc. cit.

[2] loc. cit.

day the swelling, pain and redness increased; and in three or four days a pimple was noticed under the chin. The next day the skin in this location grew red and the cellular tissue tumified, and then papules with pustular apices appeared. No fever was noticed. The boy's spirits remained bright and his appetite good. The swelling of face and particularly of the hand further increasing, the attending physician made an exploratory puncture at the seat of the first injury—only blood escaped. The Doctor then making known to the family his intention to lay open the hand by a free incision the following day, they grew alarmed and I was called in to take charge of the case.

On examination, August 15th, I found the patient in good general condition—appetite good, pulse 80 and strong, temperature normal. Heart, lungs, liver and spleen showed no signs of disease. Throat not inflamed. Tongue coated. The appearance and quantity of urine said to be normal—it was not examined. The dorsum of the hand was red and puffed and like a cushion; the skin quite tense and shining. The point of the incision of the day before was dark looking, from a few drops of clotted blood at the cut; no pus could be squeezed out at this point. No fluctuation at all in the hand, but the tissues had a doughy feel and pitted on pressure. The swelling terminated at the knuckles below, and at the posterior annular ligament above. Lymphatics could not be traced up the arm; glands in axilla not swollen. Under the chin the skin was red and shining and greatly puffed. Several small pustules were secreting a thin ichorous matter. The submaxillary glands on both sides greatly enlarged. The situation of the swelling and redness began about half an inch above the inferior edge of the lower maxilla and terminated at the situation of the ponum adami; it extended across from the angles of the jaws on either side. It was located about in the middle line. Iron-tincture of the chloride was given in large doses and poultices, first of flaxseed alone, later with yeast added, were applied to the hand and neck.

For the two following days the patient's condition slightly improved, appetite remained fair and the bowels were moved rather frequently, the motions being watery, dark and bad smelling. The swelling in the hand subsided almost entirely and that about the neck, considerably.

Aug. 18th.—It was now noticed that notwithstanding the diminution of the local symptoms the patient did not continue to improve. He grew sleepy and apathetic; eyes looked dull, though the pupils responded readily enough to light; and he complained and cried when aroused—though when once aroused he might remain bright for half an hour or more. He was profoundly anæmic. The pulse was strong and full and hard and 52; temperature, normal. The condition of the bowels remained unchanged. The urine was asked for.

Aug. 19th.—The patient's general condition, the same. Stupor, slow pulse and normal temperature remain. The bowels moved about four times during the day. The small pustules on the face had now grown to be openings in the skin, each the size of a millet seed and were secreting pus copiously. They gave the skin a worm-eaten appearance, such as is seen in carbuncle—but they did not penetrate into the cellular tissue and no pus could be *squeezed* from any of them. It appeared as if the surface was suffering from rapid molecular disintegration. The hand had returned to its natural size. The site of the incision was black (gangrenous) to the extent of about one fourth of an inch in diameter. No exudation, whatever, from it. In the centre of the dorsum was a dark blue spot that did not disappear on pressure. Sensation in the hand remained. No urine had been passed since the day before; indeed, the family could not well recollect when the urine had last been voided. It was supposed possible that some had passed at the time the bowels moved, though the motions were now not watery, but were rather of pasty consistency. The family were instructed to collect urine in a separate vessel. The treatment was now directed toward establishing the flow of urine, cups and poultices to the back, morphine; nitre and digitalis, internally.

Aug. 20th.—The patient more somnolent and apathetic, skin moist, pupils small, appetite lost, has vomited; the bowels move about every five hours; no urine has been voided, pulse still from 50 to 56 and hard; temperature 98½. Local symptoms at neck and hand remain the same. The efforts towards establishing the functions of the kidneys were persevered in. There had been noticed slight twitching about the face and increasing stupor. Still no urine passed. Was seen about 11 P. M. The bladder, by percussion and palpation, found empty. Efforts to pass a catheter were unproductive owing to improper instruments; and while these efforts were persevered in, the boy

screamed and tossed and fought. He worked himself into a perfect frenzy of passion.

The patient was now noticed to be extremely pale, and bathed in a profuse perspiration and the pulse, which ten minutes before was 54 and hard, was now about 200—hardly countable and feeble. He was in a condition of collapse. Brandy and ammonia, etc., were assiduously given by the mouth and hypodermatically and heat applied to the surface of the body, but all with no effect on his condition.

Convulsions supervened and frequently occurred with varying intensity until 4.30, A. M., August 21st, when death closed the scene.

Very unfortunately an autopsy was impracticable, and much was lost that might prove valuable and important. For instance, (1) the identity of the kidney affection, (2) its probable duration, (3), and most important, the relation, if any, existing between the cellulitis and the suppression of urine. It can be conjectured only, therefore, what these relations were.

First, it is possible the kidneys were affected as a complication of the inflammation and poisoning (?) of the hand, perhaps to the extent of a suppurative nephritis (surgical kidney).

Second, the kidneys may have been primarily affected with a form of acute idiopathic inflammation, and the cellulitis supervening and taking on its extensions and grave character from the blood poisoning in consequence of the inactive renal functions. Or, thirdly, the child may have suffered from a light form of diphtheria or scarlatina, (probably the latter), at the time of the slight indisposition that occurred two weeks or so before the child became markedly ill, and that a complicating nephritis succeeded, and that the trifling injury was magnified by the disordered condition of the blood, in consequence of the nephritis.

This sequence of affairs seems to me the most probable for these reasons: the child evidently died directly from suppression of urine due to some kidney disease, and the alarming symptoms of the last few days of his life were due to uræmia.

It is hardly possible, therefore, and not at all likely that the nephritis occurred as a complication to the cellulitis, since a suppurative nephritis or any form of inflammation of the kidney would hardly have had time to develop and kill in the few days since the time the symptoms of the cellulitis became marked enough to cause systemic disturbance to the end. Certainly it could not have been a suppurative nephritis. That there was some blood dyscrasia is also evident; but there was no apparent poison introduced into the system, as far as can be judged—positively none through the wound in the hand. The causes and the nature of the cellulitis, as it first appeared, testify to that. Is it not more likely, therefore, that this dyscrasia was the result of an ante-dating nephritis?

And though there is no positive evidence that the child suffered from any infectious disease, yet the rarity of idiopathic nephritis in children and the many occasions when (especially) scarlet fever have been overlooked and not diagnosed until its complications or its contagion made it manifest, would make it appear more likely that the nephritis was due to some such cause. However, and unfortunately, both the cause and nature of the kidney affection must remain problematical.

Search through the medical literature for the past ten years shows but few cases of latent nephritis in children, as has been before stated.

For the sake of brevity these have been arranged in tabular form, giving name of reporter, where published, sex and age of the patient, the duration of the anuria and its degree, previous symptoms, if any, of nephritis; and whether œdema was at any time present; cause of nephritis; termination of the case and the results of autopsy, if performed.

It is not believed that in ten years other such cases have not occurred. First of all the condition described is not of such marked definition that one would feel disposed to always report his case. Perhaps in some the true affection is overlooked and the death certificates are written convulsions, or some are looked upon simply as a sad and sudden termination of scarlatina. But the fact remains, these cases are rare.

Rehearsing the characteristic features of the cases in the above table and comparing them, it will be seen that the majority of the cases were males (as in all forms of nephritis); only one girl appearing in the list, and in three, sex not stated. The average age is about 6 years. The youngest 1 year the oldest 17. The few cases of nephritis reported in infants at the breast seem to have been characterized chiefly and in some instances solely by œdema. Bouchut[1] cites two cases for the purpose of proving this

disease *can* occur during infancy. J. M. Booth[1] reports a case, 3 months of age, and J. R. Morrison[2] mentions two such cases aged respectively 3½ and 5 months; in all œdema was the chief and marked symptom.

In one half the cases the anuria was complete, in the rest partial and not stated.

None gave distinct evidence of nephritis before the suppression occurred. The nephritic symptoms usually appeared simultaneously with the anuria.

In those instances where the suppression was not absolute these symptoms developed gradually and insidiously, so that it would be difficult to date their exact beginning.

Bnt whether insidious or absent, in all the early prominent and only diagnostic sign of the renal disease was the anuria[3]

In but three cases are the post-mortem appearances given; these presented as many forms of kidney inflammation, namely, acute diffuse nephritis, conjestion of kidney and suppurative nephritis.

Henod[4] speaks also of a case of hæmorrhagic scarlatinal nephritis, which presented no symptoms during life. That cases of albuminuria in the course of zymotic diseases may occur without actual kidney lesion has been referred to. But cases of this description have been reported as of parasitic origin, as well. Among others, Gancher[5] broadly concludes that "diphtheritic nephritis is a parasitic nephritis." He gives a fatal case which presented the same bacteria (lesser number) in the blood as in the urine.

The forms of nephritis in the cases without post-mortem history are unknown, but they are probably not identical.

Particular attention is called to the fact; that these cases, with one exception, did not present that commonest of symptoms of kidney implication in children—œdema; not even after the suppression had set in, and

[1] British Med. Journal, 1881, II. p 626,

[2] British Med. Journal, 1881, II. p. 777.

[3] Instances are referred to by several authors where the first sign of scarlatina or diptheria is the nephritis. Others go, as Prof. M. R. Levi, (in Lo Sperimentale, 1885, Nov.), who relates two cases, brother and sister, aged 5 and 8 years, who were brought to him at the Children's Clinic, with nephritis (with anasarca), the first signs of diphtheria that appeared in them; a brother dying of this disease shortly before. Levi claims that the first symptoms of the Diphtheria was the kidney disease, and makes proof of his views, that there can exist a "Diphteritis sine Diphtera," as well as a scarlatina without eruption.

[4] loca citato.

[5] Before the Société de Biologie, in Gaz. Med. de Paris, 1881.

that of these cases, five were of scarlatina origin, one diphtheritic, three doubtful and possibly zymotic, one probably obstructive, and one idiopathic; and, finally, that there were but three recoveries; the obstructive case, the idiopathic case, and one Scarlatina case. The suppression in the first lasted five days, its duration in the second is not stated, and in the third was 30 hours. Dr. Ripley in the report of his case[1], remarks that it is the only instance of prolonged anuria in scarlatina or diphtheria he has seen recover. This viewis attested to by West[2], Bartels[3], Thomas[4] and others.

The following general conclusions are therefore presented:

1st.—Latent nephritis, with suppression of urine, is a rare affection in childhood, not so in after life.

2d.—It occurs usually as a complication of some zymotic disease, chiefly scarlatina, (as in all nephritis of children).

3d.—In these cases of scarlet fever it appears, usually, from the end of the second to the end of the third week[4].

4th.—It is sometimes impossible to foresee the nephritis—such symptoms as somnolence alternating wiih restlessness, slow pulse, vomiting, diarrhœa, headache and anæmia should always direct attention to the kidneys. But rarely these signs do not occur until after the suppression has set in.

5th.—Contrary to the rule in kidney disease in children, œdema must not be looked for in some cases, either before or after the anuria develops.

6th.—It is known anuria may exist with complete euphonia for several hours, perhaps for days.

7th.—No particular pathological variety of nephritis occurs in these latent cases.

8th.—The prognosis is bad—about three-fourths of the cases die.

The largest quantity of liquid oxygen ever produced was two hundred grams. Yet a certain Paris newspaper finds it expedient to recommend that everybody taking out fire insurance policies, should be obliged to notify the company if there be any liquid oxygen kept on the premises, owing to its dangerous combustion-supporting properties!

[4]Delafield (loc. cit.) remarks that "kidney symptoms may develop from the very first day to the end of the ninth week—that the largest number of cases develop symptoms on the 14th, the next largest on the 21st, and the next to this on the 7th day. (Tripe).

COMMUNICATIONS.

THE OPERATIVE TREATMENT OF APPENDICITIS.*

BY THOMAS S. K. MORTON, M. D.

Since being requested by the directors a few days since to open the discussion of the operative treatment of appendicitis, I have taken a glance through the literature of the subject in order to offer, as it were, a concensus of opinion regarding the present status of the subject, as well as to draw conclusions from such personal experience as has fallen to my lot in this direction. Now I find myself embarrassed by the necessity of limiting my remarks to the few moments which are at my disposal and to crowd into them even bare mention of the most salient facts. Hence much must be entirely omitted and other points given scant attention.

The discussion being limited to operative treatment, pathology and diagnosis—perhaps the most interesting branches of the subject even to surgeons—are not to be touched upon, except incidentally. But I cannot refrain in passing from saying that as the ratio of appendicular to cæcal inflammatory affections is probably 100 to 1, hence that *differential* diagnosis in diseases of this region, which is usually impossible prior to surgical interference, is neither necessary nor important, as operative procedures up to the point of establishing diagnosis are identical for all affections of the cæcal region. Again, I would condemn without qualification needle explorations, as an aid to diagnosis. The procedure is inherently dangerous, and will furnish no indication that cannot otherwise be obtained.

The number of cases of appendicular disease discovered when we are upon the outlook for them is astonishing. A large proportion of peritonitis cases in males, and especially in children, arise from this disorder; and in all cases presenting abdominal pain, whether acute, chronic, or recurring, no matter where referred, we should think of and examine for possible appendicitis. I have come to be very skeptical of such conditions as are described as abdominal "cramps," "colic," etc., particularly when of frequent recurrence. Curious as it may appear, yet it is a fact that the great majority of the profession are only now beginning to recognize cases of appendicitis and its

*Read before the Philadelphia County Medical Society, at a Special Meeting, September 28th, 1891.

consequences as such. Formerly the affection was almost universally diagnosed as anyelse except itself. But just in proportion as the disease continues to be more certainly recognized, so surgeons are more early operating upon cases which demand interference, and, as a consequence, the mortality from the disease, as well as from the operation, is very rapidly on the decline.

Keen has said that, "the first indication in appendicitis is to call a surgeon," that the physician, who almost invariably first sees the case, and the surgeon may together watch the case, and if operation becomes necessary, interference may be prompt and well timed; while the surgeon will have the great advantage of being already familiar with the case and not disposed to delay the operation that he may acquire such familiarity. Again Mynter has well said that "we are utterly unable to judge correctly from symptoms alone of the extent and severity of appendix lesions, and for this reason alone abdominal section is and must be the safest method of treatment" in many cases.

When shall we operate? Judging from the cases that I have observed and from the writings of others, I would formulate as a good working rule: to operate not later than the third day of disease, if the patient up to that time has failed to markedly improve under rest, restricted diet, purgation, and topical applications. Especially should this rule be adhered to in cases where we have failed to move the bowels—these are apt to be the fatal ones. Further than this, we should invariably operate as soon as the presence of pus is assured; when peritonitis is developing or spreading; when signs of sudden rupture of an abscess into the peritoneal cavity appear; and where septicæmia from septic absorption is taking place. In children operation must often be performed earlier than in adults, as with them the malady is more speedy in development, more fatal in tendency, and shows a greater proclivity to involve the general peritoneum.

But let me emphasize the point that *pain* is not a reliable symptom (especially when opiates have been administered) from which to judge as to whether the patient is better or worse; most weight should be given to the strength, temperature and condition of the bowels, stomach and general abdomen.

Mr. Treves urges that operation shall not be done until the fifth or sixth day, or later. But from my reading and experience I think this is too late. He argues thus because few deaths occur before the fourth or sixth day. These cases, however, really begin to die, the third, fourth, or fifth day, although death may not actually take place before the sixth day, or later, when the possibility of benefit from operation has passed. If the case is progressing well and operation is being postponed it should be watched and observed frequently and most carefully. For we cannot predict at what moment an appendix abscess may perforate into the peritoneum or other dangerous complication arise that will instantly demand operation.

If the case is operated upon early the chances of recovery, as a rule, are exceedingly good. The mortality of appendicitis during the first forty-eight hours is almost *nil*, and the operative death-rate at that time is equally low. Later both rates increase, but the former much more rapidly than the latter. The patient, in this disease, is generally strong and well up to the moment of seizure, at which time the danger of operation *per se*, is at the minimum. Such mortality as results in operations for appendicitis, has been mainly incident to undue delay. When physicians and surgeons generally have learned definitely to recognize such cases as are operative at a time before the vital forces have been too much sapped or dangerous complications have arisen, then will the mortality rate of both disease and operation remain steadily at a low figure.

Then again the local conditions from an operative standpoint are much less serious in the early stages. We have at first simply a swollen appendix with infiltration and perhaps a few adhesions. We then do not have to deal with fœtid abscess, foul surroundings, and sloughing tissues which may have given rise to intestinal gangrene and other complications, as well as to the impossibility of securing primary union of the wound. Hernia is more common as a sequel in cases where the operation is performed late and where the surroundings are gangrenous, and we can only secure healing by secondary intent.

The cry of every writer is for earlier operations. I have found no surgeon who regrets having operated early, but almost all mourn cases that were operated upon too late. No case appears where a mistake in diagnosis has been made, despite the awful array of affections which has been drawn up as liable to render uncertain the recognition of appendicitis. On the other hand very many cases opened with the expectation of finding other disorders have proved to be appendicitis.

Who shall operate? The operation for appendicitis may prove to be the most easy;

but it is never trivial, often trying and sometimes even baffling the skill of the very best abdominal surgeons. Hence he who undertakes operation for the removal of the appendix for disease should be equal to dealing with any of the complications and emergencies of abdominal surgery. There is scarcely a complication which occurs in abdominal disease that may not be met with in operations upon the appendix. If a man knows only how to reach the appendix it is not enough, he must be able to cope with any accident or emergency that may arise. Therefore he must have had training in general abdominal surgery.

How shall we operate? There are two classes of cases to be dealt with. One, the acute, where there is perhaps abscess, perforation or general peritonitis; and, second, those where operation is undertaken in the interval between acute attacks as a prophylactic measure. The indications for the latter will be considered separately further on.

The preparations for the operation are usually of a hurried nature on account of the active nature of the disease and the sudden determination that operation has become imperative. Previous purgation, if successful, will make the chances of recovery much more bright, no matter during what stage of the disease operation is performed. Cases where the bowels have been kept open from the outset of attack are always most favorable. Locally the abdomen should be cleansed as for any other operation.

All writers now agree that the incision should be lateral. Median incision is only permissible when diagnosis from other abdominal disease is not clearly made out, as where we have had suddenly developed, violent peritonitis arise without obvious cause. Even should the median incision have been made and the affection prove to be appendicitis, especially if septic, a lateral incision should still be resorted to, for it is exceedingly difficult and dangerous to drain septic appendicitis cases through a median incision, and often it is impossible to deal with complications, or with the appendix itself, except by the more direct route. I am of the opinion that almost any complication arising from appendix or cæcal disease can best be dealt with through the lateral incision. No writer has regretted making the lateral incision, although many have regretted entering through the linea alba.

This incision should be about three or four inches in length and terminate one inch and a half above Poupart's ligament. It should be carried down to its full extent through the right linea semilunaris until the peritoneum is reached, avoiding if possible the epigastric artery which normally would be situated at the inner side of the lower extremity of the wound. I have seen serious secondary hæmorrhage from division of this artery. Having reached the peritoneum, if one does not at once get into an abscess cavity we must exercise great caution not to open the gut by mistake. Sometimes adhesions will be found binding intestine to the peritoneum in the line of incision, and in these cases it is will to go at once to the lower or upper extremity of the wound, get into the general peritoneal cavity and work upward or downward, as the case may be, to the cæcum, when all adhesions can be separated by the finger or knife and the peritoneum opened to the full extent of the external incision. Of course the incision should be increased in size if there is any difficulty in getting into the peritoneal cavity, or subsequently if difficulty arises in any manipulation from lack of working room. But as a rule the smaller the incision the better, because of the less risk of subsequent hernia. The head of the colon is then sought out. If now it is found difficult to determine the site of the appendix, the longitudinal muscular bands of the colon may readily be followed down to their termination in the root of the appendix. Then by careful manipulation one can usually trace the appendix, even through a mass of dense adhesions, and dissect it out. As a rule, in acute cases the organ will be found more or less free in the cavity of an abscess with its tip perhaps adherent to omentum or bowel. The appendix is to be dissected out with the finger, and often we do not see it until it is brought out of the wound ready to be ligated off. This manipulation closely corresponds to the modern one of removing the uterine appendages.

Now, what shall be done if the appendix is found to be bound down by a dense mass of adhesions, and if it would take a long dissection and endanger life from the time required to complete the operation? Under these circumstances I would advise that the appendix be left alone rather than run any great risk of the patient's life to complete an ideal operation. We are often compelled to operate to save life, and that alone, even if we do run the risk (as of leaving the appendix) of recurrence. I do not regard the operation as complete in any case unless the appendix is removed, and we should never

hesitate to dissect out or remove the organ simply for fear of opening up the general peritoneal cavity.

Cases of recurrence of with great violence of symptoms are upon record where operation had been performed and the appendix not removed. Here, again, we have a parallel with the removal of the uterine appendages. Who considers that he has done a complete operation when he simply drains a pyo-salpinx? yet there is a small (but constantly decreasing) proportion of these cases that must be so treated rather than endanger life by prolonging operation, shock, and anæsthesia.

If the appendix can be excised, the question arises as to how we shall deal with it after separating all adhesions. In septic cases it will be found usually impossible to invaginate the stump, after cutting away the appendix, into the cavity of the cæcum and approximate peritoneum over the remaining opening. Where we operate between attacks the appendix, as a rule, can be dealt with in this manner and the investigated stump retained by a few Lembert sutures approximating the surfaces of the cæcum over the aperture. When, however, the organ and its surroundings are swollen and gangrenous the conditions are such that it is generally impossible to investigate the stump. It has seemed quite sufficient in these septic cases to ligate the appendix a quarter of an inch from its root with strong silk, and then cut off both the appendix and the ligature ends. But ligatures will neither become absorbed nor encapsulated where septic conditions are present, and I have seen the threads coming out of the wounds months afterward from a persisting sinus, or by ulceration. So it occurred to me that we might resort to the old surgical procedure of leaving one end of the ligature hang out of the wound. That experiment I am now trying in a recent case. Chronic ligature sinuses assist in the production of hernia by interfering with solid union.

Frequently the appendix will be found with a mes-appendix. This should be ligated *en masse* or in sections, and cut away from the appendix. Then the appendix is ligated at its base and removed. Removal of the appendix is almost universally recommended, but Mr. Treves has simply straightened an appendix which he found angulated by adhesions and left it in the wound. Mr. Tait has practiced in more than one case splitting open the appendix and inserting a fine drain tube into it. From these instances it will be seen that there exists in some minds an almost superstitious fear of removing the appendix. Certainly no sentiment can exist concerning the ablation of the appendix such as there is in regard to the ovaries and Fallopian tubes? Having the appendix once in hand, it does not add to the dangers of the operation in the least degree to remove it, while recurrence of the disease is thereby rendered impossible.

Occasionally the appendix is found to have sloughed off at its root, leaving a ragged opening into the cæcum. In one or two cases the edges of the opening thus left have been inverted and closed successfully by Lembert sutures. In others the wound was left entirely open and packed with gauze; an intestinal fistula or artificial anus formed, but in time closed spontaneously. Yet another required a subsequent operation and Lembert sutures before it was cured.

Some surgeons recommend that in septic cases a little flap of peritoneum be sewed across the stump, or that it be tucked under a bit of omentum. I can see no advantage in this. It prolongs the operation and does no good, while by so doing we risk the formation of a secondary abscess pocket. Very many appendix stumps have been simply dropped into the wound again after ligation; fæcal fistulæ did not form and the wound closed satisfactorily.

Any portions of gangrenous omentum presenting in the wound should also be ligated beyond the junction with healthy tissues and cut off.

Any small openings into the peritoneal cavity may next be sewed up carefully if the general peritoneum does not require drainage.

Then in regard to irrigation. If the general peritoneal cavity has been opened extensively, or if it is septic, it should be thoroughly washed out through the lateral incision. If it has not been involved the abscess cavity and wound alone should be irrigated. Under the latter circumstance we may employ a strong bichloride solution, but if the peritoneum is to be flushed nothing but water should be used.

If the general peritoneum has been septic or extensively opened or manipulated it is essential to use drain tubes to the base of the pelvis. The ordinary straight glass tubes do not answer well, and rubber is not satisfactory. Here I have a collection of angulated and curved glass tubes, most of which have been used with great satisfaction in appendix cases. The angle makes it possible to get the tube to fit well over the brim of the pelvis, yet not to project awkwardly from the

lateral wound. By attaching a few inches of rubber tubing to the end of the ordinary cleansing syringe the bent tube can be cleaned.

The suturing of the wound is especially important if the case is *not* a septic one. Then the tissues should be sutured, layer by layer; this gives the best assurance of firm primary union and the avoidance of hernia. If, however, the wound is septic and drainage or packing is employed, secondary union is inevitable. But I would still urge that the wound be as carefully sutured as possible in all cases, leaving ample room for exit of the drain-tube or packing. And I might say, in passing, that simple packing with strips of double cyanide or iodoform gauze will be found to answer all purposes of drainage in cases where the general peritoneum does not also require drainage.

Some surgeons advise using no stitches in septic cases, but simply packing of the entire wound with gauze. But by suturing we can usually secure primary union in a portion of even a foul wound, and temporary stitching has appeared to give a certain anchorage and support to the subjacent intestines, which, when the sutures are removed, is more or less retained. The stitches, of course, are to be removed, one or more at a time, when swelling, infiltration, tension, or deficient drainage become apparent. Strips of adhesive plaster should be employed to give the wound support and approximation during granulation.

Complications such as gangrene of intestine or mesentery, must be dealt with upon general principles of abdominal surgery. If intestinal obstruction complicates the case, the site of obstruction should be ascertained, and the condition relieved, if possible, before closing the wound. Cases in which obstinate constipation has existed up to the time of operation, should be examined during its performance for possible obstruction.

Should peritonitis develop subsequent to operation, and not speedily yield to active purgation, the wound must be reopened, and the abdominal cavity irrigated thoroughly and drained. Continued obstruction could probably be best dealt with through a new median incision rather than through the original wound.

As soon as the patient comes out of ether, if the bowels have not been well emptied before operation, it is my custom to at once begin the administration of one-eighth grain doses each of calomel and podophyllin at twenty minute intervals, until purgation is accomplished. This usually takes but a very few hours. Later salines may be employed if required.

Full strength peroxide of hydrogen solution has given me great satisfaction for cleansing and washing the wound-cavity when suppuration commences and sloughs are forming—it greatly facilitates the separation of the latter. Persisting fæcal fistulæ usually close spontaneously in time. Should they not, then reopening of the parts several months later, and suturing of the cæcal or other opening with Lembert sutures is indicated, and has proved successful in several instances.

In conclusion, let me say a word in regard to operations undertaken in the interval between acute attacks, or, what may be termed, *prophylactic operative treatment.*

The indications for this measure are: Constantly recurring attacks (usually indicative of the presence of a foreign body in the appendix), which interfere with the individual gaining a livelihood, or render his life a constant burden, worry, and expense to him; also, where recurrent attacks have taken place in those, as seamen, hunters, explorers, etc., who are liable to be again attacked when they may be out of reach of adequate surgical aid. In this class of patients, operation during quiescence of the disease should be considered, and perhaps urged by the medical attendant. In most other cases, I do not think excision of the appendix should be often attempted in the quiescent period. We should rather counsel delay until the onset of the next acute seizure, when we can conscientiously urge the removal of the offending organ at once—that is, on the first or second day. This advice is given principally because of the great difficulties and dangers frequently encountered in operating during the intervals of attack when the adhesions are extremely dense. In fact, patients have died as a result of the long time required to complete the operation, because of the elaborate dissection required to free the appendix from its matrix of densely organized adhesions. In several instances the very best operators have been compelled to abandon these operations in the interval of attacks, not only without having been able to remove the appendix, but also without having been able to discover the organ in its bed of adhesions.—For discussion, see Society Reports.

Mix acids with water by pouring the acid into the water and not the water into the acid, as the latter process may cause an explosion of steam.

Society Reports.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

SPECIAL MEETING SEPT. 28th, 1891.

Dr. Thomas S. K. Morton read a paper on "The Operative Treatment of Typhoid Fever" (see page 808).

DISCUSSION.

Dr. William Pepper:—I scarcely think that I need say much, for the subject as presented is largely one of operative technique, that the views of a purely medical clinician possibly are scarcely appropriate. Assuming that the subject under discussion includes all the acute inflammatory affections of the appendix, cæcum, and pericæcal tissues, much has been said to which I should take strong exception from the standpoint of a pure medical practitioner. I believe that if every case of appendicitis were operated on, the mortality would be tenfold what it now is. For more than a quarter of a century I have been in the habit of seeing a great many cases of appendicitis every year. I base this statement partly upon the classical researches of Dr. Fitz, who has demonstrated more clearly than any other, that in a large proportion of cases of right iliac trouble the appendix shares in the trouble, if, indeed, it is not the starting-point of the trouble. Now, as a general rule, these cases recover under medical treatment and remain permanently well afterward, no surgeon being associated in the treatment of the case. In no year during the past two decades, have I failed to see a considerable number of cases of this kind and the cases that have demanded operation, as contrasted with those which get perfectly well without operation is probably at least as one to a score. I think that the assertion that as soon as appendicitis is suspected the surgeon should be called in, is quite out of accord with the experience of physicians the world over. As I have said, I think that the vast majority of cases, in first attacks at least, undergo resolution and terminate with some more or less permanent injury to the appendix, but without going on to the production of abscess, provided the treatment be instituted early and be kept up faithfully. In many of these cases there is early development of induration and fullness in the right iliac fossa, and in proportion as this appears early is it likely that the case will run a favorable course, or, if later, it develops signs of suppuration it will admit of treatment by the simple Willard-Parker extra peritoneal incision. In proportion as the symptoms are violent, without localizing phenomena in the right iliac fossa, is there danger that rupture of an abscess has occurred, to be followed by the development of general peritonitis. I am entirely at one with the speakers who insist on early operation where this latter condition exists. I have had the operation performed as early as thirty-six hours from the initial symptom, and have found suppurative peritonitis already present. I am sorry to say that in this case there was a fatal result, as will sometimes happen in the hands of the most skilful operator. I think that the experience of all will confirm the statement that the operation is a grave one. The operation of laparotomy for disease of the appendix, whether it is exploratory or radical, is not a trifling operation, and I have rather extensive records to show that it is an operation attended with a great deal of danger, even in the hands of the most brilliant operator. I should protest against the view that, as soon as the diagnosis of appendicitis is made, an operation should be encouraged.

I believe that it is possible to note the time, in a certain large proportion of such cases, when the symptoms indicate the spread of inflammation, and then I think that the operation cannot be too promptly performed.

The question of diagnosis remains, in spite of all the good work that has been done, a most difficult question. The McBurney point I believe to be largely without value, uncertain in its location on account of the very varying relations of the appendix, apt to be mistaken for points of tenderness due to wholly different causes, and apt possibly to be mistaken for sympathetic tenderness of nerve points in the abdominal wall. I therefore believe that this sign, from which much was hoped, will prove to have very little positive diagnostic value.

The rectal examination has seemed to me to be of very material value; it is true not so early as we could wish, but in many operative cases I have found the roof of the pelvis altered as determined by a careful rectal exploration. I feel that I am wholly incapable of putting in words, nor do I know that this has been done, the exact differential diagnosis of the cases which demand early operation. While this is true, I would still urge the view that this does not justify

the subjection of every patient with appendicitis to laparotomy. I trust that we shall learn to arrive at a more exact differential diagnosis. There is a combination of a certain history of the development of the case, which taken in connection with the facies, the general symptoms, and the abdominal condition, as determined by external and by rectal examination will, in the hands of an experienced clinician, serve in the great majority of cases as a basis for this diagnosis. It is difficult to state this in terms as precise as we should state the terms of a diagnosis of encysted pleurisy, but I think that in those who have studied these cases will recognize a *tout ensemble* which admits of a diagnosis of those cases which should be subjected to early operation. I believe, on the other hand, that in the great majority of cases we are justified either by the mildness of the symptoms or the localizing tendency in the right iliac fossa in urging medical treatment, and this is further justified by the very frequency of these cases.

Lastly, I shall say a word as to my entire opposition to operation in the majority of cases in the interval between recurring attacks. I think that medical records will show too many cases where thorough treatment, hygienic, dietetic, and medical has been followed by complete cure. I have had so many such cases in which cure has occurred after a number of recurrent attacks, that the adoption of a general rule that where a patient has had two, three, or more attacks he should be subjected to a grave operation like laparotomy, seems to be a dangerous postulate. I think it better to secure the consent of the patient to the performance of the operation, should alarming symptoms make their appearance in any attack, and then to persevere with carefully regulated medical treatment. There are cases unquestionably where the conditions of the patient, the fact that he may be attacked when out of reach of skilful surgical aid, make it necessary for the patient to decide between a change in his habits of life and an operation. These are exceptions, and it does not follow that a general rule that laparotomy should be performed in the interval between recurrent attacks of appendicitis, should be laid down.

Dr. Keen:—I wish to take exception to what Dr. Pepper has said in reference to not calling in a surgeon in a case of appendicitis until operation is needed. I think that it is of the most urgent importance that the surgeon be called in not to do an operation, but for consultation for his judgment rather than his knife—not necessarily to do a laparotomy immediately—but for the purpose of being ready to deal intelligently and promptly with the conditions when the time for operation arrives. He should not be called in, then, new to the case and unfamiliar with its features, and desiring, therefore, time to become familiar with it, unless the case is so serious that operation is evidently and instantly required. The surgeon should be with the physician the moment the diagnosis is made, not to do the operation then but to be ready to do it the moment that it becomes necessary. I have seen cases lost, and have lost some myself, I am sure, from delay, from the natural unwillingness to plunge right in and do a laparotomy the moment we are called to see a case that really needs it, and yet from unfamiliarity is regarded as a doubtful case. We should have every point at our fingers' end and be familiar with the fluctuations of the symptoms. Then our aid will be much more valuable than if we are called in only when the emergency for operation has arisen. A plain case every one can read and decide quickly. It is the doubtful cases that need carefully weighed decision—a snap judgment on a sudden call is more apt to be wrong than right.

Mr. Thomas Bryant, of London:—I assume that the term appendicitis as here used, includes all those cases which have been spoken of as typhlitis, peri-typhlitis, and by other names, all of which have probably more or less connection with the appendix itself. Starting with that assumption, I at once proceed to the treatment of appendicitis. Here at the beginning, although a surgeon, I agree very strongly with the observations of Dr. Pepper. I am convinced that operative treatment is most valuable in appendicitis. I am equally convinced that delay in operating is the wisest course in the majority of cases. I should like to say in this place that it seems to me that the authors are a little mixed in regard to the classification of these cases. They have included cases that are acute from the beginning, with cases that are not acute, that have a slow and steady course. The cases that have a slow and steady progress, that begin with localized pain in the right iliac fossa, accompanied with tenderness and soreness, less swelling without any very acute symptoms, are cases which you must feel can be dealt with satis-

factorily without the surgeon's knife; I do not say without the surgeon's aid, but without the surgeon's knife.

Dr. Morton spoke strongly of the use in these cases of calomel and podophyllin. Such statements rather startled me and I should have been glad to have had some evidence of its value given. I should prefer to follow the line of treatment suggested by Dr. Pepper and not give calomel and podophyllin in frequently repeated doses. I would rely more upon rest, belladonna externally and opium internally, and diet, believing that by such means and knowing that by such means the bulk of the cases are permanently cured. In exceptional cases where these good results do not occur and graver symptoms appear, the swelling increases and symptoms of peritonitis develop, the surgeon's aid becomes of immense value, and certainly where these symptoms do appear and there is a steady progression toward the bad, it is unquestionably time for the surgeon to take a hand. In all acute cases I have no doubt as to the right of the surgeon to interfere. I have seen cases where within thirty-six hours after such acute symptoms it was necessary for the surgeon to expose the part and let out the inflammatory fluids, if not remove the appendix itself. To my mind these two classes of cases which I have briefly described fairly indicate the line that the surgeon should take. Trusting very much to expectant treatment in the least acute cases and surgically interfering early in the acute.

In reply to the question in regard to the propriety of operating, whether or not the surgeon is justified in operating between the attacks, my judgment would decide in the negative. In the majority of cases there is no second attack. If there is a second attack it can be treated on the same lines as the first, only there is a tendency toward interference if the symptoms do not settle down rather rapidly. I say this because I am sure that I have seen many instances where things have settled down after a second attack without any further trouble. Because we have met with cases that after the second, third, fourth, or it may be the eighteenth attack, have at last come to the surgeon's knife, I think that we should not accept that as a decided evidence in favor of surgical interference. In fact, we must be governed by each case by itself, and we should surgically interfere only when we find small chances of nature terminating the case guided by medical skill.

Then we come to the operation. I am not sure that I am quite in accord with the authors of the papers. It is quite true that in doubtful cases of appendicitis—that is, cases in which you do not expect to find a great deal of pus or inflammatory fluid, the incision in the right semilunar line will probably be the best. In this way you come down readily on the cæcum, and you are more apt to find the appendix. The majority of cases with which the surgeon has to deal are not quite in the stage to which I have referred. There is generally much more diffused swelling about the cæcum, and that swelling gravitates backward and upwards, sometimes toward the loin. I can recall a good many cases that I have opened where I was certain the swelling was about the cæcum, where it was backward toward the lumbar region. I can recall several instances in which my attention was drawn more to the lumbar region than to any other part, and it was only by going into the history that I concluded that the trouble was located in the cæcum. The lateral incision is a good one in these cases, but it must be more lateral than the semilunar line. I have made my incision well back, corresponding to the line of the anterior superior spinous process and tending backward towards the loin. In this way you get well at the cæcum and your finger can be readily passed into the iliac fossa. You can examine the part, you can drain the part well and generally by the open treatment, not being too careful to stitch the wound, a good result takes place. I would say that in a large number of cases —my friends may say neglected cases—that an incision more posterior than the semilunar line would be the better one. The incision in the semilunar line should be reserved for cases that have not advanced to such an extent as I have just indicated. If there were time I could give the Society many cases as illustrations of the truth of what I have said.

Another point to which I should like to allude is the question whether or not these are all really cases of appendicitis. In at least three instances of cases which had presented a history of a cæcal trouble, but in which death had resulted from some other cause, I have found cicatrices in the posterior part of the cæcum some distance from the appendix. In two cases that I have treated the evidence pointed to the cæcum as the seat of trouble. In one, a boy, aged twelve years, I incised an abscess, and eventually a large orange-seed escaped. I have no reason to believe that that could have come from the appendix. In the second case a piece of bone that had been swallowed had evidently

passed through the wall of the cæcum and caused suppuration. These two cases presented all the features of typical appendicitis. They were dealt with in the way that I have stated and both recovered. We must, I think, bear in mind that these cases are not all due to disease of the appendix, and that many of these may have no connection with it.

This brings me to another point, and that is whether or not, under all circumstances, it is expedient to search very carefully for the appendix.

In these severe cases should we disturb the parts so much as is often absolutely necessary? We have had to-night good evidence of the difficulty of finding the appendix in some cases. I have always felt that in these cases we should do more harm than good if we searched too far for the appendix. I am satisfied with well irrigating the part and treating it by the open method.

Dr. Morton has mentioned hernia as following the operation. I have never seen this. That may be because the bulk of my incisions have been made posteriorly. I have done many of these operations, and have seen many others done by friends, but I have never seen hernia as a result.

Dr. J. M. Baldy:—It has always seemed to me that it was not so much a question of the diagnosis of appendicitis, as the differentiation between the operative and the non-operative cases. The diagnosis of appendicitis *per se* is extremely easy; at least, so I have found it. As far as symptoms are concerned, I know of only one that is of constant value, and that is, constant, deep-seated pain in the right iliac fossa, with induration. I think in such a case there is little question but that there is inflammation in or about the head of the cæcum, and, presumably in the majority of cases, in the appendix.

Mr. Bryant has spoken of cases where large foreign bodies have been discharged through an abscess, and claims they have come from the cæcum. He offers no evidence of this, except the size of the body. I have seen the appendix sloughed off, leaving a sufficient opening in the cæcum to admit the index-finger, so that I cannot see that the size of the body indicates in any way that it came from the cæcum, and not from the appendix.

I have been glad, and, at the same time, rather surprised to hear the McBurney point condemned. I believed that it is utterly worthless as a reliable point in the diagnosis. It is one of those attempts at refinement in diagnosis which are apt to lead only too many astray. I have tried to apply McBurney's point, but have failed in every case.

The rectal examination may be of value in many cases, but we have all seen cases—and Dr. Keen's is one in point—in which there is a small abscess high up, which could by no possibility be recognized by rectal examination. If the abscess contain many ounces of pus, it will generally extend downward toward the pelvis, and may be felt through the rectum. There are, however, so many cases in which this can not be done that we can place no definite value on this method except in a limited number of cases.

I cannot help thinking that purgation is of distinct value when I see the great relief afforded to a man groaning with the most intense pain, simply from having a movement of the bowels. It may not be curative, but in every case, whether abscess is present or not, it gives great relief. I believe that purgation should always be used. At the same time, if the patient was suffering, I should not hesitate to use opium until the purgation had acted, or after it had acted in case of necessity. The amount required is not great, and it will not interfere with the purgation. Those cases in which it is difficult or impossible to induce purgation, are going to do badly.

I know of no other intra-abdominal disease in which it requires more skill and practical experience to differentiate between those cases that should be let alone surgically, and those which should be operated on. I grant that the majority of cases of appendicitis get well without any operation. Again, there are certain cases that do badly from the beginning, and in which operation is clearly indicated. But, with certainty, there remains that large class of border-line cases in which it is next to impossible to say whether pus is present or not. If there *is* pus no one should hesitate. The operation for abscess is simple and easy. The abscess once opened, I do not think that in these acute cases any time should be lost in searching for the appendix. In trying to find the appendix, and even when found, in trying to remove it, the general peritoneal cavity will often be opened, and life will be lost where otherwise it would have been saved. Only one case, so far as I am aware, has been reported in which the abscess has been opened and the appendix left, where a second operation was required for a severe recurrent attack.

I believe with Dr. Keen that the surgeon should be associated with the case from the

beginning, although not necessarily to operate. When a physician is called in to operate, the tendency, if there is doubt—and doubt only too often exists—is to postpone the operation. If the surgeon has seen the case from the beginning, and studied the symptoms and knows the details, when the time comes he will have made up his mind whether or not to operate. If, however, the surgeon loses another twelve or twenty-four hours in hesitation, in addition to what the physician has already lost, the patient may be irretrievably lost. The deaths after operation are due not so much to operation as to delay.

It is impossible to lay down any rule as to the time at which operation should be performed in any case, or in any class of cases. In some the onset is so sudden and violent that it is impossible to come to any decision as to the seat of disease. This was the case in the patient reported by Dr. Keen, and in another instance I know of in New Jersey. In the latter case, is was not until a few hours before death that the symptoms were sufficiently marked to cause any alarm. This is often the history of cases in which the operation is postponed. The patient will be doing well until within a few hours of death, when the end comes suddenly, and the patient sinks rapidly.

Dr. Frank Woodbury :—Although as a physician I look at this subject from the medical standpoint, I am in favor of operating. To save time, I may say that I heartily coincide in the statements just made by Dr. Pepper. I also endorse the remarks of Mr. Bryant, in which he anticipated what I had intended to say—that is, that each case must be studied by itself. I think that the surgeon and physician look at these cases a little differently. The surgeon is looking for general rules to govern him in the treatment of cases, while the medical man is more in the habit of individualizing his patients. Concerning the propriety of operation and the results to be anticipated therefrom, we all acknowledge that there is in some individuals a tolerance to operative interference and to suppuration that does not exist in others. Some will survive dangerous gunshot wounds, others will perish from a slight injury. These are probably points that will enable us to determine this difference in tolerance of different individuals, and, were they in our possession, should undoubtedly enter into the question of operation, but at the present time, unfortunately, we are not prepared to formulate these points in any given cases of appendicitis which comes before us. Physicians, who are accustomed to go into the history of the patient and to investigate the antecedents of the case, know that individuals who belong to families with a high physical standard and who lead regular lives, are able to stand severe illnesses and operations, coming through them speedily and well, while others, having poor family history, bear very little surgical interference, and easily succumb to disease.

The question of the time of operation and propriety of operation really resolves itself into the query, "At what time does a case of appendicitis become a surgical case?" I would here raise my voice against the physician yielding to the temptation to put in a hypodermic needle into an iliac abscess or swelling in order to make the diagnosis. As soon as he does that he takes surgical responsibilities on his shoulders, and in no case are they likely to be more serious than in appendicitis. The physician should have sufficient surgical knowledge to determine when the time for operation has arrived, or, acknowledge his inability to decide this, he should secure the best obtainable surgical advice, not necessarily to operate, however, but to determine the propriety and proper time for operation, if found necessary.

Among the cases that come to my mind, three stand forth prominently. One was the first case which I saw, some eighteen years ago. A man in the lower walks of life, continued at his work as a machinist, making no complaint, until one day he fell on the floor of the shop in a collapse, and was brought to the Pennsylvania Hospital. He had a feeble pulse, and a Hippocratic face; the surface was cold, and, as he was dying, no attempt was made at diagnosis. He died in a few hours, and the post-mortem showed it to be a case of perforative appendicitis, with perforation and the usual foreign body. Here there was a question of operation. The patient did not seek medical advice, and there was no time for operation.

The last case I saw in my own practice occurred last spring, in a patient whom I had attended at intervals for a number of years. I had attended him a year before with a light attack of appendicitis, and warned him that if he had a subseqnent attack he should consider the question of operation. He did have a subsequent attack while away from the city, and on his return was attended by another physician for three months. The man improved and was about, but always felt a weight and pain in the right iliac fossa. He was then taken with acute obstruction of the bowels with intense

pain, and finally I was sent for. In this case nothing that was given him produced a movement of the bowels. I may say that in this case Dr. Thomas G. Morton operated on the second day after I saw him, but the patient died five days later without a movement of the bowels. The bowels were probably matted together and gangrenous.

The third case that occurs to me is one operated on also by Dr. Thomas G. Morton five years ago, which I have reported to the College of Physicians[1] and to this Society. I believe that Dr. Morton claims that this was the first case in this country where the correct diagnosis was made prior to operation of amputation of the appendix, and where the patient recovered. The patient has been well since the operation, although prior to it he had had a number of attacks. The patient is present to-night, and I should be pleased to show him to the Society. He is still wearing a light truss to protect a weak place in the abdominal wall at the lower portion of the incision. [The patient was exhibited.]

Dr. H. A. Hare:—I rise for information rather than to discuss the surgical aspect of the papers which we have heard. Like Mr. Bryant, I am at a loss to know why calomel and podophyllin, the latter in such large amounts as one-eighth of a grain every twenty minutes, should be given after an operation for appendicitis. Podophyllin is the slowest acting purge in the Pharmacopæia, taking eight or twelve hours to produce an effect, as a rule; not only this, but these drugs act on the small bowel, high up, while the appendix is in the large bowel, low down. If saline purgatives were ordered it seems to be a better treatment, for we have evidence of their great value. Even these are not without danger. I do not believe that a man can take one-eighth grain of resin of podophyllin every twenty minutes until he is purged without producing much intestinal griping and pain. Anstie pointed out the fact that podophyllin was a distinct irritant, particularly to the small intestine.

Dr. De Forest Willard:—Mr. Bryant has said that he has not seen hernia follow this operation. A boy came into my office to-day on whom I operated two years ago. He did perfectly well for a year, when on attempting to lift a heavy body the bowel protruded through the center of the cicatrix. He had worn a bandage and a truss, but I put on a heavier truss, which relieved him for a time. He returned in four months; the pressure of the truss had produced a large slough, and he came near having a perforation of the bowel. The ulcer finally healed. He now has at the outer angle of the wound a second small hernia, and at the inner angle there is a slight tendency to protrusion. The wound was a large one. The boy was in extremis at the time of operation, and there was an enormous accumulation of pus.

In regard to deep-seated pain and induration in the iliac fossa as a diagnostic sign, I have seen cases in whom there was not a particle of local pain or of induration.

The boy already mentioned had no such symptoms. He had been kicked at the umbilicus, and the pain was chiefly at that point, yet the abscess was in the iliac region.

The appendix was open, and a small mass of fæces had escaped. There was an enormous accumulation of pus extending down into the pelvis on one side. The appendix was removed, and the opening stitched.

Dr. M. F. Kirkbride:—In the past year and a half I have had four cases, but shall speak only of one. I shall first refer to the history of the case as given in a letter to the previous attendant. The physician was called on Thursday, April 3. The patient had been constipated for one day. It was at first thought that the case was one of typhoid fever, as the father had recently recovered from this disease. Calomel was given, but no action secured. Citrate of magnesia was given with the same result. The pain and tenderness in the right iliac region increased. There was some tympanites. Injections of soap and water with a few drops of turpentine were practiced with no result. Salts in one drachm doses were then given without effect. Vomiting began. It became apparent that it was a case of appendicitis with obstruction of the bowels. Injections given on Saturday morning were not retained. On Saturday a surgeon was called in consultation. Operation was decided on, but as the surroundings were not suitable the family was advised to have the patient admitted to a hospital. This they agreed to do, but at 3 P. M. decided not to do so. The physician in charge then declined to have anything more to do with the case.

I was called to see the patient on Sunday evening, at ten o'clock. The temperature was 99.5°, the respiration 36. No pulse at the wrist. The heart beats 130. He vomited everything, and for several days had had stercoraceous vomiting. I gave hypodermics of morphine and atropine, and after-

[1] Case reported in Proceedings of the College of Physicians of Philadelphia, vol. VII.

ward hypodermics of strychnine. After he had reacted somewhat I put him in the knee-chest posture, and gave an enama of sulphate of magnesia, turpentine, glycerin, and warm water, and gave whiskey and turpentine by the mouth. I also gave for several hours sulphate of magnesia in one drachm dose. The first two doses were rejected, but afterward there was no vomiting whatever. In three hours I had the tumor removed and the boy sleeping comfortably, and after that he got along nicely. On the sixth day after I was called a slough passed from the bowel. This was three inches in diameter. The case then went through that of a regular case of typhoid fever, as far as the temperature was concerned, and even showed the eruption. The diagnosis of appendicitis was made by two physicians and an eminent young surgeon.

Dr. Joseph Hoffman:—McBurney's point has been condemned, but the reasons have not been given. The position of the appendix varies. You cannot lay your finger on any special point and say that the appendix should be found. We must remember that the appendix revolves in three planes, and that, therefore, it may have three systems of revolution. We cannot expect to find th appendix in the same position. This an atomical point forever blots out McBurney's point.

In reference to purgation, I had a case of which I shall recite the points in which the use of calomel and opium comes out beautifully, so far as the apparent curative effects are concerned. Dr. Wheeler was treating a case of appendicitis with opium for some days without benefit. He then called me in and I brought Dr. Price. He was then purged with calomel after the opium treatment, and the pain entirely disappeared. Shortly afterward he went to Baltimore and had a recurrent attack, from which he died. This shows what purgation will do.

Dr. M. Price:—We are certainly slightly mixed in the discussion of this question. The physicians are talking about appendicitis without perforation, and the surgeons of appendicitis with perforation, conditions entirely opposite. Drs. Pepper and Meigs say they never saw but one single case of perforative appendicitis get well, and they reported that case themselves. It is true that this statement was reported fifteen years ago, but that does not make the disease any the milder.

There is one other point. It is absolutely fully to operate for appendicitis and expect good results, unless you can purge the patient. If you succeed, and after the operation persist in the use of purgatives, every case, so far as I know, will recover.

If at the operation there is found a barrier separating the abscess from the general peritoneal cavity, thorough irrigation of the abscess cavity is required. If this barrier cannot be demonstrated, thorough irrigation of the whole peritoneal cavity should be insisted upon. In a case operated on five weeks ago, there was well-marked thickening and induration in the right iliac fossa. I removed five or six ounces of pus, and when I came to irrigate, although I used every precaution, I found the small intestine slipping by my finger. I washed the abdominal cavity out thoroughly, and passed in a straight glass drainage-tube, held in position by one stitch at the lower angle of the wound, and then packed with gauze down to the knuckle of the intestine. The appendix was eaten off by an ulcer, and so gangrenous that I was afraid to touch it. The man was purged every day for a week, and made an uninterrupted recovery. I may mention that I have never seen a case of appendicitis with perforation and general peritoneal inflammation without a subnormal temperature.

Dr. Morton:—There are many symptoms that have not been mentioned. Bladder irritation is a prominent symptom in some cases from inflammation or pressure on the ureter, or of the bladder wall. This brings out one of the dangers in operating on the appendix. Mr. Treves has predicted that some day a portion of the ureter will be taken out in mistake for the appendix or torn out with it.

It is also to be remembered that in perityphlitis the superficial veins are more engorged on the right side of the body than on the left.

Perhaps my views in regard to the time of operation have been misunderstood. What I desired to say was that no case that is not improving should be permitted to go beyond the third day without surgical interference. I do not mean to say that all cases should be left so long. In some the operation will be required in the first few hours; in others on the first day, and in still others on the second day. The great majority of cases will recover from the present attack at least, upon purgation, topical applications, and regulation of diet.

Another danger of allowing septic processes to go on in the neighborhood of the appendix is the development of phlebitis in the branches of the mesenteric vein causing troubles in the liver. Pain in the liver is

often a sign of appendix disease. It has been held that many cases of abscess of the liver have originated in septic processes around the appendix infecting the veins. I saw Dr. Steinbach operate on a case in which the patient before operation showed a tinge of jaundice. The appendix ran upward nearly to the liver and was surrounded by a large abscess. Intense jaundice supervened after the operation, and the man died apparently from acute inflammatory degeneration of the liver. I believe that the liver trouble was aseptic complication from the appendix.

In regard to the use of calomel and podophyllin, I would say that I know very little about experimental therapeutics, but after giving the various purgatives a thorough trial I have found that minute doses of calomel and podophyllin frequently repeated give the best results in these cases. They move the bowels thoroughly and with rapidity. In the case reported from fifteen to twenty movements were secured in eight or ten hours. These small doses cannot be vomited as readily as a drachm of salts can be, nor do they produce emesis even shortly after etherization, when salines would not be tolerated by the stomach. After the bowels have been thus started and the stomach quieted as a consequence, salts will be retained, if indicated, and work with greater promptitude and efficiency.

Dr. Price :—I rejoice that in America we have adopted some of Mr. Bryant's surgical wisdom in regard to hernia. "If you find a man hanging cut him down."

I will allude to three cases in which there were recurring attacks. In one, the man had had twelve to fourteen attacks. I saw him in the last in collapse on the eighth, tenth, or perhaps the twelfth day. In this case the argument offered by the family physician was the common one, that as the patient had recovered from so many attacks he would also recover from this. This is a dangerous argument and often a fatal one. I said that this man would be dead in three hours; he died in an hour and a half. In a recent case I saw the patient on Monday. Dr. Agnew saw him on the same day, and we both urged section. The physician and family decided to wait. On the following Friday Dr. Agnew was asked to operate and refused. Many of us are now taking high ground and refusing to operate at the eleventh hour. It is not fair to surgery to operate on dying patients. Dr. Agnew has recently operated in the twenty-fifth attack, removing a huge appendix, and the boy recovered.

Deaths from appendicitis are very numerous; indeed, more so than a year ago. They were then called typhoid fever, but now our methods of diagnosis are more accurate.

Mr. Tait's recommendation of drainage has been referred to. That would be as bad surgery as to drain a huge pus-tube. The cheesy, disorganized appendage remains. No one would cut down on a sequestrum in bone disease and simply put in a drainage-tube.

I have the records of two cases of appendicitis, in one of which the opening was through the lungs and the other through the œsophagus. Dr. Hunter McGuire has reported a case in which the appendix was found floating in a puddle of pus. You will all remember the illustration in the *British Medical Journal* or the *Lancet* of a year ago of a case of hepatic abscess with a large opening through the loin. You could see the liver, the kidney, and the colon. The man lived twelve days and died of dysentery I never see a case of neglected appendicitis without thinking of this case of neglected abscess of the liver. In most cases that we see the small intestines are enormously distended and the pelvis is filled with adherent knuckles of bowels. In these you often have obstruction. In many cases the use of a purgative is simply folly before the adherent knuckles of intestine have been released by operation.

I scarcely favor the long ligature method. In these cases I have inverted the stumps, and the transfixation has been made with the finest needles. If the appendix sloughs it goes inside.

The McBurney point is wholly ununiform and worthless.

A NEW MEDICAL SOCIETY.

THE AMERICAN MEDICAL TEMPERANCE SOCIETY.

During the first day of the meeting of the American Medical Association at Washington, last May, a "call" was posted in the various halls where the different "Sections" met, inviting all physicians favorable to the formation of a Temperance Medical Society on the basis of the British Medical Society. The call was signed by Dr. N. S. Davis, of Chicago—known to physicians everywhere as the "Father of the American Medical

Association." Punctually at 2 P. M. twenty persons had assembled.

Dr. Davis took the chair and proceeded to give us information in relation to the British Society which began with only ten persons and now numbers hundreds of the eminent physicians of England. The terms of membership are the payment of a small fee and entire abstinence from the use of intoxicating beverages.

There is no pledge required, it being believed that no physician worthy of the name would desire membership if he were not a total abstainer.

The liberty of members to prescribe alcohol is not forbidden, should they deem it necessary.

The names of those present were then enrolled, and to them were added a number more of persons who had written to Dr. Davis their wish to become members, but who could not be at the meeting. A meeting was appointed to be held the next morning at 9 o'clock. There were more persons present on that occasion, and the organization was perfected. Some appropriate papers were read and discussed, and Dr. Davis spoke earnestly on the importance of strict temperance by the members of our profession, and closed by declaring, that he did not regard *the use of alcohol essential to the treatment of any disease.* Strong testimony from a man so competent to observe and with an experience of more than fifty years of practice! Dr. Davis thus outlined the purpose and object of this Society: "The object of this association is to advance the practice of total abstinence in and through the medical profession, and to promote investigation as to the action of alcohol in health and disease, and it aims at being a bond of union among medical abstainers scattered all over our country. It admits as members all regular medical practitioners who are practical abstainers from all alcoholic liquors as beverages. Members are not required to sign any pledge, but if such for any reason cease to become total abstainers, it is expected that they will withdraw from the Society."

The great object of the Society is to study and investigate the action of alcohol both as a beverage and medicine, and to promote the strictest temperance among physicians. The fact that this Society originated through the efforts of the noble man, who created our great National Medical Association, many years ago, and which has so greatly harmonized the profession, will at least protect it from being considered the outcome of fanaticism. It is to me very comforting, and shows how greatly the profession has advanced in respect for temperance principles since 1853, when a president of our State Society, in the performance of his duty to the Society, was severely denounced for merely entreating the profession to forbear the then reckless use of alcohol as medicine.

Sixty-one physicians were enrolled as original members at the meeting in Washington, and the secretary informs me that there are more than a hundred now. The secretary writes: "The meeting of the Society held in July, in Staten Island, was quite a success—thirty-two medical papers were read on alcohol. Four or five were a defense of its use, and the rest a condemnation of it."

The officers of the Society are:—

N. S. Davis, M. D., President, Chicago, Illinois.

Vice-Presidents, I. N. Quimby, M. D., Jersey City, N. J.; J. B. Whiting, M. D., Janesville, Wis.; F. E. Yoakum, M. D., Shreveport, La.; J. Taft, M. D., Cincinnati, Ohio.

Secretary, T. D. Crothers, M. D., Hartford, Conn.

Treasurer, G. W. Webster, Chicago, Ills.

Physicians desirous to become members of the Society may do so by addressing the secretary, Dr. Crothers, Hartford, Conn.

HIRAM CORSON, M. D.,
Plymouth Meeting P. O., Pa.

SELECTED FORMULÆ.

VOMITING OF PREGNANCY.

The following is recommended (*La Rassegna di Scienze Mediche*, No. 2, 1891) in the vomiting of pregnancy:

℞ Menthol.....gramme j (grs. xv.)
Alcohol.....grammes xx (f℥ v.)
Simple syrup..... " xxx (f℥ j.)
Sig. One teaspoonful every hour.

ANTINERVINE.

The substance which has also been called salicyl-bromanilide is, according to Ritsert, a mixture of

℞ Ammonium bromide.....parts 25.
Salicylic acid..... " 25.
Acetanilide..... " 50.

SCIATICA.

℞ Tinct. colchici..... .....m ¾.
Tinct cimicifugæ.....m ¾.
Tinct. aconiti ....m ¾.
Tinct. belladonnæ..... ...m ¾.
M. Sig. One dose.

—*Starr on Nervous Diseases.*

DEODORIZATION OF IODOFORM BY CREOLIN.

A patient, suffering from a bone-felon, applied for treatment to Dr. L. Vazci (*Rundschau.*, May, 1891) who wrote for a salve consisting of iodoform, two parts; creolin, one part, vaselin, twenty-five parts.

On visiting the patient the next day, he was much surprised to find that the salve was of a different color, but, what was of much more importance, there was not the slightest odor of iodoform. Most of the deodorizers contain some one of the ethereal oils which have an irritating effect; whereas creolin does not do this, but is itself a good disinfectant.

RHEUMATISM.

Dr. Staples recommends:

℞ Olei gaultheriæ.
Olei olivæ, aa.....part equal.
Sig. Apply locally to affected parts, afterwards keeping the member covered.

ASCARIS LUMBRICOIDES.

The following is said to be a specific for ascaris lumbricoides:

℞ Santonine.....gr. x.
Irisin.....gr. ij.
Sacch. lactis.....gr. iv. M.
Sig. One powder, every night at bedtime; this for children 3 to 4 years of age.

—*Med. Summary*, Sept., 1891.

VEGETATIONS ON THE GENITALS.

Dr. Uriola states that the following mixture, applied with a camel's hair brush to vegetations of the genitalia, will cause a rapid disappearance of the growths:

℞ Acidi salicylici.....part 1.
Acidi acetici.....parts 15.

—*National Druggist*, July 1, 1891.

CYSTITIS.

Wyman and deLeval recommend the following formula in all cases of cystitis:

℞ Ext. pichi fld.....f ʒ j.
Potassii nitratis.....f ʒ j.
Syr. simplicis.....f ʒ iij.
M. Sig. A teaspoonful every three hours.

—*The Satellite.*

LINIMENT FOR GOUT.

In his small work on rheumatism and gout, Dr. F. Leroy Satterlee recommends the following local application in cases of gout:

℞ Ol. gaultheriæ.
Ol. olivæ.
Lin. saponis.
Tr. aconite.
Tr. opii, aa.....ʒij.
M. Ft. liniment. Sig. Apply freely and cover with cotton batting.

RHACHITIS.

In the *Journal de Médecine de Paris* the following prescription is given for the treatment of rhachitis:

℞ Phosphorus.....gr. j.
Absolute alcohol.....ʒ v.
Spirits of peppermint.....gtt. xxx.
Glycerin.....ʒ ij.

Six drops of this mixture may be given in water three times a day, and after the lapse of one week another drop may be added.

INFANTILE BRONCHITIS.

℞ Vini ipecac.....ɱ j.
Tr. opii camphorat.....gtt. ij.
Syr. scillæ.....gtt. v.
Aq. menth. piperit. q.s. ad.....f ʒ j.
M. Sig. One dose to be taken every two hours.

—*Dixie Doctor.*

CHOLAGOGUE POWDERS FOR HEPATIC COLIC.

In the *Revue Général de Clinique et de Thérapeutique* the following treatment for the relief of hepatic lithiasis is given, based upon the fact that Binet and others have found that the benzoate and salicylate of sodium act as cholagogues. The nux vomica in the prescription aids in regulating the bowels and in relieving anorexia and dyspepsia:

℞ Benzoate of sodium } of each.....gr. lxxv.
Salicylate of sodium }
Powdered nux vomica.....gr. vij. M.

This is to be divided into 20 powders, of which the patient should take 1, three times a day for two months.—*Med. News.*

PERMANGANATE OF POTASSIUM IN DIPHTHERIA.

Er. Netzetzky says that his twenty-two years' practice convinced him that the best treatment of faucial diphtheria consists in an energetic use of permanganate of potassium.

The drug should be administered in the shape of paintings and gargle. The following strong solution should be employed:

℞ Potassii permanganatis.....ʒ j.
Aquæ destillatæ.....f ʒ j. M.
Sig. To paint the affected surface every three hours.

For gargling, which is to be repeated as often, a teaspoonful of the same solution should be mixed with a tumblerful of boiled water.

In those cases in which the child is unable to gargle, the following mixture should be given internally:

℞ Solutionis hydrogenis superoxydati, two per cent.....f ʒ ij.
Glycerinæ.....f ʒ ij.
Sig. A teaspoonful every two hours.

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO., (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

THE CONSTITUTIONAL DISTURBANCES FOLLOWING THE PASSAGE OF INSTRUMENTS INTO THE MALE URETHRA AND BLADDER.

That the passage of instruments into the male urethra and bladder is at times followed by more or less grave constitutional disturbances is a fact known to every physician, and one which has long been recognized. At no period in the history of medicine has a thorough understanding of the pathology of these affections been as important as it is to-day, when both the urethra and bladder are more frequently operated upon than ever before. It is also most desirable that the terms used to denote the different clinical conditions resulting from the use of instruments, should be clearly defined, so that, as far as possible, we may arrive at uniformity of expression in recording them. That there is need of this, a glance at the literature of the subject will fully demonstrate.

Many theories have been advanced to account for the causation of the various systematic disorders which are clinically observed, and those conditions have received different names from many writers upon the subject. The principal terms now in general use to denote these affections are catheter chill, urethral fever, catheter fever, and urinary fever. Dr. Paul Thorndike, of Boston, has contributed at the last meeting of the Massachusetts Medical Society, a very excellent paper, in which he has grouped and definitely classified in a practical manner, the various diseased states occurring after instrumentation upon the urethra and bladder. His division of the cases seems so admirably capable of containing all the different conditions met with, that we will quote his synopsis of the four classes. This is as follows:

I. The cases of "urethral shock" brought about by the simple passage of an instrument into the urethra. Very common, and, as a rule, of very little importance, but occasion-

ally terminating in speedy death. The fatal form is rare, and is usally associated with renal disease of some sort.

II. The cases of "acute urinary fever" caused, probably, by absorption of poisonous products from the urine. This acute attack at times occurring without any known cause, such as further instrumentation.

III. The cases of "chronic urinary fever," coming on after catheterization, in cases where obstructive disease had pre-existed for a long time.

IV. The cases of "septic infection" from an unclean instrument. This may be merely a mild cystitis; may extend upward and cause septic trouble in the kidneys, or may manifest itself as a true general septicæmia or pyæmia.

An examination of the literature of this subject convinces us that the above classification is plain, practical, and wide enough to include all cases. It is also founded upon the most recent clinical and experimental knowledge, so that as a good working classification it is doubly commendable.

The first class of cases includes all those due to shock. These vary from the slightest "catheter chill" to a fatal degree of shock, which is happily of rare occurrence. The most common form of "catheter chill" occurs directly after the use of instruments and soon passes away without any bad effects.

The second class includes all cases of acute fever, commonly called "catheter fever." Usually this occurs within a few hours after the passage of the instrument, and rarely persists longer than 24 hours. The etiology of "catheter fever" is still a matter of discussion. Some writers regard it as due to shock, as all admit the first class of cases are; others state that malaria is the causative factor; while others believe that it is due to uræmia. The fact that the attack does not commence until some hours after the passage of the instrument is against the "shock" theory, for we should naturally expect it to begin immediately after instrumentation, and also to be in proportion to the severity of the surgical procedure, but clinical experience teaches us that such is not the case. Again, if catheter fever is due to shock, we should expect, as Dr. Thorndike remarks, that prophylactic measures would be powerless to prevent its occurrence after urethral operations, yet from the testimony of able surgeons we know that a large proportion of urethral operations are followed by no febrile disturbances, especially at this time when perfect drainage is secured, and the urine prevented access to the wound.

Mr. Reginald Harrison, who is entitled to speak with some authority upon this subject, believes that this acute febrile attack under discussion is due to the septic absorption, and he has found in his experience that it is more likely to occur when the wound is made in the floor, than when it is situated in the roof of the urethra. He says: "A dependent position of the incision is more likely to be associated with the fever than one not so situated." If it be admitted that septic infection is the cause of ordinary "catheter fever," the question arises: which constituent of the urine is responsible for the symptoms? To determine this, Dr. Bouchard, of Paris, has recently made very interesting studies, with the result that he attributes the symptoms to the absorption of certain alkaloids formed in the intestines by putrefactive organisms, and normally excreted in part by the kidneys. These researches still lack confirmation, and it may truly be said that they have only opened a very wide field for the further study of the physiological chemistry involved. The weight of evidence proves that "catheter fever" is due to septic substances, but their precise nature must still be considered as largely hypothetical.

The third class of cases, or those of chronic fever, embraces all the cases in which fever arises after catheterization for the relief of urinary incontinence due to distension and weakness of the bladder, usually caused primarily by an old stricture or a chronic prostatic hypertrophy. The "residual urine" has slowly increased in amount, and chronic distension with consequent atony of the walls of the bladder finally occur, after which the cases come under observation. The onset, course and termination of this

type of fever are thus described by Dr. Thorndike: "The patient is instructed as to his condition and started regularly on his catheter-life. In a few days he begins to feel poorly, has chilly feelings, but not necessarily a distinct rigor. He becomes feverish, but his fever is slight and has distinct intermissions. He loses appetite, suffers from thirst, and feels wretchedly all the time. The tongue becomes dry and brown. Examination generally shows a cystitis, more or less marked, even if this condition did not exist before the beginning of regular catheterization. This condition may exist for weeks, and yet the patient recover with proper care, or it may end fatally, in which case there will be found almost invariably advanced disease of ureter and kidney."

The cause of this type of fever has been explained, in those cases in which there is associated disease of the kidneys, by the theory that the withdrawal of the urine relieves the pressure long exerted by it upon the kidneys through the dilated ureters and calices, thus inducing active congestion of the kidneys, which, owing to the want of normal elasticity caused by the chronic fibroid changes which the organs have undergone, cannot be controlled, and an acute pyelo-nephritis is the result. In a certain proportion of cases however, post-mortem examination reveals no chronic lesion of the kidneys, and for such cases no adequate explanation is forthcoming.

The fourth class comprises all cases of direct septic infection from the passage of unclean instruments. The cases differ widely; thus, we may have a simple cystitis, or it may extend up the ureters and cause septic pyelo-nephritis and death from surgical kidney; or direct infection may occur through a wound made by the unclean instrument, and we may have a true septicæmia or even pyæmia with general formation of pus in the tissues and in the serous cavities of the body.

The fact that such serious affections do occasionally follow the use of instruments upon the urethra and bladder, certainly is the strongest possible plea for the most scrupulous care in the proper cleaning of apparatus, and in all surgical procedures upon this part of the body.

CORRESPONDENCE.

PHENACETINE AND SULFONAL.

ED. MEDICAL AND SURGICAL REPORTER:

I have thought it desirable to put on record my experience with these two substances. I find phenacetine to be a much safer antipyretic than antipyrine or antifebrin as it does not have their depressing or exciting effect on the heart. I could not treat a case of epidemic influenza without phenacetine. I believe it better to use small and frequent doses. It does not give rise to gastric disturbance. It is prompt in action and decided in its effects as a therapeutic agent. It has no accumulative tendencies and is much safer for children and old people than opiates. Another advantage is that it does not lock up the secretions. In the muscular pains of la grippe it is far preferable to opium. In rheumatism I combine it with salol.

I have also been using sulfonal, the most valuable of hypnotics, where opiates, on account of stimulating and exciting effects on the nervous system are contra-indicated. In fevers where there is a tendency (when opiates are used) of over exciting the brain I have found sulfonal to induce calm and refreshing sleep with no tendency to delirium. I have a case of intermittent fever in which I rely solely upon sulfonal to induce sleep. In brain fever it would prove of incalculable benefit. In *Mania a Potu* it would prove the "*sine qua non.*"

In my experience with sulfonal and phenacetine I find that small doses (3 to 5 grains) repeated every two or three hours, or even every hour, are better than larger ones.

A. O. Stimson, M. D., C. M.,
Thompson, Pa.

A new remedy for whooping-cough is ouabaine in doses of about gr. $\frac{1}{1000}$. It has been tried with success by Dr: Gemmell, of Glasgow, and lately by Dr. I. L. Porteous, of Yonkers, N. Y.—*New York Med. Jour.*

Book Reviews.

ESSENTIALS OF BACTERIOLOGY: BEING A CONCISE AND SYSTEMATIC INTRODUCTION TO THE STUDY OF MICRO-ORGANISMS, FOR THE USE OF STUDENTS AND PRACTITIONERS. By M. V. Ball, M. D., Late Resident Physician in the German Hospital, Philadelphia; Assistant in Microscopy, Niagara University, Buffalo, New York, etc. With seventy-six illustrations, some in colors. Philadelphia: W. B. Saunders; 16 mo, 159 pp. Price $1.00.

The subject of bacteriology has, of recent years, grown to such enormous proportions and assumed so important a position in clinical medicine, pathology and hygiene that it is safe to say that during this period of its active growth it has undergone more rapid development than any other branch of medical science. Indeed, so rapid has been its advance that the text-book of to-day shows signs of age on the morrow.

There has existed an unquestionable need for a small work embodying the salient points of bacteriology, and specially adapted for laboratory use. It is just such a book that Dr. Ball has prepared. He introduces the student by referring to the classification, structure and reproduction of bacteria. Then are considered: their origin, growth, life and properties; methods of examination, staining, culture, etc.; non-pathogenic bacteria; pathogenic bacteria; bacteria pathogenic for animals, but not for man; finally, there is an appendix on yeast, odiums, moulds, actimomyces or ray fungus, and the examination of air, water and soil.

The compend is thoroughly practical, very concise, clear, well-written and sufficiently illustrated. On the whole, it is the best book of the kind in the English language.

ARTIFICIAL ANÆSTHESIA AND ANÆSTHETICS. By De Forest Willard, R. M., M. D., Ph. D., Clinical Professor of Orthopœdic Surgery in the University of Pennsylvania; Surgeon to the Presbyterian Hospital, Etc., and Lewis H. Adler, Jr., M. D., Instructor in Rectal Diseases, Philadelphia Polyclinic and College for Graduates in Medicine. Detroit: Geo. S. Davis; 144 pp. Price 25 cents, cloth 50 cents.

The subject of which this brochure treats is one of such universal interest and importance to the profession that any new publication has a just claim to immediate attention. While this work is unpretentious in size the authors have so carefully selected and condensed the material at their disposal that they have really embodied all of the important practical points in connection with anæsthesia.

They consider, *seriatim*, the history of anæsthetics, the preparation of the patient, general anæsthetics, local anæsthetics, special modes of producing anæsthesia, anæsthetics in obstetrical practice, and the medico-legal relations of artificial anæsthesia.

The book has been very carefully prepared, and it cannot be too highly recommended to the student, nurse, dentist and physician.

PERISCOPE.

THERAPEUTICS.

USE OF COLLODION IN RELAXATION OF THE MEMBRANA TYMPANI.

Dr. Lannois, of Lyons, France, calls attention (*Annales des Maladies de l' Oreille*, etc., vol. xvii., No. 1) to the above named treatment, first suggested, he says, by McKeown, of Belfast, in 1879. Employment of collodion has no inconveniences or dangers, and the author thinks that it not only holds the relaxed membrana in proper position, by its contractive and extracting power, but also that it possesses a truly curative effect, as the patients continue to hear better after the collodion film is removed from the ear.

Two cases are then told in detail illustrative of the good results of this treatment in relaxed conditions of the membrana tympani. McKeown recommended to paint the collodion on the membrana, but Lannois prefers to drop into the ear a few drops of the collodion after the membrana tympani has been pushed into the normal position by inflation of the tympanic cavity.

THE TREATMENT OF LUPUS BY LYSOL.

Lysol is a saponified phenol derived from tar oils, or, rather, from cresols by the action of nascent soap; it is a liquid containing the higher homologues of carbolic acid. Lysol differs from creoline, to which it is related, by its most perfect solubility in all proportions of water. Comparative bacteriological tests have proved it to possess higher antimycotic powers than carbolic acid or creoline, while it is less variable in constitution than the latter, and less poisonous than either.

The liquid is well worthy of extended use

by dermatologists and others called upon to treat lupus, for a short period of treatment by it suffices to produce a marked improvement in the appearance of the disease, and the results are so pronounced as to suggest a permanency, the reality of which only the lapse of time can, of course, determine. The surgeon, guided by a clear conception of the necessity for assiduous or watchful perseverance in the treatment of this disease, will perceive that this substance gives promise of ameliorative, if not curative power.

My plan is to apply, or direct the patient to apply, the lysol freely to the surface of the lupus patch by means of cotton twisted around a probe or wooden match, and to allow it to dry on. As in the employment of any other remedy intended to attack lupus nodules, it is first necessary to remove crusts and *débris* by the usual means. If this has been done, and it is found that the lupus is ulcerated, the lysol may be equally applied to the ulcerated and sound surface of the patch; it is not essential to first heal the ulcers, although if this be done by means of a simple ointment, the pain of the application is somewhat less than if made to the ulcerated surface.

Having applied the remedy myself, to show the patient how to proceed, I usually direct him to repeat the process once a day, or every other day, or less frequently if its use gives rise to much cracking of the epidermis or other inconvenience. Too frequent application is not desirable, besides being unnecessarily painful; for instance, if it be used at intervals of twelve hours, the second application is much more painful than the first. Its too frequent use causes either the formation of an impermeable and undesirable pellicle, as the result of its caustic action; or gives rise to superficial cracks in the epidermis, especially if the lupus is situated on a part of the skin naturally subject to tension. The immediate result of its application is to redden the parts, and sometimes to cause a slight œdema. This redness, with the overlying undried film of the drug, gives the part a peculiar, translucent, moist, glistening, erythematous appearance, which gradually subsides after the drying of the lysol. After a few days the scar is pliable, smooth, and of a good appearance from a cosmetic point of view, approximating the tint of healthy skin. The resulting scar seems even superior to that obtained after multiple scarifications.

The pain of the application is acute for half or three-quarters of an hour, quite disappearing in from two to three hours. This pain is less than that caused by the use of the multiple scarifier, and is not seriously objected to by patients to whose courage the prospect of the deforming sequelæ of lupus acts as a tonic.

In lupus of the nose or lips, since it is not easy to surmise how deep is the invasion, the disease should be attacked from the skin and mucous surfaces. The pain of application to the skin is much less than that to the nasal mucous membrane, and here the prior use of strong cocaine pigments has not appeared to reduce the pain. Dr. Unna has used lysol in the form of a plaster mull, and appears to have been favorably impressed with it. It is classed by him among substances which do not produce pain, and he asserts that the use of the mull is nearly painless.—Dr. Leslie Phillips, in *Brit. Med. Jour.*

THE TREATMENT OF TUBERCULOSIS BY MEANS OF SUBCUTANEOUS INJECTIONS OF EUCALYPTOL, GUAIACOL, AND IODOFORM.

Pignol (*Compt.-rend. hebdom. des Séances de la Soc. de Biol.*, 1891, No. 10) reports that for three years he has applied eucalyptol, alone or in combination with iodoform and creasote or guaiacol; guaiacol and iodoform, without eucalyptol; and creasol and guaiacol, subcutaneously, in the treatment of tuberculosis, with most satisfactory results. He uses as a menstruum sterilized liquid vaselin, olive oil, or oil of sweet almonds—preferably one of the latter two—containing twenty per cent. of the medicaments in varying proportions, of which at least from three to ten cubic centimetres are injected daily. The injections are made with antiseptic precautions into the retro-trochanteric fold. The best results were obtained from a combination of guaiacol and iodoform.

Picot (*Bull. de l'Acad. de Méd.*, 1891, No. 9) has reported the results of treatment in twenty-five cases of pulmonary tuberculosis and eight of pleurisy by means of subcutaneous injections of iodoform and guaiacol, dissolved in sterilized olive oil and vaselin, each cubic centimetre of the solution containing one centigramme of iodoform and five of guaiacol. The injections, each of three cubic centimetres, were made into the supra-spinous fossa daily, and were unattended with unpleasant local results. As an evidence of the absorption of the medicaments, the presence of iodoform could be demonstrated in the urine, guaiacol not be-

ing eliminated by the kidneys. As a rule, the injections occasioned no general reaction, but in certain cases, especially in those with fever, profuse perspiration followed, succeeded in turn by a sense of comfort and a lowering of temperature. In exceptional instances abdominal pain and diarrhœa developed in the course of treatment, but subsided on suspending the injections. In three cases of advanced phthisis, in which death took place, the changes found in the lungs were indicative of a reparative tendency. The tubercles presented an appearance of beginning fatty degeneration; the cavities were clean and dry. In one case the ulcers in the intestine showed a disposition to cicatrization. Neither in the lungs nor elsewhere was there any evidence of a fresh eruption of tubercles as a result of the treatment. In the remaining cases of phthisis the cough diminished, the sputum became less, and the number of bacilli in the sputum smaller, the body weight increased, the night sweats disappeared, the general condition improved, and the physical signs receded. In the cases of pleurisy the results were equally good. Effusion speedily disappeared, and recovery was rapid.

PARALYSIS AFTER SUBCUTANEOUS INJECTION OF ETHER.

Dr. Eberhart, of Cologne, has collected (*Centralbl. f. Gynäk.*, March 21st, 1891) cases in which the subcutaneous injection of ether caused paralysis of the muscles supplied by nerves with which the injected fluid had come in contact. In a case of Remak's in which the patient was comatose from carbonic oxide poisoning, ether was injected under the integuments of the extensor aspect of each forearm. Paralysis of the extensors of the fingers, of the index and little fiingers and of the metacarpal bone of the thumb, followed the injection. In another case, the paralysis was similarly distributed, excepting that the extensor indicis was spared; the condition did not pass away for four months. Arnozan had already noted that the posterior interosseous nerve, below the point where it perforates the supinator brevis, is especially exposed to injury from ether injections. Charpentier and Barbier have described neuritis degenerativa of the great sciatic nerve after ether injection. In Mendel's cases paralysis of the extensors of the ring and little fingers, with diminished cutaneous sensibility, followed hypodermic injection on the extensor side of the right forearm; recovery ensued in three weeks. In a case of Neumann's, ether was administered in the manner to a phthisical patient, and in both forearms. On the third day there was swelling around the punctures, pain on movement of the hands, and impaired movement of the middle finger. The latter symptom lasted for a long period. In Dr. Eberhart's own case, a plastic operation was performed on a woman for prolapsis uteri. The careful rawing of surfaces on the vaginal wall took a long while. The patient seemed collapsed at the end of the operation, and ether was injected under the skin of the right forearm, a hand's breadth below the olecranon, and at a second point, midway between the elbow and wrist. On the second day, partial paralysis of the extensors of the middle ring, and little fingers was noted; they could be extended, but the extension could not be maintained. There was no pain, and no lesion around the punctures. Faradization did little good till massage was added. It was six weeks before the extensors regained their complete power. The patient afterwards suffered from peculiar sensations in the forearm whenever the weather was changeable. It is not likely that these neuroses are due to direct wounding of the posterior interosseous nerve by the point of the syringe. The nerve is probably inflamed by direct contact by the ether.—*Brit. Med. Jour.*

ALKALIES IN UNIVERSAL PRURITUS.

C. Lange, (*Hospitals Tidende*, No. 21, 1891,) calls attention to the fact that most text-books present one with a most cheerless prospect in the section on universal pruritus. Arsenic internally and carbolic-acid compresses locally are the means most frequently relied upon. The writer has found a very prompt action in sodium bicarbonate combined with lithium carbonate in four cases of universal pruritus, namely in two ladies, of which two were over fifty, and an old gentleman, in which cases the usual remedies had failed. The pruritus, in one case, in a fifty-one year old lady, who was formerly well, and by no means hysteric, which had localized itself in the genital region, was so severe that her friends feared that she would either lose her mind or throw herself out of the window. She became emaciated and hollow-eyed, and presented pruritus of the entire body. Only hot compresses, as hot as could be borne, with large doses of chloral, would produce sleep. The administration of the alkalies mentioned, together with carbolic-acid compresses, improved her condi-

tion in a few days; in six weeks she was markedly better, but still required hypnotics and a compress at night. In three months no more hypnotics were necessary. In the urine of two other patients an abundant precipitate of uric acid and urates was found.

THERAPIE OF HUCKLEBERRY.

Prof. Winternitz recommends a decoction of huckleberries (saccinium myrtillus) in the different forms of diarrhœa. He covers the dried berries with cold water and cooks them for two hours, stirring them up quite frequently. After the mass is syrupy-like, he separates it from the remaining berries and presses the juice from them out. He then cools the juice, after which it is ready for use. One to two teacupsful of this juice per diem is the dose.

Winternitz claims that this preparation will act beneficially in the most pernicious cases of diarrhœa.

He uses this decoction in gonorrhœa as an injection, and claims to be very successful with such treatment.—*Blœtter fuer Klin. Hydrotherapie.*

MEDICINE.

ANALYSIS OF TWO HUNDRED AND SIXTY-TWO CASES OF CHOREA.

Goodall (*Guy's Hosp. Reports*) has analyzed the above number of cases of chorea occurring in the hospital during eleven consecutive years. Seventy-four of this number were males and one hundred and eighty-eight females. The youngest case was a female infant of one year; the oldest case a man of thirty-six years. There were one hundred and four cases that had recurrence of the disease. The smallest number of attacks occurred during the summer months. Hemichorea was present in sixty cases. In one hundred and fifteen cases the heart was normal, twenty-one of which number had had rheumatic fever. In one hundred and thirty-five cases there was some cardiac or vascular change. As no mention is made of the presence or absence of hypertrophy or dilatation, it is impossible to make out what per cent. of these the author regards as being chronically diseased.

There were eleven fatal cases, in which death was due to changes in the endocardium, emboli probably being formed in many cases. Seventy-one cases had had rheumatic fever; in only sixteen cases did choreic manifestations precede the fever.

The family history showed chorea in twenty-eight cases, mother, brother or sister having been affected. There was no history recorded of a father having had the disease. As causes are mentioned rheumatic fever, fright (forty-five cases), irritation, pregnancy, injury.

PERITYPHLITIS.

Sonnenburg (*Berliner klinische Wochenschrift*, No. 2, 1891) advises operation if the presence of pus is recognized. In the sero-fibrinous exudations around the cæcum an operation is excluded because they are absorbed. The larger the exudate at the beginning, the less likelihood is there of a purulent collection around the appendix, and the greater the probability of an infiltration around the cæcum. The small exudations which are, perhaps, circumscribed at the beginning, and situated usually at the classical space above Poupart's ligament, originate almost always from the appendix. Moreover, the greater the violence of the initial symptoms, the more apt is the trouble to be an exudation or phlegmonous process around the appendix. In most of the author's cases, violent pains in the umbilical region developed suddenly at night or after a movement, and was followed by vomiting with diarrhœa or constipation. In a few hours there was pain in the ileo-cæcal region, and indican in the urine. In perforation there is apt to be a small, hard, resistant space above Poupart's ligament, dull on percussion and sensitive to pressure. Even a slight rise of temperature, as 100.5°, if pathognomonic of pus. In cases where a small, indistinct fluctuation exists, an incision should be made down to the peritoneum and the wound tamponed, puncture of the abscess being made later. The incision should be long, curved and similar to that employed in ligation of the common iliac artery, and to avoid subsequent hernia it should be made as close to the crest of the ilium as possible. After several days, or as soon as adhesions have formed, the abscess is to be opened and drained. The wound is dressed daily, but not irrigated, and heals in four or five weeks. Of twelve of the author's cases in which immediate incision was done, five died of sepsis which was present before the operation. The following conclusions are submitted: (1) Endeavor to diagnose the simple from the purulent forms of perityphlitis. The sero-fibrinous cases do not require operation; but in patients suffering from tuber-

culosis or intestinal disease these may become purulent and then require a simple operation. (2) Purulent exudations originating in the vermiform appendix cannot be absorbed. (3) The more superficial the exudation, the earlier is operation indicated, that is, within the first few days of the beginning of symptoms. (4) If the exudation is small, the operation should be done in two sittings, as early as possible after the beginning of the disease.—*Univ. Med. Mag.*

THE NATURE AND TREATMENT OF STAMMERING.

Emil Behnke (*Jour. Laryngology and Rhinology,* July, 1891). The author declares that the terms stammer and stutter should indicate the same condition, rejecting a former distinction that stammer should refer to that form of obstruction in which there is inability to pronounce vowels, and stutter to that form of impediment in which the consonants are at fault. The causes of these disturbances are attributable to the nervous centres controlling the mechanism of respiration, phonation and articulation.

Children afflicted with stammering do not, as a rule, outgrow the habit; ridicule or severity will increase the difficulty.

Conditions needing surgical or medical interference, such as spinal curvature, post-nasal adenoids, decayed teeth, intestinal worms and phimosis, may prevent cure of stammering until their removal.

Cases of stammerers are divided into two classes—those in which fault lies in management of respiratory apparatus, and those in which it does not. In the former the prognosis is more hopeful. To test patient, he is placed flat on his back upon a couch, and is drilled in methodized and graduated series of sounds and inspiration, produced by diaphragm and muscles of abdominal walls, the hand of the trainer upon the epigastrium accentuating these movements.

If after such practice the patient shows improvement, a favorable result may be expected from treatment. In those cases in which obstruction does not depend upon imperfect respiration, Behnke attributes much of the trouble to "an involuntary exaggeration of all the stops and checks taking place in the vocal apparatus from glottis to lips, and he must therefore be trained to make these closures as shortly and lightly as possible." Thus a short aspirate may be inserted after a consonant; as G-h-eorge instead of George, or, as patient would say, G-g-g-eorge; and p-h-a, instead of pa.

Stammerers sing and whisper without difficulty, because in singing there is almost continued tone, and in whispering there is absence of tone. It is advised "to dwell on vowels at expense of consonants—and if vowel difficult to sound, it should be preceded by a short inspiration. Another beneficial exercise is to speak slowly, with teeth overlapping and pressed tightly together.

Result of treatment influenced by severity of case, intelligence of patient, also existing morbid conditions, especially those due to chorea or other nervous disturbances.

CHILBLAIN OF THE LIP.

Taenzer, in the *Monat. f. prakt. Derm.* gives the case of a patient of 33 years, who has suffered since he was 12 years old from a complaint common enough, but interesting to dermatologists from its location. It is called by the author "Lippenfrost," or, in English, chilblain of the lip.

According to the patient the trouble made itself manifest during the rigorous winter of 1870–71, by a sensation of smarting in the lower lip, with tumefaction and a reddish-blue coloration. In the beginning of April, 1871, the trouble disappeared spontaneously after having resisted all medical treatment. In October the affection reappeared exactly the same as at first, except that it was more painful owing to the presence of deep fissure. Desquamation was present, which was renewed daily for many days. During the following March all the symptoms disappeared as before, having resisted all medical treatment, only to reappear during October, and this condition of things continued regularly—the complaint always appearing in October and always disappearing when the warm weather began. Pruritis, always present, was increased on touch. The fissure, closed during the night, opened in the morning when the patient ate or talked, and gave rise to considerable pain with slight hæmorrhage. There was never any ulceration with resulting cicatrice, and when the complaint disappeared in the summer it left no trace, either objective or subjective. The upper lip was never affected.

Toward the end of October the complaint begins by a desquamation which lasts from six to eight days, and is followed by a sensation of burning and itching in the middle third of the interior lip. The color is from a bright red, or bluish red to a brownish red; the lip is tumefied at this point. The

exfoliation is completed in one day and the lip has, in appearance, a normal aspect, but it is very sensitive. Then the process begins again and all the phases are repeated, the complete cycle requiring from six to eight days. This is kept up until the warm season sets in, when it disappears spontaneously.

No treatment gave durable results except that the pain and itching could be relieved by hastening the cicatrization of the fissure by means of gutta-percha with lead plaster and balsam of Peru.—*Annales de Derm. et de Syph.*

SURGERY.

NITRITE OF AMYL IN CHLOROFORM ANÆSTHESIA.

Two recent deaths from chloroform administered for anæsthetic purposes direct attention anew to the various methods of resuscitation when dangerous symptoms appear. Of these methods none seems more promising than that in which nitrite of amyl is used. Dr. F. A. Burrall, of New York, believes that there is an essential antagonism between this drug and chloroform, and in a letter to the *Medical Record* refers to ten instances in which life was doubtless saved by the amyl. He sums up his views in these words: "In deciding upon remedial measures we must depend on both the observations of scientists and the teachings of clinical experience. With such light thrown upon the action of chloroform, let us suppose that a patient who is inhaling chloroform suddenly develops dangerous symptoms. Of such symptoms a tendency to fatal syncope is the most frequent. What conditions are present under such circumstances, and what shall be done to avert a fatal issue? We may hold that the cerebral vessels are contracted, and the central nervous system is losing the blood supply on which its activity depends. Circulation and respiration are faltering and death may occur suddenly at any moment. It is not a time for the application of any one method or remedy, but all the usual aids, as well as the reserves, of science should be immediately employed. The first indications are to revive circulation and respiration, since what arouses one seems to awaken the other. I think that, as nearly simultaneously as possible, the head should be lowered, the neck extended, nitrite of amyl given hypodermically or by inhalation, and artificial respiration practiced by the Sylvester method, since this method is the most covenient. It should not be forgotten that pressure on the abdominal aorta increases the blood-pressure in the carotid. If asphyxia be present, it would seem that the neck should be extended and the head raised higher than the feet."—*Brooklyn Med. Jour.*

RESECTION OF THE THORACIC WALL FOR OSTEOCHONDROMA.

Professor Ivan K. Zarübin, of Kharkov, relates (*Transactions of the Kharkov University Society for the advancement of the Experimental Sciences*, 1891, vol i, p. 1. with 3 figs.) the case of a well-made but rather thin and anæmic, young Cossack, who sought his advice on account of a steadily growing and occasionally painful tumor of seven years' standing. It measured 21 centimetres horizontally and 19 vertically, and occupied the right side of the chest between the nipple line and the postaxillary line, from the sixth to the ninth rib. The new growth was hard, nodulated, immovable, and non-adherent to the skin. The integuments over it were thinned but otherwise normal, and the nearest lymphatic glands apparently unaffected. An osteochondroma of the thoracic wall was diagnosed. The huge mass was removed together with the involved portions of the seventh, eighth, and ninth ribs. The gap left in the chest measured 17 centimetres in a horizontal and 16 in a vertical direction. On opening the thoracic cavity the lung collapsed, but only partially, owing to pleural adhesions around the periphery of the new growth. None of the serious respiratory or cardiac disturbances usually observed in similar cases occurred, and the hæmorrhage was only trifling. The cavity was gently cleaned with gauze, soaked in a 1 per cent. boracic acid solution, after which a long drainage tube was inserted, and the skin wound (which was crucial in shape) was closed with silk sutures. The tumor, which was much larger than an adult man's head, weighed 6 pounds and 6½ ounces; its point of origin was the seventh rib. Under the microscope it was found to consist of new osseous tissue in its central part, and of hyaline cartilage in the peripheral part. For the first two days the patient was much collapsed and cyanosed, and suffered from agonizing cough and obstinate vomiting. Subsequently his general condition slowly improved. A good deal of pus continued to escape from the tube for about seven or eight weeks. On the sixty-first day after the

operation the tube was removed; the wound was soundly healed throughout. On the hundredth day the man was discharged quite well, having been supplied with an appropriate pad to protect an extensive and deep depression, which remained at the site of the resection. According to the author, similar cases of resection of the thoracic wall for new growths have been reported by Billroth, Fischer, Leisrink, Maast, Richerand, Sédillot, Vasilieff, Volkmann, Waltmann, and Witrel. Of the number 6 recovered, while 4 died.—*Brit. Med. Jour.*

INGUINAL COLOTOMY.

In the *Centralblatt für Chirurgie*, No. 30, 1891, Dr. Landow, of Göttingen, describes an abnormal condition of the sigmoid flexure, which is regarded as one of practical interest, as the possibility of its occurrence in any case of inguinal colotomy would contraindicate the practice advocated by Madelung of stitching up the lower opening after complete division of the gut, and allowing the lower and detached segment to fall into the pelvis. In two cases of inguinal colotomy recently observed in the Göttingen clinic, where the usual practice is to divide the gut and to stitch the two open ends to the external wound, it was noticed that the discharge of fæcal matter always took place from the lower and not from the upper opening, although at the time of the operation the lower portion of the gut was traced downwards towards the bladder and the upper portion in the reverse direction. In one of these cases, which terminated fatally, it was found at the necropsy that the sigmoid flexure, which was very long and freely movable, passed upwards and outwards as far as the splenic flexure of the cæcum and then curved downwards and towards the middle line, reaching the rectum after a long and tortuous course. The division of the gut having been made in the ascending portion, what was supposed to have been the distal opening was that nearest the cæcum, whilst the supposed upper opening corresponded with the divided end of the inferior segment of the elongated and contorted sigmoid flexure.—*Brit. Med. Jour.*

THE ABORTIVE TREATMENT OF BUBOES.

Welander (*Archiv fur Dermatologie und Syphilis*, 1891) endeavored to eliminate a specific bacteria from chancroidal pus, but failed. The staphylococci and other cocci found were readily killed with mercurial lotions. Believing that buboes were caused by the transference of the staphylococci and streptococci, by means of the lymph channels to the glands from the chancroid, he endeavored to find a mercurial preparation which, when injected in concentrated form, would not cause intense pain or marked irritation. The material here used was benzoate of mercury, in one per cent. solution, with one-half per cent. of sodium chloride added. One or two injections of a half-gramme of this liquid were made into the gland. The skin was previously cleansed, also the syringe. A compress of sublimate solution was bound over the gland. Redness of the overlying skin was treated by penciling with itchthyol solution, 1 : 2-3. The details of thirty-two cases are given. In twenty-seven of these fluctuation was either absent or doubtful. In eighteen hospital cases healing occurred without discharge of pus; in two some pus oozed out through the injection puncture. These cases were kept at rest. In nine private cases healing occurred without discharge, and three discharged pus. In eight cases, in which fluctuation was marked, all sooner or later discharged through the injection opening, none absorbed. Most of them pursued a relatively favorable course, and in only two cases was incision necessary. There are sixteen cases still under treatment. In summing up, seventy-three per cent. of the cases gave favorable results. It is to be hoped that a mercurial preparation will be found that causes less pain and infiltration than the benzoate of mercury; but as yet we know of none. Whether the theoretical grounds on which this treatment was founded are accepted or not, it cannot be denied that by this means buboes have been healed without the occurrence of those unsightly and lifelong-lasting scars, as has heretofore been the case.—*Univ. Med. Mag.*

INFECTION AND TUMOR FORMATION.

Schleich (*Deutsche Med. Woch.*) remarks that infection of the organism never arises from dispersion of aggregations of leucocytes. On the contrary, every tumor is a tissue of new-formation, which possesses an analogy to the development of the fecundated egg. Has the vital energy inherent in the cells from the first physiological impregnation been dissipated, so will the cells lose their resistance, and react moreover to all impressions in a manner quite different from usual. Such a weakened cell becomes a pathological "sperma," and impregnates another cell. Both the impregnating and impregnated

cells are cells of the tissue from which the tumor itself develops. A cell or pathological "sperma" fructifies; another cell comparable to the ovulum is fructified, and thus begins the tumor, since, inside the organism, a tissue cell which has become infectious (sperma) infects (impregnates) a second cell. Sleich regards tumor formation as a kind of endogenous infection. Oestrich remarks, that while this theory has never been disproved, there has certainly never been the slightest demonstration of its truth.

REMOVAL OF A STONE FROM THE BLADDER BY VAGINAL CYSTOTOMY.

In the *Pittsburgh Medical Review*, 1891, Reamy, of Cincinnati, records a remarkable case, in which, after the removal of a stone weighing 365 grains, *per vaginam*, it was necessary to perform four operations to close the resulting vesico-vaginal fistula, which was half an inch in length. The stone would have been removed by the supra-pubic operation if the operator had realized its size. The urethra was dilated to the size of the little finger; no paralysis followed.

Owing to smallness of the vagina, the child being but six years old, together with the fact that the child was quite fat, made the operation for closure most difficult; and at the fourth operation the parts were much altered, considerable sloughing had occurred, and incrustation with urine salts; the edges of the wound were everted, ragged and spongy.

The left ureter was seen to be discharging urine from the wall of the fistula. With much difficulty the ureter was dissected up, the mucous membrane of the bladder cut away sufficiently to uncover it; the free end of the ureter, liberated by the dissection referred to, was not cut off, but turned into the bladder. Seven No. 30 silver wire sutures were introduced into the fistula and allowed to remain two weeks; upon removal union was perfect. Though Parvin, Campbell, and others have turned an exposed ureter into the bladder, this is probably the first case in which this manipulation has been successful in a subject so young.

GYNÆCOLOGY.

CASE OF ACQUIRED ATRESIA HYMENALIS.

In the *Australasian Medical Gazette* for June, Henry Forbes, M. B. et Ch. M. Aberd., relates the following history: E. S., thirty years old, domestic servant, single, was admitted, on the 2d of January, 1891, into the Charters Towers Hospital, complaining of dysuria and a swelling of the abdomen. Two days before, she had seen Dr. Browne, who sent her here.

She said she had enjoyed very good health at home, but since her arrival in Queensland she had suffered more or less from debility, though not enough to interfere with her work. She had been an inpatient at the Towers Hospital in June, 1890, when I attended her for a specific sore throat and a papular rash. Some time before this she had had a vaginal discharge following coitus, and afterward a swelling in the groin. These were treated by a doctor, but he can give me no particulars. I examined her at that time for the rash, but I did not notice any abdominal enlargement. Quite recently she had been Dr. Browne's patient for arthritis of the ankle, but complained of no abdominal inconvenience till a day or so before admission. She first menstruated at twenty, and has been very irregular throughout, sometimes missing several months. Her menses lasted usually a day, were very scanty, and were accompanied with great pain. Since her first admission into the hospital in June, 1890, she has not seen anything, and she thinks not for some time before; possibly not since she last indulged in sexual intercourse, the result of which was the vaginal discharge.

On admission, her ankle was swollen and walking difficult, the left thigh œdematous and tender, urination frequent and painful, and a large swelling occupied her abdomen, extending well above the umbilicus. A catheter showed the urethra and bladder normal. Rectal examinations: a tight, rounded tumor, filling the pelvis and flattening the rectum against the sacrum, and vaginally the finger encountered an elastic swelling bulging between the majora and yielding to pressure. At the upper part of the distended hymen were some cribriform markings, but no visible cicatrix. On abdominal palpation was felt a large, tense swelling, rising out of the pelvis, extending almost to the umbilicus, and continuous with a smaller and harder tumor that reached two inches above the umbilicus, and was of the shape of the enlarged uterus. From the upper angles of the smaller tumor could be distinctly traced two hard, cord-like bodies, extending one toward each iliac fossa, and ending in ovoid enlargements. Percussion over the umbilicus gave a distinct thrill to the bulging hymen, and a

hypodermic syringe introduced into it withdrew the characteristic tarry fluid of retained menses.

Dr. Browne and Dr. Paoli saw the case, and we agreed to tap. The smallest trocar was entered a little above the center of the hymen, and the fluid was very slowly withdrawn. After it had ceased to flow, a bistoury, guided in on the cannula, made a permanent opening. A large uterine irrigator was introduced into this, and the vagina—enormously dilated—was washed out with a hot saturated solution of boric acid till the fluid came away clear. The opening was dressed with salicylic wool. The syringing was continued daily for the next ten days; the discharge, which never became offensive, ceased in five, and the temperature on the two nights following the operation just reached 100° and then became normal.

The patient never had any abdominal tenderness, was kept in bed for three weeks, and at the end of that period menstruated freely and easily.

Vaginal examination immediately after the operation showed the vagina to be an immense cloaca filling all the pelvis, and the finger could detect at the top a large ring of soft tissue representing the changed cervix. I examined her on Saturday, the 4th of April. The hymenal opening is now quite patent, the vagina has almost recovered its usual shape and consistence, but the cervix is still soft and swollen (though much smaller), and the os admits the tip of a small finger. Her menses are now regular and easy.

Notes.—1. Acquired atresia of the hymen or the lower part of the vagina seems to be rather a rare condition. Dr. Matthews Duncan, in his *Clinical Lectures*, says: "Sometimes the vagina becomes closed by the healing of sores, the result of sloughing from pressure during parturition, or the reselt of syphilitic infection; but though cases of stricture, more or less tight, and having a small lumen from these causes, are not uncommon, I have not seen one of complete closure (atresia), with retention and accumulation."

In this case I should think the atresia was produced either by the healing of a syphilitic sore (though no scar was visible), or by the efforts at intercourse producing inflammation of a tough hymen with possibly a very small opening.

2. The total absence of subjective symptoms. She never noticed her increase in size even till the dysuria called her attention to it.

3. The fluid removed measured sixty-five ounces. Duncan says the quantity of accumulation varies much; that in his own practice he never saw more than fifty ounces, though he had heard of a well-authenticated case which had one hundred and five ounces.

THE ULTIMATE RESULTS OF VAGINAL HYSTERECTOMY FOR CANCER.

Leisse (*Archiv fur Gynäkologie*, Band xl., Heft 2) replies to the criticisms of the statistics of the Dresden clinic by presenting a tabulated statement of the histories of all the patients, so far as they could be obtained. These are compiled with great care. Of eighty patients who were heard from upwards of two years after the operation, 56.25 per cent. were still living. Since eight of the deaths were not due to a recurrence of the disease, this leaves the actual mortality only 17.8 per cent. Thirty-seven of the forty-five surviving patients were examined at the clinic, so that there was no question as to their local condition, and in the other cases reports were received from competent physicians. The following are the facts: Of eighty patients examined over two years after operation, forty-five were free from recurrence; 58.6 per cent. (out of fifty-eight patients examined) were well after three years; 59.5 per cent. (out of forty-two) after four years; 60 per cent. (out of thirty) after five years; 66.6 per cent. (out of nine) after six years; and the two patients who had survived the operation seven years were both perfectly well.

COMPLETE AMENORRHŒA IN A FERTILE WOMAN.

Dr. Marion Dunagan (*Archives of Gynæc.*, August, 1891) states that a pregnant colored woman, already the mother of ten children, assured him that she never menstruated in her life, and was 19 years old and the mother of two children before she knew that such a phenomenon occurred in women. She was an unusually stout and healthy woman, did hard work constantly for her living, and the only inconvenience that she experienced was an occasional swimming in the head, which was but trifling. Dr. Dunagan holds this case proves conclusively that menstruation and ovulation are not essential to nor dependent upon each other.—*Brit. Med. Jour.*

OBSTETRICS.

EARLY CURETTING IN PUERPERAL INFECTION.

M. Charrier discusses (*Archives Générales de Médicine*, August, 1891) early curetting as a prophylactic and therapeutical measure in puerperal infection. It is only of recent years that the uterus after delivery has been looked upon as a wounded surface, and the difficulty of keeping this wound healthy and aseptic is shown by the not inconsiderable number of women in whom delivery, and more especially abortion, has been the starting point of a number of more or less serious accidents. The fever may be of short duration, and the infection an attenuated one, but as soon as the patient returns to her ordinary life the trouble begins. Most often the operation of early curetting is one of urgency, and there is little time for preparing the patient. M. Pozzi looks upon repeated shivering, a temperature of over 39° C. in the axilla, the general state of the patient, the pulse, etc., as affording pressing indications. The curetting is done in much the usual way with strict antiseptic precautions and with great gentleness, a blunt and non-cutting instrument being used. The uterus is washed out, and the cavity tamponed with iodoform gauze. Anæsthesia is not necessary. The amount of fœtid *débris* brought away may be extraordinary. The author says that this treatment is indicated in cases of slighter infection, when abdominal tenderness, less marked fever, and fœtid lochial discharge are present. Antiseptic injections may render the *débris* powerless from a bacteriological point of view, but such patients do not thoroughly recover. The objections raised against this treatment are that intra-uterine washing out is most often sufficient; and, secondly, the supposed gravity of curetting the uterus after delivery. But if anything remains behind in the uterus these injections cannot be counted upon; and, again, if the operation is done with care, it is never followed by evil consequences. Puerperal accidents, rare nowadays, will no longer be feared if washing out the uterus and curetting be used. If this treatment of puerperal infection has not as yet passed into practice it is because it has been adopted too late in the case, or has not been carried out with the necessary precautions. If this be done, the maladies of the uterus and appendages appearing later will be diminished in numbers. M. Charrier gives details of five illustrative cases.—*Brit. Med. Jour.*

INDICATIONS FOR CÆSARIAN OPERATION.

Piskacek (*Arch. d'Obstet. et de Gyn.*, April, 1891). In absolute contraction of the pelvis the author pronounces himself in favor of the Porro operation. His reason is the danger of a second Cæsarian section in the event of a new pregnancy and the risk of uterine rupture should the operation not be done immediately at the onset of labor.

In pelves flattened less than to 7½ c.m. and in pelves generally contracted to 7 c.m. neither version, perforation nor the conservative Cæsarian section is to be thought of so long as the time for premature labor has not passed.

If the pelvis has a diameter of less than 7 c.m. he advises Porro (on election of the mother) to prevent a subsequent pregnancy. If the woman rejects abdominal section, even though the child cannot be saved by induced labor, the latter operation or induced abortion must nevertheless be done in the presence of absolute contraction.

Podalic version as an alternative of section on the relative indication, an atypical application of the forceps or embryotomy on the living child will the more rarely be the choice of procedure the less time is lost in waiting. With the primipara version must never be preferred. With multiparæ it must be resorted to only in the most favorable conditions.

The author thinks the infantile mortality of craniotomy is compensated in a year by the possibility of having a living child in another pregnancy and the fact that women after Cæsarian section do not readily become pregnant again, to say nothing of the mortality of the Cæsarian operation. Thus Cæsarian section is conservative only in certain conditions, that is to say in conditions favorable to the operation, for example when a living birth is impossible at or near term, per vias naturales, when the mother desires expressly to have a living child and assents to the operation after the danger has been fully explained to her.

In the main Piskacek employs Cæsarian section in multiparæ only when they have lost their children in previous births. In primiparæ there can be no question when there is at the beginning of labor a rigidity of the cervix that threatens rupture of the uterus. In all other cases he considers per-

foration practiced upon the living fœtus not only legitimate but imperative. Only the conservative operation of Saenger and not the Porro can come in competition with perforation.

A CHILD CRYING IN UTERO.

Dr. McLean reported the following case: (*Trans. N. Y. Obstet. Soc.*) In August last, I was called to see Mrs. S., æt. 30, in labor at term with her fourth child. The waters had escaped, and while rectifying a malposition of the head by the insertion of the hand to the pelvic brim, atmospheric air was admitted to the uterus, and the child commenced respiration and crying in utero. The occiput was turned forward. While I was applying the forceps, the child was crying lustily, the voice sounding as if coming from the cellar. Others heard it, and it was curious to note the consternation in their faces. This crying was kept up for four or five minutes, when delivery was safely accomplished. The mother and child did well. The air was expelled with the secundines. I had never known such a thing to occur. The case is entirely different from those cases frequently seen of spasmodic cries while the child's head is in the vagina; the head was in the uterus and in fact slipped away from my hand several time,s crying all the time. This phenomenon was witnessed by Dr. Tracy and the nurse present.

PÆDIATRICS.

SPURIOUS WHOOPING-COUGH.

Prof. Hobart A. Hare in a lecture at the University of Pennsylvania, said: You are probably aware that whooping-cough, while always existing in large cities in sporadic cases, occurs, as a rule, in epidemics which may be long-continued or short in their duration. At the present time this city is thus afflicted, and during the early spring months of last year a large number of cases were presented at this clinic. You have, in consequence, seen so much of this disease that I should not have brought this boy before you were it not to show you an aberrant form of pertussis, if we can so designate it. The child, who is 5 years of age, has been suffering with a spasmodic cough without the development of any whoop for some four weeks, and has not lost its appetite, strength or sleep during that time. While the cough frequently occurs at night, the patient is only partly aroused, and, as soon as the spasmodic expiratory movements cease, falls back on his pillow and is at once in slumber. On only one or two occasions have the spasms interfered with the breathing sufficiently to alarm the parents, and these only lasted for a few moments. There has not been vomiting, conjunctival or aural hæmorrhage, nor any nose-bleed, all of which symptoms may appear in cases of well-developed or severe whooping-cough. Practically, then, the only thing we are asked to do for this child is to discover the cause of the cough and to remove it, if possible. As you are probably aware, cough is a frequent symptom of many conditions not directly affecting the air passages, and it may arise from gastric disturbances which are acute or chronic, from intestinal irritation, from the drying of the mucous membrane of the larynx by the heat of fever, and in other cases it may be a habit which is as difficult to cure as chorea. Cough may also be due to relaxation or hypertrophy of the uvula, to enlarged tonsils and nasal disease. Besides these causes we have, of course, the acute diseases of the respiratory system. On examining this boy, however, we find that none of those conditions predisposing to cough can be said to exist, and the lungs are perfectly normal, while the bronchial tubes contain very few râles which are not constantly heard. As I have already told you, his appetite and general health are unimpaired; and his tongue, you notice, is unusually clean and devoid of those appearances indicating gastric or intestinal trouble. He is not a nervous child, and has never had chorea or any nervous affection. The cough is not a habit cough, as it is too violent and prolonged, and the expiratory efforts are so frequently repeated before inspiration occurs that some cyanosis or reddening of the face occurs. The case lacks all the other signs common to whooping-cough except this series of expiratory spasms; and the chest, as I have stated, is free from the signs of bronchitis, nearly always accompanying this disease to greater or less extent. Having told you everything that the case is not, you are probably waiting for a description of what it is. So far as I am able to determine, it is a case of spurious or abortive whooping-cough, a diseased condition which seems to have been quite common during this month and last, for I have seen several other cases which were equally marked. Very recently, Guido described to the Italian Congress of Pædiatry (Rome, 1890) a form of paroxysmal and spasmodic cough which resembles whooping-

cough, and yet which is not the true disease. He noticed a great number of these attacks during the epidemic of influenza, and the following distinguishing features were noted:

There was a greater frequency of the attacks at night than in the day, there was almost never any vomiting, and the signs of bronchitis were less disseminated than is usual in whooping-cough. There was absence of hæmorrhage and of the bacillus of Afanasieff, which, you remember, is supposed to be pathognomonic of pertussis. In five autopsies there was found a lesion in the pharynx and not in the larynx. The treatment consisted in the administration of antispasmodics, the bromides and those measures which are generally employed against true whooping-cough.

Gueneau de Mussy has also recognized a pseudo-pertussis which is practically indentical with that of Guido and thinks it a symptom indicative of reflex irritation of the pneumogastric nerve following direct irritation of lymphatic ganglia. Indirectly it may arise from hypertrophy of the nasal mucous membrane, and Tasano states that he has seen a case in which cure followed the excision of the hypertrophied tissue. These cases seen by Tasano, if accompanied invariably by nasal lesion, can only be considered as reflex coughs, and rarely the disease of which we are speaking. If due to nasal hypertrophies, the cough should be constant, but in all the cases named it has run a definite course of five or six weeks.

I do not know what to consider the cause of the attack in this child, unless it be some state coincident with the conditions consequent upon the recent epidemic of la grippe, which is even now scourging our Western cities. This, as I have just stated, is the opinion of Guido in regard to his cases. The treatment is identical with that usually employed in whooping-cough—namely, full doses of antipyrin or acetanilide three times a day, accompanied by one grain of tannate of quinine in a quinine chocolate morning and night. By full doses of antipyrin and acetanilide, I mean one grain of the former and one-half grain of the latter at each dose for a child of five years. If cyanosis comes on, the dose must be decreased. Small doses of the bromides are also of service. Lactucarium is useless except in the form of the syrup as a vehicle.—*Ann. Gynæ. Pæd.*

EPIPHYSEAL FRACTURES IN THE TREATMENT OF WHITE SWELLING.

Iscovesco (*Rev. Mens. des Mal. de l'Enf.*, May, 1891) has observed epiphyseal fractures in two cases of coxalgia, and in two cases of white swelling of the knee, which were produced during attempts at treatment of the joint. He draws the following conclusions:

1. In certain cases of chronic articular disease there is true softening of the contiguous epiphyseal cartilages.

2. In the four cases referred to the children were under ten years of age.

3. In none of the cases did the fracture of the epiphysis appear to affect the prognosis unfavorably.

4. When this accident occurs it is necessary to treat the limb by immobilization with extension in a favorable position.

5. In the cases referred to, not only did the fractures undergo favorable evolution, but they seemed even to have a favorable influence upon the evolution of the articular disease, so that it is an open question whether osteoclasis of the contiguous joint might not be a favorable adjunct in the treatment of white swelling.

HYGIENE.

PARASITES IN MALARIA.

Since Laveran discovered a parasite in the blood of several patients suffering from malarial fever ten or twelve years ago, many other observations on this interesting subject have been made both by himself and by many other writers, Continental, American, and Indian. One of the latest papers on the subject is a dissertation by Dr. Romanovski, of St. Petersburg. He thinks that the malarial parasites are so inseparably associated with the disease that the blood of patients supposed to be suffering from malaria ought to be examined as a matter of routine, as the sputum of phthisical patients is, for microbes. He finds that the amœboid parasite of tertian fever has a nucleus which acts by means of a fibrous metamorphosis of the chromatin network, and not by a direct method. When quinine is administered in sufficient doses it causes the destruction of the amœboid parasite, the degeneration, which is easily observed, chiefly affecting the nucleus. With regard to the prescription of quinine, he says that it should be given in two doses of about fifteen grains each during the twelve hours immediately preceding the attack, because during that period the number of adult parasites is at its maximum. From some observations made with tincture of sunflower Dr. Romanovski was led to the conclusion that

this drug, though not without its influence on malarial fever, cannot be considered as a satisfactory substitute for quinine. He appends to his work references to more than 120 articles bearing on the subject, some few of which are in Russian, but the great bulk are in more accessible languages.—*Lancet.*

IS TYPEWRITING INJURIOUS TO THE EYES?

In this age of typewriters, the question suggested is one of interest, at least to eye specialists.

In a letter to the *New York Medical Times*, Dr. Geo. L. Freeman discusses the fallacy of the current opinion that typewriting is necessarily injurious to the eye.

As indicative of what expresses the present opinion, we quote the following paragraph which has been going the rounds of the medical press:

Almost every typewriter, sooner or later, has trouble with his eyes. The typewriting machine is supposed to save the eyes, but the effect is quite the contrary. The eyes are all the time in motion while writing, and the rapid jerking of the eye from one point to another on the little keyboard soon tires the muscles and makes the eyes, and sometimes the whole head, ache. Then a great many girls have the habit of turning up the carriage to see what has been written, and leaning back in the chair while reading it. This, too, is bad, for the reason that it requires a rapid adjustment of the eye to the different distances, and so tires the whole organ. The only way to save the eye when using a typewriting machine is to acquire such facility that it is not necessary to look at the keyboard, and the eyes will be saved the thousands of little jerks to and fro which do so much harm.

Dr. Freeman then cites his own experience as follows:

I have been using a typewriter for about ten years, and during the latter half of this period with the left hand alone, the right hand being disabled. I was first led to try the machine by reading a very emphatic testimonial in its favor by the eminent English ophthalmologist, R. Brudenell Carter, who stated that he had found it of the greatest assistance to himself, and especially recommended it in cases where the sight was weak or imperfect in any way. This should be almost enough to settle the question, even if the above quoted objection founded on *eye-jerking* were not so palpably nonsensical. But I would invite the contribution of further evidence on this point, both from specialists and professional typewriters. I do not believe that "almost every typewriter has trouble with her eyes"—or *his*, either. Are not most people, while awake, constantly adjusting the organ to different distances, with as much rapidity as when looking at "the little keyboard?" From my own experience, I am firmly convinced that physicians, instead of finding fault with these admirable contrivances, ought to be the strongest advocates of their more extended employment.—*Medical Age.*

MEDICAL CHEMISTRY.

A NEW ALBUMEN TEST.

In *Fresenius' Zeitschrift für Angewandte Chenue*, Dr. A. Jolles gives the following test for albumen in urine, which he claims to be sensitive to within one one-hundredth of one per cent. of albumen. To 10 ccm. of the suspected urine add an equal amount of strong hydrochloric acid. Do not agitate the mixture, but immediately add with a pipette two or three drops of liquor calcis chlorinatæ. If albumen be present, a white turbidity will at once show itself in the upper part of the tube.

METHOD OF DISTINGUISHING THE BUTTER OF MARGARIN FROM NATURAL BUTTER, WITH NITRATE OF SILVER.

By this reagent, M. Brulle has succeeded in distinguishing the butter of margarin. Treated by this reagent, natural butter preserves its color, while pure margarin becomes brick red. This latter tint is less apparent when treating a butter to which margarin has been added; nevertheless, the practiced eye can readily recognize a mixture not containing more than 5 per cent. of margarin; with 10 per cent., the red tint is very pronounced.

GALLATE OF BISMUTH, OR DERMATOL.

Under the singular name of "dermatol," Dr. R. Heintz, a medical practitioner residing at Breslau, designates a chemical preparation which is said to be quite new, namely, the *basic gallate of bismuth*, and he recommends this compound as an antiseptic capable of being employed as a substitute for iodoform in the dressing of wounds and

ulcers, etc. The basic gallate of bismuth, or dermatol, presents itself as a fine, absolutely inodorous powder of a saffron-yellow color. It is non-hygroscopic, and appears to be quite unaffected by exposure to light and to the air. As this compound is insoluble in ordinary liquids, it can only be employed as a powder. Besides its antiseptic properties, which are said by Dr. R. Heintz to be strong, he claims also for it a stimulant and astringent action, which makes it valuable in the treatment of wounds and ulcers, and tends to hasten their cicatrization. He states, moreover, that, "on account of its insolubility," poisoning by it is impossible; but sulphate of baryta, which is a perfectly insoluble powder, acts as a poison and has been used for killing rats, etc. Dermatol, we are assured, does not produce any local irritation whatever, and, according to the writer above named, it may be substituted for iodoform in all cases where the latter is indicated, and may actually be used internally, he says, in the dose of 30 grains per diem, in diseases of the digestive tract, especially in the profuse diarrhœa which is present in catarrhal and ulcerous affections of the intestines. That we have here a new and non-irritant powder, supposed to possess strong antiseptic powers and to possess astringent qualities, no one will deny; but that it will replace iodoform in all its indications is saying more than any practitioner will accept, though it may prove equal to the latter in the external treatment of ulcers, and prove applicable in certain cases, for instance in diarrhœa, where iodoform would not be prescribed. In this instance it would be calculated to replace the subnitrate of bismuth with advantage, as being more astringent and perhaps possessing greater antiseptic powers.—*Monthly Magazine.*

NEWS AND MISCELLANY.

CINCHONA CROP OF 1890 IN JAVA.

The official report of the government cinchona plantation in Java states that the crop of 1890 amounts to 534,562 pounds, 142,396 pounds being cinchona succirubra, 6,447 pounds cinchona Josephiana, 342,271 pounds cinchona ledgeriana, and 43,448 pounds cinchona officinalis; 100,000 pounds of bark were collected in the first quarter of 1891. The bark sold at Amsterdam out of the crop of 1890 sold for 1½ pence per unit for common kinds. The cinchona ledgeriana brought good prices, and even better ones were realized by the bark of the cinchona succirubra, viz., up to 2s 4d per pound. The "Melattie" Company's cinchona plantations in Java have done well in 1890, and the shareholders receive a dividend of 11 per cent., after placing £250 to reserve, and writing off £166.

THE CHINESE TREATMENT OF HYDROPHOBIA.

A Chinese journal, referring to the dangers of hydrophobia, points out that the European doctors have not yet discovered an effective treatment for this disease. In order to determine whether the disease is really hydrophobia, the following method is recommended by a Chinese contemporary for this purpose: Get a gong or any large brass utensil and strike it before the patient. If he is suffering from hydrophobia he will at once show signs of madness; then fan him with a large palm-leaf fan, and he will crouch down as if in great fear. When the presence of the disease is thus ascertained, the next step that should be taken—a most important one—is to search the hair of the patient. There will certainly be found one hair of the color of vermilion, and rather stronger and coarser than ordinary hair. This particular hair should be entirely pulled out, not even the smallest part of the root must be left, otherwise the disease cannot be cured. When this has been done a prescription must be prepared, and the drugs used should be of such a nature as will expel the poison from the place in which it is.—*Brit. Med. Jour.*

CHOLERA IN CHINA AND JAPAN.

That dreaded scourge, the cholera, a correspondent writing from Shanghai, China, says, is rapidly beginning its annual ravages. It had been confidently hoped that as the summer passed and few serious cases of the plague occurred, the year might run by without the fatality which has overtaken Chinese cities in past years. But within the past fortnight the disease has been gaining headway rapidly, and already seven Europeans are known to have suddenly died from cholera. That the disease has been playing havoc in the native-crowded cities has been known, but its attacks upon foreigners, who had thus far managed to ward it off, is something almost unprecedented, and augurs badly for the settlements of foreigners along the Chinese coast.

Physicians who have been familiar with Asiatic cholera in all its forms for several years think that unless the winter season with its frosts sets in early and checks the spread of the plague the mortality during September and October bids fair to be very great, probably surpassing that of the same months of last year. The hot, dry summer which Eastern China has just experienced, and the consequent illnesses of the mass of the people, have rendered them particularly liable to catch the germs of the disease and their constitutions little liable to withstand its ravages.

At Amoy and Foo-Choo the number of daily deaths is, indeed, alarming, and at Foo-Choo, a large city near Shanghai, the mortality has been much more serious than during last summer, when it raged so terribly throughout this region.

In Japan, also, the returns show a gradual increase in the number of deaths in the larger cities, Nagasaki heading the list. On account of the great loss experienced last year by the disease checking the usual influx of summer visitors and the trade of foreign steamers, the Japanese authorities are trying to keep the spread of the cholera from public knowledge, and it is only from private sources that the true state of affairs is known. The Japanese seem to be as subject to the disease as the Chinese, and the mortality seems almost as great, in spite of the better climate and medical aid with which Japan is equipped.

THE APPETITE OF OUR ANCESTORS.

Although our modern ways of cooking are more refined, and all sorts of spices are employed to whet our appetites, it is a lamentable fact that we cannot approach our ancestors in the amounts of food with which they were able to regale themselves.

The Journal de la Sante cites the following from an old book on cookery, dated 1523:

"On the 6th of August of this year a certain nobleman dined, as was his custom, in the apartment of his wife. The dinner was an ordinary one consisting of two services, one of which was partaken of by all the servants. There were a few guests. The meal was simple but substantial. First service: boiled capon, breast of mutton, a piece of beef and kid, a swan, a pig, a breast of veal, roasted capon, custard. Second service: Pullets, quails, pigeon, a venison pie and several tarts."

To illustrate the vigorous appetite of the women of those times, the following is quoted from the same book: "On the 24th of October of this year, two ladies breakfasted on the following: A piece of beef, a goose, sweet-breads and a capon." That is not bad for a simple breakfast.—*Dietetic Gazette.*

ENORMÓUS MICROSCOPE.

The Poeller Physical Optical Institute, of Münich, have under construction an enormous microscope for exhibition at Chicago in 1893. It will magnify to 16,000 diameters, or, as ordinarily fitted, to 11,000 diameters. An electric light of 11,000 candle-power is to be used for illuminating the image, which is to be projected on a screen. As the heat from this powerful light would derange the focus by expansion of the metal, an ingenious device is used to cool the metal. This is a small copper cylinder filled with liquid carbonic acid under a pressure of 350 pounds to the square inch. It is connected with the microscope in such a manner that an electric regulator automatically opens a valve and allows a drop of the acid to escape in a spray on the metal to be cooled. The liquid immediately evaporates and produces intense cold. The whole cost of the instrument is said to be nearly $10,000.—*Scientific American.*

HOW TO LAUGH AT THE MOSQUITO.

I notice that some one recommends the use of camphor against the mosquito nuisance. I have used camphor for this purpose for some time, though I have not found it necessary to burn it. I take a piece of camphor fully an inch square and half an inch thick; this I lay on the bureau—always exposed—in daytime, and on or near the pillow at night. This is the only remedy I ever tried that afforded thorough relief. Even a mosquito bar lets the mosquito in and bars the air out. Have two windows and door of the room wide open, no bars, and draft through. Have not been annoyed by mosquitoes since using the camphor, except to a very light extent for a night or two in case of storm and unusual draft through the room. I think then an additional piece or two of camphor would have prevented that. The mosquito has been a great annoyance to me, but I feel that I can now laugh at him. If others find the remedy as effectual as I have it will be a boon.—*Exchange.*

Clinical Lecture.

THE DIAGNOSIS OF INFLUENZA.

BY JAS. M. ANDERS, M. D.,

PROF. OF THEORY AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE AT THE MEDICO-CHIRURGICAL COLLEGE.

Gentlemen: The man before you, A. D., aged 42 years, carpenter, had bronchitis a short time prior to an attack of la grippe last winter. He presented himself at the hospital a few weeks ago giving us the following history: The present attack came on suddenly with severe chills, fever followed by profuse sweating, headache, pain in the limbs and great physical prostration. When you leave these halls next spring and enter into practice for yourself, you will meet cases presenting themselves to you with a history very similar to this, and which cases you must distinguish from the "grippe," for many will suppose themselves to be suffering from this disease. The energies of an epidemic of la grippe are expended in from two to four weeks, and it does not recur in the same place for several years as a rule. Hence you will only rarely meet with it. True, there will be sporadic cases, but most of the self-diagnosticated cases you will meet with next spring and the following winter you will after careful study look upon as cases of ordinary catarrh. The cause of la grippe is a specific poison which rapidly reproduces itself in the atmosphere, a fact that accounts for the rapid spread of the disease.

It affects all persons in all conditions of life, though the feeble and the aged are first affected. It occurs in two forms, mild and severe. The mild form is more liable to occur in persons who have been previously in good health. The severe form in persons previously run down, and is apt to leave the system, particularly the nervous system, more vulnerable, and is characterized by an exaggeration of the leading symptoms with especially greater physical prostration.

There may be said to be three forms as regards classification of the symptoms, namely, nervous, abdominal and catarrhal. In the nervous type there is more physical prostration, severe pains throughout the body, much headache, especially over the root of the nose. The abdominal type is especially liable to occur in children and is attended with vomiting and purging. In the catarrhal form there is a dry, racking cough with little or no expectoration. The complications liable to occur are capillary bronchitis followed by collapse and consolidation. The sequelæ are phthisis and chronic bronchitis. To diagnose ordinary bronchitis from that occurring with la grippe, you must pay attention to the history as well as the physical signs and symptoms. The bronchitis with "grippe" is attended with more fever, harder cough, less expectoration occurring during an epidemic, irrespective of seasons without history of exposure or change of temperature. In ordinary bronchitis you have the history of exposure to cold or wet, and most cases occurring during the winter and spring months and absence of epidemic. The symptoms which this man suffered from during his attack were those of a severe cold, great physical prostration and pains throughout the body. He now has more cough than during the primary attack. Last spring he was treated at the Dispensary, improved. Some weeks ago he again presented himself when I made a careful examination of his chest and found evidences of phthisis; had a specimen of his sputum examined and in it were found the tubercle bacilli. Now, how far does "grippe" influence the development of phthisis. In cases where a marked predisposition exists grippe, especially if not properly met, will be likely to be followed by this dreaded disease.

When chronic bronchitis previously existed, as in this case, phthisis is liable to be produced. There is another disease liable to

be confounded with grippe, viz., typhoid fever. Indeed, patients often present themselves imagining they are suffering from grippe when they are really starting with typhoid. They will complain of pains throughout the body, physical depression, loss of appetite, chills, fever. In grippe the fever will not have the insidious onset nor show the same regular rise during the early stage, neither will there be the enlarged spleen nor the abdominal eruption. Turning now to the physical examination of this patient we find on inspection depressions above and below both clavicles and less movement on the left side over the same area. He is also much emaciated. Palpation—vocal fremitis more marked on the left side; normally vocal fremitis should be more on the right side. This then would indicate some consolidation on the left side. Percussion—there is no difference in favor of either side, this also indicates a slight degree of consolidation of the left lung where the percussion note over right apex is natural because normally there should be more pulmonary resonance on the left side. Auscultation—I do not hear any rales, but bronchovesicular breathing on the left side, an increase in the bronchial element. A lessening of the vesicular. We, therefore, are justified in concluding that he is suffering from insipient phthisis or tubercular infiltration probably as a result of the grippe. The treatment of grippe might here be briefly mentioned. It is symptomatic. Quinine should be given in pretty stiff doses for its tonic effect, to keep down the fever and for its controlling action over the catarrhal process; morphia controls the laryngo-bronchial irritation and thus allays cough and produces sleep. Another good remedy in the bronchitis of grippe is the muriate of ammonia in doses of gr. x every two hours. In the present case we should endeavor to arrest the tubercular process. The best remedy we know of for this purpose is creosote beginning with moderate doses and gradually increasing until the system becomes well saturated. I shall order him creosote half a minum four times a day. As a tonic and reconstructor of tissue, we shall also prescribe the compound syrup of hypophosphites. The diet shall be generous, especially milk, eggs, tender meats, etc. He should spend as much time as possible in the open air. In conclusion, I should like to insist that you treat the sputum of these patients antiseptically as a precaution against spreading the disease through contagion.

COMMUNICATION.

TREATMENT OF LARYNGEAL PHTHISIS.*

BY ROBERT LEVY, M. D.,

DENVER, COLORADO.

PROFESSOR OF PHYSIOLOGY AND LARYNGOLOGY, GROSS MEDICAL COLLEGE OF DENVER; LARYNGOLOGIST TO ARAPAHOE COUNTY HOSPITAL, STATE WOMAN'S HOSPITAL, STATE FOUNDLING ASYLUM, ETC., ETC.

The treatment of laryngeal phthisis is of absorbing interest, and largely on account of the great strides that have been made in the last decade. Compare the writings of ten years ago, of Morrel Mackenzie, Browne, Schnitzler and many other prominent and conservative men with their words of to-day, and if they do not give so sanguine an outlook as those of more enthusiastic writers, there still appears such marked feelings of hope, that despair, at any rate, has disappeared. In 1880 Mackenzie[1] said, "the prognosis of laryngeal phthisis is always extremely unfavorable, and it is not certain that any cases ever recover."

To-day his words[2] are at least hopeful. Heinze[3] in 1879, said, "a cure of laryngeal tuberculosis will probably never be obtained." To-day Sedziak[4] says, "the curability of so-called laryngeal phthisis is undoubtedly possible," and "partial recovery from laryngeal phthisis, viz., the cicatrization of single ulcers, must be considered not only as possible, but even apparently often obtained." When we study the literature on the curability of this disease we find that rare cases[5] of cures are reported as having occurred without treatment, *i. e.*, spontaneously. Sokolorvski[6] even says he has seen many cases of spontaneous cure of phthisical ulceration of the larynx and Mr. C. J. Symonds[7] goes so far as to make spontaneous recovery "a strong argument against local treatment." With the aid of local treatment, there seems to be even less diversity of opinion as to the curability of this affection, although many more cases of partial cure, *i. e.*, cure of single ulcers, have occurred, than of complete cure. However, when we read of such specimens as Krause[8] and Sajous[28] show, in which, after death, microscopical examination proved the cases cured, we can no longer doubt its possibility. And, indeed, I am strongly inclined to the

*Read before the Colorado State Medical Society, June, 1891.

belief that partial cure or healing of single ulcers, which I also have often observed, ought not to be pronounced cures. One cannot be absolutely certain of a permanent cure unless the patient, dying from pulmonary consumption or other intercurrent disease, presents a larynx, which on microscopical examination reveals no indication of tuberculosis.

In a discussion following the reading of Dr. Rice's[9] paper before the American Laryngological Association, 1889, but one gentleman[10] expressed a decided opinion that laryngeal tuberculosis could be cured, while four[11] expressed decided doubt. Still, despite many doubts as to the actual curability of this disease the fact remaining that partial cures are frequent, has given us hope, where formerly existed only despair, has led us to increased energy, and has given our patients much comfort instead of constant suffering. For these blessings we have to thank new methods of treatment. I need but to quote Robinson[12] (1879) in proof—"I for one, affirm emphatically that all caustic substances are radically wrong when applied to the ulcerated laryngeal surfaces of phthisis." Compare this statement with articles of to-day on the subject, teeming as many are with recommendations of lactic acid, chromic acid, galvano-cautery and other harsh remedies. True, there is still a minority who discourage irritating measures, but we believe they will yet join the majority. The treatment resolves itself into prophylactic, curative and palliative:

Prophylactic.—We can not emphasize too ardently the many rules laid down for the prophylaxis of pulmonary tuberculosis, viz., proper climatic conditions, perfect sanitary surroundings, the disinfection of sputa, etc. But pertaining directly to laryngeal phthisis, whether primary or secondary, the hygiene of the upper air passages, I believe, is a most important factor. I rarely see a case of pulmonary consumption that does not present some abnormal condition of the nose, pharynx or larynx, irrespective of any tuberculosis tendency. That each case of phthisis shall breathe properly through the nose is of paramount importance in preventing a chronic catarrhal laryngitis, which having once obtained furnishes good soil for the development of tuberculous laryngeal complication. Thrasher[93] calls attention to this fact, although his article was unknown to me until after writing the above.

Curative.—In speaking of remedies for the cure of this disease, we bear in mind those which have been known to have produced partial cure as well as complete cure. The measures can be divided into local and general, the former being of even greater value than the latter. In this view we believe with Daly[13] who said, "if I were to be denied one or the other in the treatment of tuberculous ulceration of the larynx, I should certainly elect to be deprived of the constitutional treatment." The local remedies are of three kinds, viz., medicinal, surgical, and a combination of these two in the treatment with lactic acid. *Medicinal.*—The remedies used in the form of sprays, insufflations, inhalations, and applications directly to the larynx by cotton sponge, or brush are so many, that no one man can treat sufficient cases with each, to prove or disprove its efficiency. I mention a few of the less important ones which have given satisfaction to some, but which I have never even tried. Masucci[14] believes that *calcium phosphate* is preferable to iodoform or lactic acid. Guinier[15] lauds *sulphur water*, particularly those of Raillére Springs, as producing an improvement, and even cure, in tuberculous ulcers of the larynx.

Pyoktanin has been applied by Scheunmann[17] who claims to have cured some cases of laryngeal phthisis with this remedy. *Balsam of Peru* has produced improvement, but no healing in a series of experiments by Prof. Simonoosky,[18] and Schnitzler[19] has seen benefit from the same remedy. Inhalations of hot air have produced no effect according to the experiments of Moser[20] and of Nykamp,[21] while Fournier, mentioned by Sedziak,[22] recommended them. *Creolin* and *B-Naphthol* have proved of very little value in the hands of Favitsky.[23] Bassols Prim[24] recommends inhalations of oxygen as a parasiticide. *Resorcin* has been used by Frounstein[25] and by Fronheim,[26] the former showing several very flattering results, the latter preferring it to cocaine to relieve pain. This has been a rather favorite remedy with me to diminish the discharge in chronic inflammations of the upper air passages, and I have found that the co-existence of laryngeal phthisis is no contra-indication to its use. The distressing symptoms due to increased secretion may be relieved, but only temporarily, by a spray of a ten per cent. solution of resorcin.

For years I have used a solution of *Tinct. Ferri. Chlor.* ʒj to ℥j of water as a spray in those cases of laryngeal phthisis with slight thickening over the arytenoids and a congestion of the vocal bands. While this remedy acts very slowly, it nevertheless has done much in my hands towards restoring

the voice in such cases. The only reference I can find to any iron preparation in this disease is in the very admirable article by Sedziak,[27] who speaks of Morrel Mackenzie using a solution of 1 to 30 of ferrum sesquichloratum.

The above list comprises only a few of the long line of medicaments used. It would be only tiresome and of little worth to recount any more. Three remedies however remain, that are, I believe, to be of more value than any already mentioned and that vie for supremacy with all known means of local treatment. These I wish to speak of at some length; they are *menthol*, *iodoform* and *iodol*.

Menthol.—Dr. A. Rosenberg first called attention to this drug in diseases of the nose and throat in 1885. His object was to find a remedy to take the place of cocaine on account of the latter's costliness[29]. Menthol answered admirably, and continuing his experiments he presented in several succeeding articles[30] a most flattering experience on its use in laryngeal phthisis. He uses preferably a ten to twenty per cent. solution in olive oil, dropping it into the larynx at longer or shorter intervals. In addition, inhalations of a twenty per cent. solution are used frequently by the patient. The results obtained depend upon the anæsthetic and parasitic properties of menthol; and while but four cases of cicatrization of ulcers have been recorded, and even less has been accomplished against infiltrations, nearly all who have used this remedy agree, however, that it produces marked amelioration in the pain, dysphagia and cough. We may mention among those who are more favorably impressed with the remedy, Hyndman[31], who uses it in sprays, Beehag[32] who follows Rosenberg more closely, H. Smith[33] who uses a hot spray of vaseline with menthol and iodoform, Ossendoosky[34] who applies it with a cotton application, F. Potter[35], C. S. L. Knight[36], Lennox Brown[37], and others. I have used menthol in a number of cases and am favorably impressed. The following case illustrates its beneficial action:

Mrs. W. F. D., aged 37, duration of illness one year. On examination find the following, marked emaciation, considerable cough, aphonia, no dysphagia. Pulse 112, Resp. 134, Temp. 100° F. at 11:30 A. M. Lungs: large cavity in right side, left apex consolidated. Larynx: large, characteristic infiltration over both arytenoids, extending up the ary-epiglottic folds. Bacilli abundant. Treatment for the present, supporting. One week following the first visit found the patient suffering great dysphagia. Examination revealed both arytenoids spotted with numerous pin-head, superficial ulcerations. Treatment: daily insufflations of iodoform with three to four inhalations of five drops of 15 per cent. menthol in oil. In one week dysphagia had disappeared and the larynx presented the same picture as on first examination. I invariably use iodoform with the menthol inhalations except when applying the latter directly to the larynx, which I do but seldom, and then by means of cotton.

Iodoform.—This is a remedy upon which I depend more than any other, using it alone or in combination with morphia and a bland powder. With the menthol, as well as the lactic acid treatment, iodoform serves me as an adjunct. First, having cleansed the larynx, a spray of cocaine, three to five per cent., is used for the purpose of allaying sensibility. This having been accomplished is of great value in preventing the cough, caused by and the dislodgement of the powder. I then insufflate a portion of the following:

℞ Morph. sulph. ..... gr. x.
Pulv. iodoform ..... ʒ jss.
Pulv. acaciæ ..... ʒ ij.
M.

The morphia relieves pain for a length of time after the effects of the cocaine have disappeared and the acacia adds to the adherent properties of the iodoform. Under this treatment alone, I have seen single ulcers heal very rapidly. The author uses iodoform alone in infiltration without ulceration, and believes to have seen slight absorption take place. Lactic acid, however, is far preferable in this condition. The adherents of this method of treatment have been, and are still, very numerous. We may mention, Bosworth[38], Masser[39] (placing it above lactic acid), Luc[40] (employing both lactic acid and iodoform), Schnitzler[41], Semon[42], Butlin[43] and a great host of others.

Iodol, has been advanced principally to substitute iodoform on account of the latter's disagreeable odor. Those who claim as good, if not better, results with this drug, are not very numerous. Lublinski[44] and Peinado[45] have reported success with it. Personally we have never seen so good results with iodol as with iodoform, although we gave it a fair trial. The disagreeable odor of iodoform can be greatly disguised by a few drops of oil of bitter almond or by coumarin, first recommended to me by a druggist.

Among all remedies for laryngeal tuberculosis, there has never been one which has

so rapidly gained favor as *lactic acid.*, From the time when Krause, in 1885, published his first report, medical literature has not ceased to abound in successful trials of the remedy. Dr. H. Krause[46] had his attention first called to lactic acid by an article by Mosetig-Moorhof, who used it in lupus and caries fungosa. His method was to use from a ten to eighty per cent. solution, passing as rapidly as possible to the stronger. He applied these by means of cotton or sponge, rubbing the parts as thoroughly as possible. He also, to reach more deeply situated ulcers, dropped the remedy by means of a syringe, and in cases of hard infiltrations first scarifying and then rubbing with the acid. He claimed to be able to heal ulcerations, lessen infiltrations and remove excrescences. Gottstein and Heryng[47] corroborated claims. Major[48] in 1886 endorsed Krause's statements and wrote favorably of submucous injections. Jellinek[49] in 1886 endorsed the use of lactic acid, and showed good results in shallow ulcerations and soft infiltrations. Heryng, 1887, recommended submucous injections of lactic acid[50] and incising swollen parts and rubbing them with the acid[51]. Among the first to use the lactic acid in a spray was Leets[52].

These are some of the pioneers in a form of treatment which is the best, we believe, that has up to the present time been given us. It is to Krause and Heryng that we owe our greatest acknowledgements, and it is with their names that it is closely associated. While to Krause is given the honor of first applying the remedy, to Heryng is due a more satisfactory and extensive method of its application. Indeed, this method of treatment is called the Krause-Heryng method. The latter too, has changed it from a purely medicinal to a partially surgical procedure. From the lactic acid treatment to the purely surgical is but a step and then by way of Heryng. Among the adherents of this treatment are Golinetz[53], Mikitin[54], Löschs[55], Simanorvski[56], Lauenberg[57], Symond[58], Beale[59], Greville MacDonald[60], Lennox Brown[61], Bronner[62], Butlin[63] and a long list of others. It is impossible to separate the treatment with lactic acid from that by curetting. The two go hand in hand, Heryng having proposed the latter and Krause rapidly adopting it. By means of a small curette, Heryng scrapes such ulcers as resist lactic acid rubbings, infiltrations, and new growths, after which the acid is applied. In 1890 he reported 482 cases of which 52 had lactic acid applied and 37 were curetted, these latter being very bad cases. He claims 15 cases of absolute cicatrization, lasting more than three months, and 32 of cicatrization for a less period. Krause[64] reports 71 cases with 43 cured or ameliorated by this method. Sedziah[65] reports more or less favorable effects in 73.5 per cent.

Our experience with lactic acid has been confined to rubbings with or without previous scarification, and allows us to draw these deductions, viz., superficial ulcers heal rapidly but only temporarily; soft infiltrations break down quickly leaving ulcerations whose tendency is to heal under treatment; tuberculous excrescences are most markedly affected by strong solutions of lactic acid, and disappear with the greatest rapidity, yielding truly beautiful results; hard infiltrations are unaffected by the acid alone; scarifications, unless deep and numerous, do not increase the acid's efficacy. My practice has been to supplement this treatment by insufflations of iodoform, except in cases of soft excrescences, and therefore only in these latter, can the good that resulted be attributed to lactic acid alone. Too much care cannot be exercised in applying solutions of proper strength, (that is, not too strong, until the patient tolerates the remedy), and in allowing it to remain as long and thoroughly in contact with the parts as possible.

We pass now to the *surgical treatment* proper, and I cannot help repeating that from the lactic acid to curettement pure and simple is but a step, and a confusing one, when the literature is consulted. However, Heryng alone is responsible for this treatment, and we find him advising it in cases in which, despite deep incisions and energetic rubbings with lactic acid, the ulcers refuse to heal[66]. Beschorner[67], Schæffer[68] and Treuman[69] recommend the treatment by curettement. A spoon after that of Volkman or one devised by Heryng is used.

The *galvano-cautery* has met with but little encouragement, principally on account of the liability to œdema that sometimes follows. Gouguenheim[70] however, as well as Schmiegelow[71], has reported good results. Still, a more purely surgical treatment is that recommended in primary tuberculosis by Betz[72], viz., laryngectomy; and that for the removal of tuberculous tumors. Gouguenheim[73] is most active in recommending surgical interference in these cases and gives as indications for this procedure dyspnœa and apnœa, dysphagia and aphonia. He uses either a cutting forceps similar to Mackenzie's or a "larnygeal punch" devised by himself. Dehid[74] discourages surgical inter-

vention, but states that, if removal is determined on, electro-cautery should be performed.

Tracheotomy in laryngeal tuberculosis has been earnestly advocated by Robinson[75], M. Schmidt[76], Seifert[77] and others, while probably the strongest opponent to this procedure is Lennox Brown[78]. Robinson[75] as early as 1879, believed it to be a palliative remedy of much value, although he at the same time believed phthisical laryngitis to be rarely tuberculosis. Schmidt claims that it lessens dysphagia, reduces laryngeal swelling, and improves the general health[76], and reports 15 cases[77], in five of which cicatrization took place. Those in favor of tracheotomy use it not only to relieve dyspnœa, but also, in early cases, to prevent mechanical irritation by the passage of air over the larynx, to lessen the danger of infecting the lungs in primary laryngeal cases, to rest the larynx and to more readily make topical applications.

An impetus given by Koch in his publication regarding a cure for consumption has caused an overflow of new so-called cures. Among those taking a prominent place in our minds to-day are Koch's tuberculin, Liebreich's cantharidinate of potash, and the Gibbes-Shurley treatment. Considering the length of time these remedies have been given us, many and varied are the experiences of investigators, and all have something to say of their effects in tuberculosis of the larynx. I consider it of interest, only historically, to study the reports appearing but a few months after these discoveries, and shall be content to refer only to those of the most recent dates, believing that time will prove their value and that a too hasty judgment now will distort our future conclusions. In speaking of these remedies we omit all matters referring to technique, indications and other interesting questions, and refer only to their effects, as reported.

Koch's Tuberculin.—That the larynx is a place pre-eminently suited for the study of this remedy was early recognized, and should time forbid its use in the cranial cavity, its application to the larynx may still be permissible as partaking of the nature of external tuberculosis. Tuberculin has caused ulcers to heal, it has caused ulcers to develop, it has removed excrescences and infiltrations and has produced great swellings and œdema. It has improved larynges and has destroyed them. What do some statistics show?

Mr. Lennox Brown[80] reports 13 cases of laryngeal and laryngo-pulmonary tubercu-

Name.	Most marked subjective symptoms.	Most marked objective symptoms.	No. of injections.	Total quantity.	Time from first to last injection.	Result.
1. E. L.....	Voice, husky.	Inter-aryt thickening, redness between vocal bands anteriorly.	27	*mgr.* 719	3 mos. 20 dys.	Thickening greatly diminished.
2. J. B.....	Complete aphonia, dysphagia.	Ulcer on left ventr. band. Both aryty's very thick. Vocal bands thickened and injected.	14	104¼	2 mos.	Slight voice at times. Ulcer gone. Vocal bands normal in color. Arty's greatly wrinkled.
3. W. H. H.	Voice, husky.	Thickness inter-aryt. Right vocal band notched in centre and red.	9	39½	2 mos. 20 dys.	Aryt's, greatly thickened. Increased discharge.
4. J. S. L....	Voice, husky.	Both aryt's thick. Right vocal band thick and red. Inter-aryt excrescences.	8	52	21 dys.	No apparent change.
5. J. J. D....	Voice, husky.	Larynx anæmic. Excrescence inter-aryt.	12	141	25 dys.	No apparent change.

losis observed under himself. Prof. Krause, and Prof. Gerhard, and although the cases have been followed but a short time, offer conclusions of more flattering than a careful study of their histories warrants. Of the 13 cases 7 seem improved, 1 presents negative results and 5 seem worse. Sir Morell Mackenzie[81] reports 7 cases with 1 improved, 1 negative and 5 unimproved or worse. In Flataus' cases[82] the results were good in 3 and bad in 2.

Schnitzler[82] shows one good result and another good so far as the larynx was concerned, but bad so far as the lungs were affected. Schreiber[82] reports 1 improved and 4 negative. Irsay[82] reports 2 improved and 1 worse. It would be tiresome to continue these figures, and I will hastily report a few cases observed in Denver. Through the courtesy of Drs. Elsner and Mener we have examined some 20 cases. In only 5 were the laryngeal appearances markedly tuberculous, although a greater or less catarrhal thickening was observed in nearly all. The following table gives the observations in the 5 cases mentioned.

It will be seen by the foregoing table that of 5 cases, 2 have improved, 1 grown worse and 2 remained unchanged. Number 2 grew so much worse, as far as his lungs and general condition were involved, that he has since died, and number 3 grew so much worse, both as to his laryngeal and pulmonary troubles, that treatment was stopped and the method of Shurley substituted. He is failing very rapidly. *

The remedy suggested by Liebreich and that of Shurley have been tested still less than that of Koch. However, a few reliable men have given us an idea, at least, of their values. The Liebreich cantharidinate of potash or soda is given in doses of two to four decimilligrams. P. Heyman[83] has seen ulcers in the larynx clear, and swellings lessen. B. Fraenkel[84] has seen improvemeut in the aphonia and a cure of ulcerations. Lennox Brown[85] reports two cases in which the Liebreich remedy had to be substituted for the Koch. In one it caused no change, in the other dysuria compelled its discontinuance.

The *Shurley-Gibbes* treatment consists in the use of hypodermic injections of iodine and chloride of gold and sodium, and the inhalations of chlorine gas made respirable by the presence of a spray of sodium chloride. In 27 cases reported in the *Therapeutic Gazette*, April 15, 1891, we find 13 with more or less laryngeal complication, and the results, referring only to the larynx, are as follows:—improved 5, worse 3, no result noted or negative 5. We have seen but one case treated by this method. This is No. 3 of the above table, and as stated, Koch's tuberculin had already been given to the detriment, we believe, of the patient.

The *climatic* treatment of the laryngeal consumption can be of scarcely less importance than that of the pulmonary disease, and still very little has been offered in medical literature to guide us. Even the question of climate for the latter is an unsettled one in many respects; still it has not been neglected by eminent writers. What little was said on the question of climatic influence in laryngeal phthisis was universally opposed to high altitudes, until Wagner[86] stated that he believed cases of laryngeal tuberculosis could remain at high altitudes provided the pulmonary complication had improved. Ingals[87] believes high altitudes of benefit in laryngeal phthisis, only when their injurious effects are more than counterbalanced by their beneficial influence on the general disease. Dr. S. E. Solly, of Colorado Springs, believes "this climatic influence is, as a rule, beneficial in laryngeal phthisis."[91] He reports 7 cases[92] of laryngeal phthisis, all but one of which improved, more or less, in this climate.

We have endeavored to record our cases with special reference to the effect of this high and dry atmosphere, and present the following table.

Some explanation of this table may be necessary, and while its conclusions are open to considerable criticism, it at least paves the way for more accurate and scientific results. Many of the cases were observed by us only a short time. The length of "residence in Colorado" was reckoned from the time of their arrival, only to the last date of our observation, so that many of those informed may since have grown worse, or vice versa. All the cases reported have had more or less treatment, both local and general. Our judgment of improvement or otherwise has been, of course, based in the majority of cases upon the patient's statements, except in those cases which remained under our care for some length of time.

Nor have we endeavored in the table to separate the incipient cases of either lung or laryngeal disease from those more advanced. In a general way we may sum up as follows: Of the 30 cases observed, the lungs were improved in 16, worse in 10, unchanged in 4. The larynges were improved in 12, worse in

*This case has died since reading of this paper.

12, unchanged in 6. Of those in which the larynges grew worse, 5 were improved or unchanged as to their lungs. We believe, therefore, that while this high altitude may not be as beneficial to laryngeal as to pulmonary tuberculosis, it is certainly not deleterious to any extent. Eleven cases of the 30 originated in Colorado, but it is questionable if the climate had much causative influence, for we know the natural tendency to secondory laryngeal development upon pulmonary phthisis, particularly in advanced cases, of which we see a great many here.

General Treatment.—Concerning this, I wish merely to emphasize the necessity of maintaining the best possible nutrition, as is recommended in pulmonary phthisis. Favorable hygienic surroundings are of great importance, and, inasmuch as dysphagia is a most demoralizing symptom to the patient, his nervous and mental conditions need some attention. Often the pain is so great that the patient can swallow hardly anything despite his desire to do so. Wolfenden[89] has endeavored to partially overcome this by having the patient suck liquids through a rubber tube, while lying stomach down, and legs raised. Woodvine[90], evidently not knowing of Wolfenden's article, recommends about the same procedure, except that the liquid is made to pass to one side or the other by the patient lying on one cheek.

Palliative.—As to these, the main indication is to relieve pain. Cocaine undoubtedly stands first in this respect, and although disagreeable in taste the patient prefers it to constant suffering. Particularly before meals, say ten minutes, it is of service in allowing more comfortable deglutition. I use it preferably in the form of a lozenge, each one containing one fourth of a grain and dissolved slowly in the mouth. A three per cent. to five per cent. spray may also be used, especially if a nurse can apply it.

Bromides and Phthisis.—M. Féré has found that saturating a person or animal with bromides predisposes to tuberculosis.

THE USE OF CHLOROFORM IN LABOR.[1]

BY E. T. RULISON, M. D.,
AMSTERDAM, N. Y.

The victim of any disease or accident requiring a surgical operation is given an anæsthetic (without even a request being made for it) to enable him to pass through the ordeal without pain. The dreaded surgical operation is thus deprived of its greatest terror and the patient awakes with a happy feeling of relief and with a minimum amount of shock. This being admitted without debate, why are the great majority of our lying-in patients allowed to endure the travail of childbirth without the hand of science being extended to them in relief? As a rule the woman in labor is allowed to endure the most excruciating pain to the bitter end without one effort being made to alleviate her sufferings. And why? Simply because tradition handed down by one old woman to another says it is wrong and in fact wicked to interfere with the laws of nature.

To this specious kind of reasoning we have all listened and have, perhaps, too often allowed ourselves to remain inactive. How many of us insist upon using chloroform in all cases not contra-indicated? In nearly every case of confinement you will find some who are prejudiced against its use because they know nothing whatever about it. When offered its use and opposition is met with, the physician is too apt to shrug his shoulders and imagine he is relieving himself of all responsibility by simply saying, "Do just as you like". When he does this he is shirking an imperative duty, just the same as the surgeon would that neglected to administer an anæsthetic when about to do a capital operation. The patient and assistants must be properly educated to its use and ofttimes the nurse will bear a little educational work before she will act in full sympathy with the attending physician. Notwithstanding the ignorance existing concerning its use, the principal reason for its not being more generally used is due to the fact that physicians are timid in using chloroform as they usually do by clumsily employing a handkerchief as an inhaler. By this mode of administration, either the physician must attend to it himself or some one competent to do so, and even then its use is attended by no little risk, as fatal narcosis may follow a temporary suspension of vigilance. As a result, the use of chloroform is generally unsatisfactory and is not given with that confidence which inspires its constant and continual use. Several years ago, I came across one of Dr. Batterskall's inhalers and at once the idea occurred to me that it was just what I wanted to use in my confinement cases. It is so constructed that not a drop of the anæsthetic is lost. The reservoir is cylindrical in shape and so arranged with valves, openings, etc., that the anæsthetic can be easily given in large or small quantities as desired. During the first stage of labor, the inhaler is so regulated that a small amount of chloroform is used, just enough to make the patient comfortable, but not sufficient to produce full anæsthesia.

The inhaler being elongated in form and weighing over 19 ounces, makes it unnecessary for any one to attend to the anæsthetic except the patient herself. As soon as unconsciousness approaches, the inhaler drops from the face and consciousness of pain gradually returns, when it is reapplied. When the head is well down on the perineum and only a few pains are necessary to complete the delivery, some one is directed to keep the hood of the inhaler to the face until the head is delivered, when the anæsthetic is withdrawn and not given again unless some complication should be discovered requiring its use. By the proper administration of chloroform in labor the following results are sure to be attained:

1. No pain—hence no nervous shock—consequently the "inevitable chill" does not appear.

2. It reduces the number of perineal tears to minimum.

3. It shortens labor and in several ways greatly relieves the attendants.

4. Childbirth being robbed of its chief terror, the tendency to resort to criminal practices is reduced and population consequently increased.

5. Brings increased respect for the medical attendant. The gratefulness depicted upon the countenance of the woman when informed by her attendant that she is a mother (having become so without pain) can not fail to arouse in him thoughts so pleasing that he is apt to forget, for a moment, that a doctor has any trials.

[1] Read before the N. Y. State Medical Association, New York City, October 28, 1891.

The salts of strontium, particularly the lactate, are said by Drs. Dujardin-Beaumetz and Paul to diminish albuminuria about one-half.

THREE CASES OF GONORRHŒAL SEPTICÆMIA IN PUERPERAL WOMEN.

BY ALICE MACLEAN ROSS, M. D.,

RESIDENT PHYSICIAN IN THE WOMAN'S HOSPITAL, DETROIT.

The following cases are interesting because they illustrate the various effects that may be wrought by gonorrhœa during the lying-in period. A multitude of pelvic troubles in women are now laid at the door of this disease, with good reason, and I am convinced that if in all cases of late puerperal septicæmia a cause were carefully searched for, gonorrhœa would be answerable for an astonishingly large number. In August of this year I attended three women in confinement, two of whom I knew to have had gonorrhœa because I had treated them for it. In the third case the diagnosis was made afterward. In the first case there were absolutely no bad symptoms. The second developed an ordinary septic endometritis, and the third had septic fever which went on to pyæmia.

Case 1.—Ada J., entered the Hospital a month before confinement. She had gonorrhœa which I did not entirely cure before labor came on. A vaginal douche of bichloride of mercury, 1-4000, was given in the first stage, and the same regularly after delivery. She had no rise of temperature and made a normal recovery.

Case 2.—Carrie D. entered the Hospital July 17, and was delivered of a boy on Aug. 20. She had an antiseptic vaginal douche, (corros. sub., 1-2000), before delivery and this was kept up regularly afterward. Her temperature ranged between 99° in the morning to about 100° in the evening until the sixth day when it suddenly rose to 103°. Intrauterine douches of bichloride 1-4000 were given twice daily. There was tenderness over the uterus, and this together with the temperature gradually diminished and disappeared upon the eleventh day, and recovery was good.

Case 3.—(This case I treated under the direction of Dr. H. W. Longyear, visiting physician to the Woman's Hospital). Hattie G., aged 15 years, entered the hospital May 2. She had no idea when her last monthly period occurred or how far along in gestation she was. I examined her and judged that she was somewhere between the sixth and seventh months of pregnancy, and found all the parts apparently healthy. At the time of the examination, there was no increase in the vaginal secretion, no excoriation of the external parts, and the patient denied having had the "whites" or a discharge of any kind.

Aug. 6.—She was delivered of a male child, weighing 5¼ pounds, after a normal labor. The temperature immediately following was 99°, but soon went down to normal. During the next three days it ranged between 99° in the morning to 100½° in the evening. Suspecting that this oscillation was due to malarial fever from which about one-half my patients have suffered, yet fearing septicæmia, I gave quinine gr. iij t. d. and ordered bichloride vaginal douches.

Aug. 10.—Free passages from the bowels during the night relieved the system of much offending material, and in the morning the temperature was normal, but in the evening the thermometer registered a body heat of 101-2°. No area of tenderness could be found upon deep pressure over the uterus or pelvic apparatus, and the lochia had no bad odor. There was no symptom save the increase of temperature that would indicate anything wrong.

Aug. 11.—The trouble which had been brewing burst forth, with no warning chill the temperature rose in the afternoon to 104.2°, and this pyrexia was accompanied by diarrhœa. Intrauterine douches of bichloride were given twice a day, much pale shreddy material was washed from the uterine cavity, and the fever gradually diminished under this treatment. The babe's eyes were attacked by a violent ophthalmia the same day as the onset of fever in the mother.

Aug. 15.—Temperature this A. M. was 98.4°, P. M. 99.4°. The aspect of the case seemed bright and a termination of the sickness close at hand, but our hopes were not to be realized. The column of mercury commenced to climb, and during the next five days ranged between 99° and 102° morning and evening.

Aug. 21.—Great soreness and stiffness of the joints of the shoulders appeared. There was no redness or swelling over the affected portion, but the patient experienced great pain on motion, and complained very bitterly at night. Profuse sweating of the body accompanied this condition. The elbow joints were next involved. The systematical disposition of the joints affected is worthy of note. These rheumatic symptoms were combated with salol, alkalies, phenacetine, salicyllate of soda, and phytolacca, to little or no purpose.

Aug. 30.—A chill announced the pres-

ence of pus. This was located back of the shoulders in the scapular muscles of the right side; a large abscess formed here.

Sept. 8.—This collection of pus on right shoulder was evacuated and ℥ viij discharged.

Sept. 13.—Abscess in exactly similar spot on the left shoulder was opened, pus from this was examined by Dr. Hickey, of Harper Hospital, but was pronounced free from gonnococci.

Oct. 14.—Soreness was complained of in left side of pelvic cavity with pain after emptying the bladder. No fluctuation could be detected and all disappeared under hot applications.

Metastatic abscesses formed successively upon the right hip, left arm, left breast, over the crest of the ilium, and upon the right thigh—seven in all—and after the opening and discharging of the last, there has been a return of appetite, increase in strength, and the patient is convalescent. The fact of the child's having a violent ophthalmia and this coming on the same day as the onset of fever in the mother, together with the appearance of rheumatism, make the diagnosis of gonorrhœa certain. I believe this to be a case of the latent form, and its history is probably this: the germs of this disease lodged upon a thickened mucous membrane which resisted their attack, or they were inert, and made but little inroad. Little inflammation causing little increase in the secretion occurred and the trouble was passed by unnoticed. After the birth of the child, the placental site formed a point very favorable for attack. The numerous blood vessels leading from this surface afforded a ready channel for the entrance of the infecting material into the blood. This accounts for the almost utter absence of pelvic symptoms, and for the virulence of the systemic poisoning. The infection took place through the blood vessels instead of through the tubes and pelvic cavity. The result was a violent septicæmia, accompanied by gonorrhœal rheumatism, the former going on to pyæmia and seven metastatic abscesses forming in various parts of the body. These cases illustrate the varied results of gonorrhœa in the puerperal woman, and the great danger to which she is exposed by it. I feel sure that this disease is at the bottom of many cases of septicæmia that puzzle the antiseptic accoucheur. Suspicion may be directed towards it by a late onset, the sixth day being usual.

The range of temperature preceding the onset is worthy of notice. I have seen curious rises of temperature from apparently no cause whatever, and I have had twenty-four cases of real old-fashioned ague after childbirth, but I believe that this peculiar oscillation, from little above normal in the morning to 100° or 101° in the evening, immediately following labor, to be indicative, almost invariably, of septic absorption. It may continue for six or seven days, and gradually disappear, or it may be the precursor of graver trouble. Look out for it. I feel convinced that an antiseptic intra-uterine douche is the proper thing early. No harm can possibly be done if it is properly conducted, and serious trouble may be prevented.

SWEET OIL IN THE TREATMENT OF GALL-STONES.[1]

BY THOMAS J. MAYS, M. D.,

PHILADELPHIA.

A COLLECTIVE INVESTIGATION BY THE THERAPEUTIC SECTION OF THE PHILADELPHIA POLYCLINIC MEDICAL SOCIETY.

The subject of the action of sweet oil in the treatment of biliary colic and catarrh of the hepatic passages has recently been warmly discussed. There are many who regard this agent as being very much overrated, while many others believe that it has a very beneficial influence on this disease. In view of the divided opinions on, and the importance of, this matter, the Therapeutic Section of the Philadelphia Polyclinic Medical Society has, as a part of its scientific work, undertaken a special collective investigation concerning the clinical value of this drug in gall-stone colic. With this end in view, the undersigned committee was appointed, and directed to send a number of circulars to the members of the profession, of which the following is a copy:

"Sex and age of patient? Seat of pain? Jaundice? Previous attacks? Did you test any other remedy, and with what results? Result of treatment with olive oil? Remarks."

To these circulars, nineteen replies were received, and thirty-seven cases of gall-stone colic treated with olive oil were reported. To these members of the profession the warmest

[1] Read before the Polyclinic Medical Society, September 9, 1891.

thanks of this committee are due for the promptitude with which they responded. Additionally the committee imposed the task upon itself to collect as far as possible all the previously reported cases of biliary colic which were treated according to this method, and succeeded in gathering records of seventeen cases, making altogether a list of fifty-four cases.

An analysis of these fifty-four cases shows that there were about one-third more females than males who suffered from gall-stone colic; that two died, that in three, negative results were obtained, and that in fifty, or in 98 per cent., positive relief was afforded. These results make a better showing still, when we consider that one of those who died was suffering from adhesive obstruction of the bile-ducts—a disease which no procedure, either medical or surgical, could have remedied. Nor do these figures give us a true estimate of the favorable action of olive oil in this disease; for two of the observers state that they have treated forty other cases of biliary colic without a failure, but of which they had kept no record—making in all a collective return of eighty-nine cases—showing the great value of this drug.

These cases illustrate, then, the positive efficaciousness of sweet oil in the treatment of gall-stone colic, and the question naturally arises, therefore, as to the manner in which this agent acts. Dr. Rosenberg's experiments ("Ueber die Anwendung des Olivenöls bei der Behandlung der Gallensteinkrankheit," *Therapeutische Monatshefte*, December, 1889, S. 542) demonstrate beyond a doubt that it largely increases the quantity of bile secreted, while at the same time it diminishes its consistency. But how does it accomplish this? Does it stimulate the biliary channels by coming in contact with their openings into the alimentary canal? Or is it decomposed into fatty acids and glycerine through the instrumentality of the pancreatic juice, and does the "glycerin so liberated exert in the duodenum an action similar to that which takes place when it is introduced into the rectum," causing a powerful reflex peristalsis—an ingenious theory suggested by Dr. D. D. Stewart?[2] Or does it act in accordance with the hypothesis formulated by Virchow, who shows from his own experiments (*Therapeutische Monatshefte*, 1890, S. 86) that it is absorbed from the alimentary canal, is excreted by the liver, and is thrown into the bowels again through the biliary passages? The last of these theories appears to be most rational, because it explains certain well-known features in its action, and also places it on a level with the action of other cholagogues. We may conceive then that the beneficial influence of oil consists not so much in dissolving the biliary concrements, as it does in increasing the biliary excretion, in flushing, and in lubricating and washing out the passages of the liver. (A table of the cases was here reported.)

Another point of interest is the proper dose of the oil. Are large doses necessary? It appears not, for eight of the cases received only dessert-spoonful doses every three or four hours, and apparently with the same prompt and positive relief as that which was afforded by doses of from five ounces to one and two pints. If this should be confirmed by further experience it would be a great practical gain in view of the fact that a great many persons show a strong aversion to all kinds of oil, especially if they are to be taken in large quantities.

Furthermore, according to the observation of Dr. Stewart, it does not appear to make any difference whether olive oil or cotton-seed oil is used. Indeed it is well known that much of the oil which is sold as olive is in reality refined cotton-seed oil; and Dr. Stewart's observation tends to show that in all probability any bland oil will have the same effect on the disease under consideration.

In conclusion, the committee desires to congratulate the Polyclinic Medical Society on the selection of a subject for collective investigation which has proven so fruitful of practical results as that which is embodied in this report; and expresses the hope that it may continue its good work of testing therapeutic agents in a clinical way. It is true that animal experimentation often points out the path in which the usefulness of a drug lies, but clinical and collective research is after all the crucial and final test of all true therapeutic progress.

THOMAS J. MAYS, M. D.,
HOMER C. BLOOM, M. D.,
Committee.

The value of cocaine in yellow fever, originally affirmed by Thorington, is confirmed by Dr. Joseph Levi, who finds it to check, or to prevent, at times instantaneously, the constant and debilitating vomiting. He administers the remedy in doses of from ½ to 1 grain every hour, or as required.

[2] "A Suggestion as to the Action of Olive or Cotton-seed Oil in Gall-stone Colic." By Dr. D. D. Stewart. *Medical News*, November 23, 1889.

Society Reports.

POLYCLINIC MEDICAL SOCIETY.

SEPT. 9TH, 1891.

A paper on "Sweet Oil in the Treatment of Gall-Stones," was read by Dr. Thos. J. Mays. (See page 853.)

Dr. William S. Stewart:—I wish to show the Society a stone which was obtained this summer from a lady between seventy and eighty years of age. She had suffered with periodical attacks affecting the bowels and passing off with simple treatment. On the last occasion she suffered excruciating pain in the region of the cæcum and I was sent for. Thinking there might be some inflammatory affection in this region and that possibly abdominal section would be necessary, and finding a mass in the right iliac region, I placed her in the knee-chest position and gave her a very large injection. After as much as possible had been injected, I had her sit on a jar. Not experiencing relief, I continued the injections while she was in this position, using flaxseed tea. This was continued for five or ten minutes. She was then put to bed and another injection given. I then left her, and shortly afterward she got up and this huge gall-stone was passed. (About the size of a hen's egg.)

Some twenty-five years ago my attention was directed to the method of treatment by olive oil by a lady from California. I had seen her some time before in a debilitated condition from frequent attacks of biliary colic. I inquired the cause of the improvement, and she told me that she went with a friend to see a quack, who at once told her that she had gall-stones, and directed her to take half a pint of sweet oil in the evening and rub the right side frequently during the night, telling her that when her bowels were opened she would pass many gall-stones. It happened just as he said, and she had entire relief. Since then I have taken advantage of this hint.

I use the spirits of chloroform in combination with olive oil during the period of attack, and recommend that the oil be continued in doses of two tablespoonfuls before each meal, for a period of several weeks afterward. In this connection I recall to mind an amusing occurrence that happened in the army. A soldier was suddenly taken with biliary colic, and the assistant surgeon, an ignorant man, who had been promoted from the position of hospital steward, was called. He at once prepared a dose of chloroform, and taking it to the patient said: "Take this. It may do you good or it may kill you. Try it."

Dr. John C. Da Costa:—My results with olive oil have not been so brilliant nor so quick as those reported in the paper. Opiates and chloroform will relieve the pain, but phosphate of soda does not seem to act as well as reported. Calomel between the attacks acts well; corrosive sublimate still better. One case will illustrate what I have to say. A hysterical woman has had at least five or six attacks in two years. I was disposed to think that all the attacks were not due to gall-stones until she brought me the stones which she had just passed. She was treated with olive oil in half-pint doses. Since then she has had four or five attacks. In the last two she did not consult me until they were over. She takes half a pint to a pint of olive oil at one dose and lies down. In twelve or fourteen hours (not two or three as in some of the reported cases) she is relieved. The oil seems rather to lengthen the interval between the attacks.

Dr. M. Price:—The committee deserve great credit for its thorough investigation, but I cannot see the brilliant results referred to. In my experience I have not found the spasm of biliary colic to last many hours. How olive oil can relieve the pain, unless it is by a lubricating process, I cannot understand. Many stones are of a soft non-irritating nature, and if the spasm in the gall-duct is relieved there is no trouble; the stone passes readily except when the duct is inflamed. Within a month I have seen two post-mortems. In one, a man, there were found two hundred and fifty gall-stones in the bladder. The man had never had an attack. In the other, that of an old lady with cancer of the kidney and a stone in the kidney, the gall-bladder contained five or six ounces of grumous fluid and a number of soft gelatinous stones. She had never had any symptoms referable to the gall-bladder. There is another form of stone in which the treatment could be of no benefit, and that is in those hard ones which we see in cancer, and which in many cases, I think, are the cause of cancer of the liver. Where the stone is large and produces constant irritation there can be no possible benefit from any treatment except tremendous doses of morphia. The stones which I show you are hard and were removed by section.

The history of the cases reported, is of this character. You prescribe a remedy to which the patient submits and endures the pain until

the spasmodic period of the disease passes. Chloroform and morphia during the continuance of the spasm seems to be the only rational treatment.

In this whole series of cases has there been a post-mortem? It is very difficult to say when you have a patient suffering with spasmodic pain in the gall-bladder that it is due to gall-stones. Four or five years ago I saw a travelling minstrel who had had attack after attack, and been treated by the best surgeons in the country for gall-stones. He had received olive oil and many other methods of treatment. I said to him there was no use of doing anything until we found out what was in the gall-bladder. I operated, and after breaking up adhesions reached the gall-bladder and found it perfectly healthy. The patient was completely relieved. His symptoms had simulated gall-stones so much that many surgeons wanted to open him for gall-stones.

In regard to cases of obstruction of the gall-duct.[1] There are cases simulating gall-stones which are not relieved by medical treatment, but which could be relieved without trouble by abdominal section. It has been suggested by one of the best surgeons in this country to open the abdominal cavity and drain the gall-bladder, then to take a rubber ligature and unite the duodenum or ileum to the gall-bladder, and then with a whipped suture unite the peritoneum of the bowel to the peritoneum of the gall-bladder. In the course of three or four days a fistula forms and then the abdominal opening can be closed with silkworm sutures previously introduced. There is no question that gall-stones of the size that I have shown should be removed. It is my firm belief that gall-stones of this hard, irritating nature may in time produce malignant disease of the gall-bladder or of the gall-duct.

I think with Dr. Mays, that the explanation of the benefit of olive oil, if it exerts any, is to be found in the lubricating and stimulating qualities of the oil, and that it relieves spasm simply by its purgative effect. I cannot see where the benefit can come in. It has no solvent effect, and it cannot remove a stone whose diameter is ten times that of the gall-duct.

Dr. James B. Walker:—In my experience, the question is not so much what will relieve the attack, as what will prevent its recurrence. If one would send out a series of questions in regard to the usefulness of any particular agent in gall-stones, would he not receive replies very similar to those given to-night? Take calomel, or any other agent which acts as a laxative, and it will terminate an attack of gall-stones, if it is a terminable attack. The question is: What will prevent recurrence? So far as this report goes, it seems to give to olive oil a favorable position as an agent for preventing recurrence. This is the most favorable report that I have seen. Still these are not exceptional results. We meet with cases of gall-stones where the attack is never repeated. Unquestionably, in many cases the recurrences are due to the number of gall-stones. Sometimes, however, the attack terminates without the discharge of the stone, and yet there is no recurrence for months. I have a patient who recently passed a calculus, resembling a mulberry both in shape and appearance; he passed this after a number of attacks under my observation. The attacks were treated with morphia and calomel, followed by phosphate of sodium and nitro-muriatic acid. After each attack there would be a return to health for a period. In at least ten attacks, the fæces were examined without result. At times a detritus was found, looking like a crumbled stone. This was found in the last attack, and it was thought that the stone had crumbled and passed; however, the following day another severe attack occurred, in which blood was passed, and in the centre of a clot of blood was found the calculus as large as the last joint of the index finger, and without facets. This was, unquestionably the cause of all the trouble.

I believe that any laxative agent which will promote peristalsis and free biliary discharge will relieve the immediate attack if the stone can escape; then some agent to relieve the catarrh of the duodenum and the hepatic catarrh will be required. I have used olive oil in several cases, but my experience has not been satisfactory. The case just referred to received six ounces of olive oil on two occasions without benefit; other patients have received equal doses without success. The best remedy that I have found for old, recurring cases, where there seems to be an impacted stone, and where even cancer has been suspected, from the cachexia, is spirits of chloroform. In two cases, sisters, seen at intervals of five years, this seemed to be the agent that turned the tide of events after repeated efforts with other remedies. I gave it in teaspoonful doses three times a day. The cases immediately changed their

[1] In the doctors' report of the case of stricture of the gall-duct with death, the post-mortem found no stone; in this case it was stricture, and not stone, under treatment.

character, the jaundice disappeared, and improvement in the general health took place. I believe the chloroform, which is known to increase the liquefaction of the bile, is of value in these cases; this, with phosphate of sodium, or some other sodium salt, or, where the patient is wealthy enough, a visit to the Carlsbad Springs. Here the waters are taken with a strict dietary for three weeks; when the patient is emaciated to a certain degree, he is sent to some other place for recuperation, to return for three successive years. This will often effect a cure. I have a patient who has been benefited by this course. After her return from the first visit to Carlsbad she had three attacks during the year; after the second she had two, and her general health was excellent. She is now returning from her third visit.

Dr. Streets, of the Navy, has mentioned to me an interesting case where he used olive oil. The patient, a sailor, was seized with an attack of gall-stones, and was at once put upon the use of olive oil. The discharges were saved, and there were obtained a number of soft, pulpy bodies, which had a very odd appearance. They were somewhat globular, and not faceted. These were placed on a surface so that the oil could be absorbed, and they shrunk in size, showing them to be faceted gall-stones. It seemed as though the oil had penetrated these in some way, either before or after leaving the biliary duct. They were unquestionably gall-stones.

Dr. A. B. Hirsh:—There is possibly one class of cases in which exception might be taken to Dr. Price's remarks in regard to having a remedy that would obviate future attacks, that is, those cases of distortion of the anatomy of the parts where no operation would avail. In the majority of cases of cholecystotomy we allow for drainage for some time, in the hope that the habit of inspissation of bile may be overcome. Those cases in which peritonitis is associated with resulting obstructive bands, and where, after closure of the fistula the symptoms recur, are not satisfactory ones to deal with. I have met with several such cases, and in these any remedy that offers a promise even of relief should be welcomed.

In regard to the cases reported by practitioners who see but few, and then only at long intervals, there often remains some doubt as to the correctness of their diagnoses. Dr. Porter published in the St. Louis *Weekly Medical Review*, in the spring of 1889, a paper in which he analyzed a large number of such cases reported of supposed relief of gall-stones by the use of olive oil; he appeared to show that the treatment had no scientific basis; that the cases had not been followed sufficiently long, and that, if anything, the observers had been careless in taking notes.

Dr. Mays:—I am here, perhaps, as the innocent champion of olive oil in the treatment of this disease. Having had some very favorable results from its action in three cases of gall-stones, I proposed the subject to the Polyclinic Medical Society for further investigation. From my own experience with it, I think that we ought to be very careful and not make any dogmatic statements concerning the action of this oil. Even if we do not know how an agents acts, we are warranted in ascribing some usefulness to it if it does the work which was intended it should perform, and especially if we were unable to accomplish this with anything else. I believe the cholagogue action of olive oil has been denied this evening, and in answer to this I would say that Rosenberg's experiments, which show its powerful influence on the biliary secretion, have been before the profession for at least a year and a half. Rutherford found that sodium salicylate was one of the best cholagogues, but the former demonstrated that the olive oil excelled the latter agent as a biliary stimulant. In view of this influence it is easy to see how it acts in this disease, and it is also easy to see how the sodium salicylate acts beneficially in similar cases.

Dr. Price seems inclined to doubt that the concretions which are evacuated after the oil is administered are true gall-stones. This is, of course, difficult to determine in many of the cases which are reported, but at least in one instance (Dr. D. D. Stewart's case) the concretions were examined by Dr. Leffmann, and by him pronounced true gall-stones.

I can hardly agree with the opinion of Dr. Walker that the sending out of inquiries concerning the action of any agent in biliary colic would have brought similar favorable replies. There is too much unanimity, I may say, in the reports favorable to the action of the oil to give the least countenance to such a belief. Besides, we endeavored to guard against this very uncertainty. The circular asked expressly whether any other agents had been given, and with what results. In the great majority of cases all the known remedies had been tried, with doubtful results, or with failures. Many observers stated that no agents had given such signal relief as sweet oil.

If we believe in the efficacy of cholagogues

to relieve the attacks of biliary colic, and are in search of an agent having a similar action to prevent their recurrence, then I think it is useless to advocate the action of chloroform in this disease, as has been done to-night. So far as I know, chloroform is not a cholagogue, but may act by relieving the spasm of the gall-ducts, and by having a solvent action on the calculi. I can more readily see how olive oil would prevent such recurrence, since it is one of the best stimulants to the hepatic secretion that we possess.

SELECTED FORMULÆ.

INDIGO AS AN EMMENAGOGUE.

Indigo as an emmenagogue was proposed by S. L. Gount since 1887. In 14 cases of amenorrhœa, J. L. Jones has recently obtained good results. He recommends the following prescription:

℞ Indigo.....grammes lx.
Subnitrate of bismuth.....grammes xv.
M. Sig. Half a tablespoonful in a half glassful of sweetened water, three times a day.

—*Journal de Médecine de Paris*, Sept. 20, 1891.

OINTMENT FOR INTERTRIGO.

The following ointment is recommended for this erythematous condition of the skin:

℞ Boric acid.....grammes 0.50.
Lanolin..... " 50.
Vaselin..... " 10.

—*Journal de Médecine de Paris*, Sept. 20, 1891.

BROMOL AS A LOCAL ANTISEPTIC.

According to C. Rademaker, the following prescription can be used with success in treatment of ulcers, locally applied:

℞ Bromol.....grammes v.
Olive oil..... " cl.
M.

℞ Bromol.....grammes iv.
Vaselin..... " xxx.
M.

—*Journal de Médecine de Paris*, October 11, 1891.

BROMOL IN DIPHTHERIA.

Rademaker recommends the following in the local treatment of this disease:

℞ Bromol.....part j.
Glycerine..... .....parts xxv.
M.

—*Journal de Médecine de Paris*, October 11, 1891.

REMOVAL OF SUPERFLUOUS HAIR.

Dr. E. O. Leberman offers the following formulæ, which, in his hands, have proved quite successful. (This formula is recommended by McCall Anderson):

℞ Barii sulphidi.....℥iss.
Zinci oxidi.....℥vj.

Mix with sufficient water to form a paste, apply for three minutes, and then wash off.

For the removal of stiff, coarse hair, the formula of Neumann is serviceable:

℞ Calc. hydrat.....℥iss.
Orpiment.....℥iij.
Amyli.....℥j.
Aq. calcis.....q. s.
Ft. pasta.

The paste should be spread over the parts from which the hair is to be removed as thick as the blade of a knife. The softened hairs should be scraped from the skin with a dull knife or ivory spatula, the parts washed with warm water and afterward thoroughly dried. A bland ointment should then be applied to the reddened surface. The length of time these pastes should remain upon the skin is best determined by the severity of their action. They both cause slight itching, which sensation is followed by an intense burning; when the latter begins, the paste had best be removed. The effect of chemical depilatories can scarcely be more than temporary, as their action can extend no deeper than the epidermis; the hair-bulbs remaining, a new growth will soon appear. Great care should be exercised in their application, and their effects should be carefully watched, for sometimes deep and painful ulcerations occur by their incautious use. However, they serve a purpose, and if properly applied will often leave the skin free from hirsute appendages which disfigure it.—*Amer. Jour. Med. Sci.*

EXPECTORANT.

℞ Liq. ammon. acetatis.....℥iv.
Spir. aether. nitr.
Syr. ipecac.
" tolu.
" scillæ, aa.....℥j.
Vini antimonii et pot. tart.....℥j.
M. Sig. Teaspoonful every two hours.

—*Weekly Med. Rev.*

FOR DELIRIUM TREMENS.

℞ Paraldehyde.....gr. v.
Bromide of ammonium.....gr. x.
Hydrate of chloral.....gr. x.
Tinct. hyoscyamus.....gtt. x.
M. Sig. Take at one dose.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING Co., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

THE SURGEON IN RELATION TO APPENDICITIS.

Post-mortem examinations and anti-mortem abdominal sections have shown conclusively that inflammation in or about the head of the cæcum—heretofore known as perityphlitis, paratyphlitis, etc.—is due almost without exception to inflammation, ulceration, or perforation of the appendix vermiformis. Hence, the labors of the practitioner are simplified, and when presented with a case having the symptoms and signs of inflammation in the right flank, he no longer flounders in a sea of doubt concerning the nature of the case, but, having excluded fæcal impaction, properly names it appendicitis. Practical medicine is much indebted to pathology for this simplification of what has been heretofore a very confused subject. The most important question in relation to appendicitis which now awaits solution, is the relation which the surgeon should bear to the physician in the management of the disease. At the present time the physician treats the case until in his judgment death is inevitable without operation, and then recommends that the surgeon be called to operate. This position, practically, was maintained by the physicians taking part in the recent discussion before the Philadelphia County Medical Society—notably by Dr. Pepper. This position is justified on the ground that generally the disease terminates favorably by the use of medical means alone.

On the other hand, it practically reduces the surgeon to the position of the barber-surgeon of old, who acted only under the direction of the physician—good results being due to the wise counsel of the physician, and bad results to the poor technique of the surgeon. This, however, is a minor matter compared with others involved.

Surgeons, almost without exception, insist that the surgeon should be called in consultation as soon as the diagnosis is made, not necessarily to operate, but to become famil-

iar with the case, so that if the necessity for operation arises, he will be ready instantly to operate, and thus to give the individual patient the utmost chance for recovery. The question as to necessity for, and the time of operation is as much, if not more, a surgical than a medical question, and surgeons contend that it is not fair to the patient nor to themselves to have these questions settled, perhaps incorrectly, by the physician before the surgeon is summoned. Their contention is based upon the fact that only too often the physician lets the golden moment pass by when operation might save, and summons the surgeon only when operation can be done as a "last resort" which generally means that the patient is thereby hastened out of the world. Here the surgeon takes the responsibility, and surgery the bad name of the physician's blunder. Again, the surgeon claims, and with justice, that unless he is called at once, that the entire class of cases, of perforation of the appendix with general peritonitis is doomed; and that the class of acute cases, in which the tendency to localization of the peritonitis is slight, and the course of the disease short, without early operation, is greatly endangered. This is because it is natural for the surgeon when first called to a case to wish to postpone radical measures until he is familiar with it. He must be satisfied that operation is advisable as well as the physician; especially, as the responsibility rests with him. Moreover, when the surgeon sees the patient with the physician from the first, operation can be done as a formal procedure, with everything in readiness as it should be, and not as an emergency operation as is necessarily the case when the surgeon is called at the last minute. This position was ably sustained by Dr. Keen, in the discussion already mentioned, and will be supported by every surgeon who has seen the evil results of the usual practice. We trust that the points involved will be considered seriously by the readers of the Reporter, and we feel convinced that the early counsel of the surgeon will save many cases, otherwise fatal.

Correspondence.

Obstetrical Anæsthesia.

To the Editor of the Medical and Surgical Reporter:—Having just read an article in the Reporter under date of November 7th, written by Dr. J. B. Carrell, of Hatboro, Pa., upon the subject of "Obstetric Anæsthesia" I cannot refrain from hastily complimenting him in his views upon the subject. In fact, it has been my practice for the last 30 years, to use anæsthesia, in just such cases as he describes, with good results. It relaxes the os-uteri, and stimulates the nerves, and gives the woman *confidence* in protracted natural labor cases that something more is being done to relieve her from her condition, than merely the old mandate to tell her to "bear down and take advantage of her pains."

I, too, consider the practice *par excellence*, in just those cases described by him, and am not a little surprised that more physicians do not more generally catch on with the same opinion, and employ the same practice.

C. A. Voorhees, M. D.
827 N. Sixth Street, Philadelphia.

Bichloride of Gold and Drunkenness.

To the Editor of the Medical and Surgical Reporter:—Referring to the so-called "Bichloride of Gold Cure" for drunkenness, permit me to say that as the remedy is looked upon as a secret preparation we have the right to guess at its composition. I would suggest from the slight knowledge we possess regarding the therapeutical effect of the remedy, that something besides gold enters into its composition. It cannot contain bichloride of gold, for no such compound of gold is known. It is fair to presume that the remedy consists in part of a four per cent. solution of hydrochlorate of cocaine, with one quarter grain of hydrochlorate of morphia, and one eighth of a grain of ter-chloride of gold and sodium, in every ten drops of the cocaine solution. The secret of cure may be imagined to rest npon the *letting-down* process of substituting the anæsthetic properties of cocaine, and the sedative effects of morphia for strong drink. Ter-chloride of gold was used twenty years ago by Dr. Hoffman, of New York city, as a cure for alcoholism, and failed.

The chlorides of gold do not possess, so far as is known, any curative properties, much less being an antidote for alcoholism.

Any medicine coupled with total abstinence might with just as much reason be looked upon as a cure for drunkenness. Alcoholism is not a disease. The same criticism may be applied as well to the excessive use of opium, cocaine, or cod liver oil. No one asks that the use of these articles be prescribed, neither do they demand medical treatment. Like most medicaments, alcohol is powerful for evil, as well as for good, and its administration should be under the control and guidance of competent persons.

The indiscriminate use of alcohol should no more be permitted than should that of opium or strychnine. From an economic point of view, the remedy for alcoholic abuse is as difficult as for the excessive use of tobacco or for the suppression of the social evil. The sad death of Col. Mines, the champion of the chloride of gold cure ought to shake the faith of all drunkards who have fixed their hopes upon the remedy, and teach them that the cure for their habit does not rest upon medical art, but upon their determination to abandon the use of alcohol.

Book Reviews.

EPIDEMIC INFLUENZA: NOTES ON ITS ORIGIN AND SPREAD. By Richard Sisley, M. D., Member of the Royal College of Physicians, of London. London and New York: Longmans, Green, & Co., 1891, 8 vo., 150 pp.

There are many physicians who believe that epidemic influenza is not contagious; others who believe that it is contagious, but that contagion exercises only a small influence in its spread; and still others who believe that it is not only contagious, but that it is chiefly in this way that the disease becomes epidemic. Certainly no views can be more pernicious to the welfare of the community than those which would lead to the belief that the spread of a disease is not due to contagion when such is the case. It is to counteract such evil influences that prompted the author to prepare this work.

We have read the book with great interest and satisfaction, not only on account of its dealing with the important question of the contagiousness of epidemic influenza, but because the appearance of the work at the present time, when we are again threatened with this disease, is extremely apropos.

Dr. Sisley gives careful consideration to the nomenclature, definition, origin and spread of influenza; to the noted epidemics of the past; to the incubation period; to the relation of influenza to that in animals, etc. He certainly furnishes a great deal of data which makes it evident that it spreads from the sick to the sound by contagion, that isolated cases precede an epidemic, that epidemics spread along the lines of human intercourse, etc.—in fact, he finds that in every case where the course of the disease has been studied with care it is apparent that it spread in the same way as any other contagious disease.

Dr. Sisley has undoubtedly expended a vast amount of labor in the collection and study of statistics. He has given us a book that is well-written and bears evidence of much thought. If his conclusions are regarded, much sickness, suffering and death, will be spared in future epidemics.

PERISCOPE.

THERAPEUTICS.

TREATMENT OF SCIATICA AND OTHER NEURALGIAS.

Mordhorst (*Therapeutische Monatshefte*) claims that the diagnosis of sciatica is not always easy. Inflammatory thickening of the rectus femoris and other muscles, and rheumatic affections of the trochanter major and others around the hip, and especially in the tendon of the tensor vagina femoris, often small masses varying in size from a lentil to a bean—urates, probably.

In cases of neuritis the treatment essentially consists of a hot bath fifteen minutes to one hour in duration and followed by rest in bed for another hour, and to be followed by electric massage, per author's method. This consists of the cathodol application, surface area 100 cm., to the sciatica notch, while a revolving cylinder connected with the anode is passed down the limb along the nerve, with decided pressure, and returning with slight contact, to prevent break in the current. Strength of current, five to ten milliampéres. Thirty-six cases were treated; thirty recovered, six improved. Average length of treatment, three to six weeks.

MUSTARD PLASTER AS A REMEDY FOR COUGH.

Dr. Pavel M. Gorodtzoff, of Daghestan, Caucasian Russia, draws attention (*Vratch*,

No. 32, 1891, p. 733) to the prolonged application of sinapisms as an excellent means of relieving troublesome cough. He tried the method in 11 cases of epidemic influenza (with severe respiratory complications), 10 of croupous pneumonia, 16 of dry and 4 of exudative pleurisy, 3 of pulmonary tuberculosis, and 23 of acute bronchitis. Every day throughout the illness a freshly prepared mustard plaster, measuring about 9x6 inches, was applied to the chest, and left on during the whole night, or even for twenty-four hours. In the case of adults the mustard was usually mixed with an equal part of wheat or any other meal, while in persons with tender skins, or in children, a one to 3 mixture was employed. In order to prevent any excessive irritation of the skin, the plaster was applied one day to the front of the chest and on the next to the back, on the third again to the front, and so on. In none of the cases were any serious burns inflicted, the patients bearing the application perfectly well. The sinapisms of course constituted of only a part of the treatment, other measures being employed as required. The writer draws the following conclusions: 1. In certain affections, especially in influenza, pneumonia, and acute bronchitis, a mustard plaster is a safe and effective substitute for morphine and other narcotics usually administered for relieving cough. 2. In other cases, especially in exudative pleurisy and phthisis, it is a valuable adjuvant to narcotics, allowing the administration of them in much smaller doses. 3. While relieving cough the plaster also improves the pulse and respiration; the former becoming fuller and slower (by 5 or 6 beats per minute), the latter deeper and similarly less frequent. 4. The effects seem to depend upon the mustard volatile oil, which may penetrate into the system through the skin and lungs. 5. Sinapisms applied in the way indicated appear to promote the absorption of inflammatory effusions both in pleurisy and pneumonia.—*Brit. Med. Jour.*

THE THERAPEUTIC USE OF EXTRACTS OF ANIMAL TISSUES.

The persistence and ingenuity shown by Dr. Brown-Séquard in his study of physiological effects of the juices obtained from the testicles and other glands of the bodies compels attention and interest. It seems to have been quite well proved that the injections of testicular juice have no such "dynamogenic" power as was at first alleged. That this and other secretions, however, have no physiological influence is certainly improbable, and, according to Brown-Séquard and his co-workers, is positively untrue. In an article on "The Action of Liquid Extracts Obtained from Different Organs," by Drs. Brown-Séquard and D'Arsonal (*Archives de Physiologie,* 1891, No. 3), evidence of this belief is presented, and the technique of preparing and using the extracts is described. These authors assert that each gland of the body has two functions, one, that of secreting a substance from the blood, the other, that of supplying to the blood some needed constituent. It is this latter substance which it is proposed to obtain and use therapeutically. It is stated that the secretions themselves contain some of the dynamogenic or other substance required by the organism. In illustration, the extraordinary fact is cited (p. 492) of a young physician who injected hypodermically some of his own sperm into his invalid wife's tissues. Her strength improved, and after four injections she was well. This is truly an extraordinary method of fulfilling the conjugal relations, but they do rude things in France.

The authors quoted give a number of illustrations to show that injections of the fluid of certain glands relieves symptoms caused by extirpating those glands. Thus, in the case of a dog suffering from the effects of the total removal of the thyroid, the symptoms were relieved by the injection of juice of the thyroid. A total extirpation of the pancreas causes, it is said, diabetes, but if a small part of the gland is left this accident does not occur; and this is thought to be due to the so-called external or extrinsic action of the gland upon the blood.

A wide therapeutic field opens before the scientific imagination if the views suggested above are true. Thus in myxœdema, injections of the thyroid juice should be used; in Addison's disease, the juice of the suprarenal capsules; in diabetes, the pancreatic juice; in leucocythæmia, the juice of the thyroid glands, spleen, and medulla of bones; in muscular weakness, the muscle juice.

The injection of these juices, however, unfiltered and unsterilized, is not free from danger, the testicular and ovarian juices alone excepted. Other juices are liable to cause death from septicæmia.

In order to render injections aseptic and harmless, our authors submit the fluid to a pressure of CO_2 of 40 atmospheres, and then pass it through a specially constructed filter. Bacteriological tests by MM. Straus and

Gamaleia show that the fluid now contains no micro-organisms, and experimental tests show that its use causes no accidents.

The juices are extracted with glycerine, and after they have been treated so as to be made innocuous, are kept in sterilized flasks. According to our authors, over 15,000 injections have been made by various physicians in Paris. With such a large experience it is unfortunate that no reports of definite therapeutical results are yet furnished. We trust that these will come later.—*Med. Rec.*

THE ACTION OF STRONTIUM AND ITS SALTS.

In a recent note presented to the *Societé de Biologie*, J. V. Laborde (*La Tribune Médicale*, July 16, 1891) has given the results obtained by him from an experimental study of two salts of strontium, the orthophosphate and the bromide. The results corroborate those previously obtained and reported to the same Society with regard to other salts of the same metal. Both these substances seem to act favorably on the general nutrition.

The strontium was advantageously given to dogs in the proportion of thirty grains of the metal to seventy grains of the orthophosphate per kilo (about two and a quarter pounds) per body weight. To a young and healthy dog weighing twelve kilos (about twenty-seven pounds) were given during 111 days twenty-four and three-sixteenth ounces of the pure orthophosphate of strontium, with apparently no evil consequences. The animal was then killed by puncturing the medulla, and *post-mortem* examinations showed no lesions of the organs. The stomach, the liver, the intestines, the kidneys and lungs were absolutely normal. As in previous observations, there was complete absence of tænia in the intestines of the animal, the cause of this being evident.

Finally, upon chemical analysis, traces only of the metal were found in the liver and the urine; 100 grammes or 1,500 grains of bone gave ten grains of the metal strontium. As the phosphate of strontium is a nutritive and assimilable mineral substance, it is thought that it will render great services, especially in dietetics.

The bromide of strontium seems to be more active than the preceding salt; hypodermatically administered, it produces complete anæsthesia at the point of injection, accompanied with infiltration and œdema. In about fifteen minutes, when the general system is affected, there are noticed diminution of the reflexes, tremors of the head, in the case of a guinea-pig, and a tendency to somnolence and stupor. In three or four hours these symptoms disappear, but the local paralysis, œdema and anæsthesia at the point of injection remain for a longer time; while the reflexes or excito-motor functions are diminished or abolished, the action of the salt upon the cerebrum and upon the peripheral motor and sensory nerves is comparatively slight. To produce these symptoms large doses were administered. Strontium bromide is certainly not very poisonous. For instance, to a dog weighing ten kilos (about twenty-two pounds) sixty grains of the salt were given by the mouth. The animal vomited once, showed restlessness at first, and then went to sleep. With no other deleterious effects the dog entirely recovered. It appears, therefore, that the fundamental physiological actions of the last remedy are similar to those of the potassium salt, with the important practical difference that the first-named substance is less poisonous, and may be said to possess the activity of the potassium and the relative and absolute innocuousness of the metal strontium.

According to the author and from the experimental evidence so far obtained, this salt should be given a trial in those cases where the use of bromide of potassium is indicated.—*Univ. Med. Mag.*

TREATMENT OF THE DEAFNESS OF OTITIS MEDIA SICCA.

Dr. C. Miot (*Gazzetta degli Ospitali*, No. 39, 1891) noticing that the hearing of these patients improved when hyperæmia was present, and secretion of mucus took place, undertook to reproduce these conditions in patients suffering from otitis media sicca by instillations. He dropped in vaseline with and without iodine, which was admirably borne by the mucous membrane of the tympanic cavity, while the hearing became more acute and distinct and the noises were diminished. Chatelier observed at the same meeting that intra-tympanic injections may cause hyperplastic growths of the tympanum. Miot has never observed such effects to follow.

ETHER SPRAY AND COCAINE.

Schleich (*Deutsche Medicinal Zeitung*, 1891, No. 44,) recommends the previous spraying with ether of any part in which cocaine is to be used. It must last half a minute, after which time one can employ

numerous injections of cocaine—not more than 0,01-0, 03—cocaine being necessary to make large areas completely anæsthetic. This same method is to be employed in cases where division of deeper layers is necessary, each one being treated in turn, as was the skin. In this way the author has made small resections and bone operations without giving any pain.

OIL OF PEPPERMINT AS AN ANTISEPTIC IN EAR TROUBLES.

During the past three years Dr. B. Pientkowski (*Deutsch Med. Zeit.*) has been using ol. menth. pip. as an antiseptic in ear troubles, and he reports that it is superior to the other antiseptics now in use. After the ear has been cleansed with a 5 per cent. sol. of sod. sulph., a 5 per cent. sol. of the ol. menth. pip. in alcohol is injected several times and a tampon soaked in the same solution is inserted and allowed to remain 24 hours.

In the most obstinate cases he found that the discharge lessened, and in some cases even ceased within two weeks. He claims the following advantages for it: 1. It does not in the least irritate the mucous membrane. 2. On account of its antiseptic properties and easy diffusibility it stops the process of suppuration. 3. It is absolutely safe. 4. It is not objectionable on account of any bad odor.

ANTIDIAPHORETICS.

1. *Camphoric acid* has been used by Dr. Combemale (*Jour. de Méd.*, March 1st, 1891), as a diaphoric, and has been found to diminish, almost with certainty, the exaggerated functional action of the sweat-glands, having not the great disadvantage of causing phenomena of delirium, nor, like agaric, does it produce free purgation.

2. *Agaricinic acid*, is recommended by Prof. Combemale, of Lille, France, (*Gazzetta degli Ospitali*, No. 51, 1891, *Cincinnati Lancet-Clinic* August 29th, 1891), as a remedy having a decided action in phthisical patients upon the exhausting sweats. It is also efficacious in the sweats of other intoxications and infections.

3. *Hydrastis canadensis* has been found by Dr. Cruse (*Allg. Med. Zeitung*, 1891, *Cincinnati Lancet-Clinic*, August 15th, 1891) an efficient remedy in night-sweats. He tried the remedy in a case with hæmoptysis, and noticed that the night-sweats did not come on as usual. He gave thirty minims of the fluid extract, and always with complete success; and, what is more, the sweats kept off after the hydrastis had been omitted for three weeks. He met with similar good results in a number of other cases.

4. *Ergotine* is praised by Da Costa in doses of 0.10 (1½ grs.) three times daily.

5. *Homatropine gromohydrate* is used by Frommüller subcutaneously, .005—.003 at a dose.

6. *Physostigmine* is recommended in pill form .006 (1-10 gr.) per dose of the extract. Eserine, hydrobromate, sulphate and salicylate are also employed, .001 (1-64 gr.) 3 to 4 times during the night.

7. *Picrotoxine* has been used successfully by Caldwell, Senator and Westbrook, .0012-.003 (1-40 gr.) subcutaneously.

8. *Tincture of Belladonna* is also employed externally, 4 gm. (1 fl. ʒ) of the tincture to 30 grm. (1 fl. ℥) of water (Radakow, *Deutsche med. Zeitung*).

9. *Chloral hydrate* is spoken highly of by Nicolai. Eight grams (2 ʒ) of chloral hydrate dissolved in two glasses of water, and equal parts of this solution and brandy may be sponged onto the body.

10. *Sulfonal* is regarded by Dr. Canteé (*Gazzetta degli Ospitali*, No. 54, 1891) as superior to camphoric acid or the tellurate of sodium in the night-sweats of phthisical patients. It does, however, not yield constant results.

MEDICINE.

THE DIAGNOSIS OF INTRACRANIAL HÆMORRHAGE AND ACUTE SOFTENING.

Dana (*Medical Record*, July 25th) analyses the symptoms in a series of 74 cases, of which 50 were due to hæmorrhage, and the remainder were equally divided between embolism and thrombosis. Premising that his paper is based solely on fatal cases, he points out that brief severe attacks of loss of conciousness with some hemiplegia indicate obstruction, and preliminary mild seizures also indicate obstruction. Consciousness is less permanently and severely affected in cortical and meningeal than in central hæmorrhages, unless the former are very extensive; it is most severely affected in ventricular hæmorrhages, and in the latter consciousness is speedily lost; if convulsions supervene the clot has broken through the cortex to the surface of the brain. If consciousness is not lost at first, but is so shortly after the onset, the case is probably one of embolism. Con-

vulsions never occur at the onset; they are due to hæmorrhage or occasionally to cortical softening. Early rigidity occurs in about half the cases of ventricular hæmorrhage, and is more marked on the paralyzed side, less often in other forms of hæmorrhage, still less frequently in thrombosis, and most rarely in embolism. In hæmorrhage the pupils are contracted and irregular, especially if the lesion is cortical or meningeal; the pupil on the side of the lesion may be dilated. Alternate conjugate deviation signifies a surface lesion. Some loss of cutaneous sensation occurred in a fifth of the cases of hæmorrhage, and in a much larger proportion of cases of softening. The peculiarities of the temperature in acute softening as distinguished from those in hæmorrhage are the rarity of primary subnormal temperature, and its presence, if it does exist, only on the non-paralyzed side; also the slighter tendency to inequality of the temperature on the two sides and its slower rise if a rise occurs. —*Brit. Med. Jour.*

HEREDITARY TREMULOUSNESS.

Most persons are aware that it is not rare to find several members of a family with shaky hands. So many symptomatic forms of tremor have been distinguished by living authorities on nerve disease that the subject of hereditary tremulousness is of interest. M. Debove has recently contributed an essay on this question to the Paris Société Médicale des Hopitaux. He has traced some distinct family histories. Hereditary tremulousness is, he says, a distinct disease. It runs both in the paternal and the maternal line. It begins in childhood and increases with age. The oscillations are rapid, 8 to 10 per second; they cease during complete rest. The tremors are noted when the hand is held out straight, continue when it is voluntarily moved, but without exaggeration. They may involve the extremities, the eyelids, lips and tongue. The upper extremeties are the seat of predilection in this disorder. Differential diagnosis is important. Comparing the above symptoms with tremor in other diseases, it is found that in senile tremor the head is chiefly involved, the vibrations are slower (3.5 per second), and the disorder appears late in life. In paralysis agitans the tremors continue during rest, and are accompanied by contractions. In disseminated sclerosis the shaking is increased during voluntary movement. In general paralysis the tremors involve the tongue and modify the speech in a characteristic fashion. Alcoholic tremors resemble the hereditary form, except that in the drunkard there is a distinct trembling of each finger not observed in Dr. Debove's hereditary cases. Mercurial tremors intermit during rest, and are produced or exaggerated by voluntary movements; they greatly resemble the corresponding symptom in sclerosis. In exophthalmic goitre the trembling involves the trunk and members, but spares the face and tongue. Dr. Debove considers that hereditary tremulousness requires further investigation.—*Brit. Med. Jour.*

SUGGESTIONS RESPECTING SCIATICA.

Dr. G. Eliot (*N. Y. Med. Jour.*) says:

A large proportion of cases of sciatica are neuritis, and not simply neuralgia.

Temporary relief of suffering should be secured by hypodermic injections of morphine, atropine, or of theine.

Among the curative agents salicylate of sodium and iodide of potassium are especially valuable—the former in acute, the latter in chronic cases.

Considerable benefit may often be derived from the administration of the more purely neurotic drugs—aconite, belladonna, and gelsemium.

Cantharidal blisters are of very great service in promoting the cure of the disease, when used in conjunction with appropriate internal treatment.

COMPLETE PARALYSIS OF PHARYNX AND LARYNX AFTER DIPHTHERIA; EXTREME PROSTRATION; RECOVERY AFTER SUBCUTANEOUS INJECTIONS OF STRYCHNINE.

F. N., a previously healthy young man, aged 22, was admitted on February 9th, 1891, suffering from increasing general weakness, especially of the lower limbs, and partial paralysis of the pharyngeal muscles, the soft palate being motionless and insensitive. The voice was "nasal," and fluid food occasionally returned through the nose, but deglutition was unimpaired for solid food. He had been attacked two days after Christmas, 1890, with diphtheria, from which he had suffered acutely for two weeks, the symptoms of paralysis coming on within a fortnight of the presumed recovery from the acute disease. General muscular weakness and the pharyngeal paralysis were at first the only symptoms. The knee-jerks and superficial reflexes were still present but delayed. All the functions appeared to be normal ex-

cept the action of the bowels, which was very sluggish. There were no ophthalmic symptoms; the lungs were quite free, and the heart's sounds fair. The pulse was about 88, and the temperature sub-normal. For the first ten days there was no obvious change, but on the eleventh the breathing became shallow and a troublesome cough came on, which was manifestly due to the entrance of food into the air passages. The muscular weakness was not quite so great, but the knee-jerks were quite absent. Two days later the patient's condition was very much worse. The voice was entirely lost, as also the power of coughing, and by the laryngoscope it was seen that the vocal cords were motionless in the cadaveric position, and that only the most feeble adductor movements could be induced by the attempts at phonation. The patient was then in such a complete state of prostration that nutrient enemata could no longer be retained, and attempts to feed through an œsophageal tube were equally unsuccessful owing to the completely paralyzed state of the muscles of deglutition. A certain amount of conjective broncho-pneumonia had been set up by the attempts already made, and the patient was quite unable to rid himself of the bronchial mucus, so that it was necessary to invert the upper part of his body over the edge of the bed from time to time to allow the discharges to trickle out. The heart's action was very rapid and feeble, and it appeared that nothing but a fatal termination could be possible.

Subcutaneous injections of strychnine (3 minims of the liquor strychniæ) were administered, and within a short time a decided improvement in the strength of the cardiac action was noted; and little by little, as these injections were repeated, a steady improvement took place. On the following day the respiratory movements were deeper, and the sputum could be forced out, although no cough could be produced. In the course of the next two days the general improvement continued, and nutrient enemata could be retained; the muscles of respiration and deglutition showed decided increase of power. The soft palate was motionless still, but there was slight return of sensation on one side of it. The laryngoscope showed that slight movements of adduction were produced in the vocal cords, although they could not be abducted beyond the cadaveric position. On March 2nd, a painful purulent discharge due to suppurative inflammation of the middle ear set in. The patient seemed to be losing ground again, and the muscular weakness became very much more marked in the limbs, while signs of the broncho-pneumonia, which had almost subsided, reappeared in the left lung. Once more the injections of strychnine were resorted to, 5 minims being given every four hours. Improvement followed, and within five days the soft palate was seen to move well for the first time, full sensation having returned to it. The laryngeal movements were perfect as far as adduction and tension were concerned, but abduction, although much more free than it had been, was still far from complete. During the next month, while the powers of respiration, phonation, deglutition were completely restored, there was no corresponding recovery of muscular power in the limbs. By slow degrees these movements have been nearly recovered under careful rubbing, faradization, and practice of movements in a wheel chair. The patient is now convalescent.

Remarks.—The chief interest in this case centres round the fact that recovery is possible after the most extreme degree of paralysis after diphtheria. The patient at his worst had all the aspect of a dying man, being absolutely prostrate, unable to move, only breathing by the most shallow respiratory movements, and unable to rid himself of the mucus in his tubes without mechanical inversion. He had, moreover, the peculiar sour, earthy smell which has so often been described as associated with the approach of death. The mode of recovery of the laryngeal movements is especially interesting, as illustrative of the law insisted upon by Dr. Semon and others, that paralysis of the vocal cords affects the movements of abduction before those of adduction, and that recovery takes place in the reverse order, abductor power being recovered before the movements of adduction returns.—*Dr. Clifford Beale, in Brit. Med. Jour.*

ON LEUCODERMA SYPHILITICUM.

Following Professor A. I. Pospeloff's suggestion, Dr. Fiveisky, of Moscow, has carried out an extensive series of elaborate clinical observations, mainly on prostitutes, inmates of the Miasnitzky Syphilitic Hospital, in order to study the clinical history and diagnostic value of "*leucoderma syphiliticum.*" The outcome of the author's important and exhaustive research may be summed up somewhat as follows:

1. Leucoderma syphiliticum, or "primary pigmentary syphilide," constitutes a very common cutaneous manifestation during the

condylomatous stage of syphilis. Most frequently it is localized on the lateral and posterior surfaces of the neck, but sometimes, besides those classical regions, it may also affect the lateral aspects of the chest, the epigastric region, and, though exceedingly rarely, the thighs. It never attacks either the hairy scalp, or face, the inner surface of the mamma, the buttocks, forearms, hands, legs, or feet.

2. There exist three distinct varieties of the exanthem, which may be termed *leucoderma marmoraceum*, *l. maculosum* and *l. retiforme* ("lace-like form").

3. In 40 per cent. of cases the rash makes its appearance during the third month after the first syphilitic symptoms [concerning which point—as well as some others—Dr. Fiveisky differs from Dr. Ehrmann: *vide* the *British Journal of Dermatology*, August, 1889, p. 346], in 20 per cent., during the fourth; in 20 per cent. during the fifth; and in the remaining 20 per cent., in the course of the second half of the first year.

4. Occasionally it may be observed simultaneously with gummatous manifestations.

5. In women, leucoderma occurs more frequently than in men; thus, it is observed in from 45 to 49 per cent. of all female condylomatous cases, and only in 28 per cent. of male ones. [Professor Fournier found the rash in 50 per cent. of female patients, and in 35 per cent. of male.]

6. In some cases the exanthem proves to be limited to a certain isolated area, while in others it may occupy a more or less extensive cutaneous territory.

7. In men, the extensive form is met with nearly thrice as frequently as in women; it is observed in about 50 per cent. of all male cases of leucoderma, and only in 18 per cent. of female cases.

8. The disease commences with an increased pigmentation of the skin (usually of the neck). After a while there appear minute circular or oval white patches or islets, which gradually increase in size to attain about that of a sixpenny piece. Subsequently the lesions become stationary, to persist for a more or less prolonged period, after which the white spots gradually grow less pronounced, and ultimately disappear without leaving any mark.

9. The duration of the rash varies from one to seven years. Most frequently it lasts three or four years.

10. In the case of a relatively late development, the manifestations of leucoderma are usually mild.

11. An intense rash of the kind, as a rule, develops in such patients as either have not undergone any mercurial treatment about the beginning of syphilis, or in whom the specific treatment has been irregular or defective. In those who have been subjected to an early and regular mercurial treatment, the cutaneous affection commonly assumes a mild form. Neither mercury, however, nor iodide of potassium produces any apparent impression on the course or duration of the exanthem itself.

12. Leucoderma constitutes one of the most characteristic and most reliable diagnostic signs of condylomatous syphilis.

[In the course of a discussion at the meeting, Professor Pospeloff stated that according to his opinion, leucoderma offers even a more common and a more important diagnostic sign of syphilis than enlarged lymphatic glands.]

Professor A. H. Gay, of Kazan, indicated the possibility of the rash involving the hands as well. Thus, he happened to observe a case of a young man in whom, about three years after the infection, a typical leucoderma developed on the dorsal surface of his fingers.

Several years ago Dr. Jebüneff, of Kharkov, also indicated (Sprimon's *Medicine in* 1886, vol. ii. p. 956) the high diagnostic value of the exanthem. He even laid down the proposition that leucoderma occurs solely in syphilized persons. According to his observations on twelve prostitutes, the rash tends to spread *pari passu* with the advance of the condylomatous stage of syphilis.

At a meeting of the Sevastopol Naval Medical Society, Dr. Gavril N. Grivtzoff, of Nikolaiev, read a paper on the subject (*Meditzinskia Pribavlenia K'.Morskomü Sbornikü*, April, 1891, p. 230), in which he relates a case of an unusually extensive leucoderma, involving the neck, chest (both anteriorly and posteriorly), lumbar region and thighs. The most interesting feature of the case, however, consisted in the fact that the rash developed in the course of a *gummatous* stage, appearing simultaneously with a movable subcutaneous gumma (about the left elbow joint), neuritis of the right ulnar nerve, considerable exostoses of various bones, and arthoopathies. The author is inclined to believe that the exanthem in his patient (a sailor) was of nervous origin.—*Jour. Cut. Dis.*

OBSERVATIONS UPON THE TREATMENT OF CERTAIN CASES OF FATTY HEART.

Dr. Arthur H. Weiss Clemon in the *Med-*

ical Press, states there are three objects toward which treatment of these cases must be directed:

Firstly. To get rid of the fat already superabundantly accumulated in the tissues.

Secondly. To prevent its further deposition.

Thirdly. To improve the efficiency of the heart muscle.

These indications are accordingly to be met in the following manner:—

Firstly. By a systematic course of well regulated exercise, which by increasing the process of oxidation shall necessitate an increased consumption of stored-up fat, and its consequent removal.

Secondly. By prescribing a dietary which shall contain a minimum of fat forming articles, and in which the amount of fluid ingested is restricted to the smallest quantity.

The third indication is met in attending to the other two, but some further assistance may be given in the careful exhibition of such heart tonics as strychnia, digitalis, and strophanthus.

Regarding the exercise, the form advocated by Oertel is the systematic practice of long walks, especially in mountainous districts, the effects of which may be briefly summarized as follows:—

1. The process of tissue oxidation is increased, and consequently accumulated fat is consumed.

2. The increased demands made upon the heart's activity, as shown in the increased number and force of its contractions, has the same effect in improving the tone and contractile power of the organ that the practice of ordinary gymnastic exercises has upon the development of voluntary muscular power.

3. The increase of the loss of water from the body, due to increased perspiration and loss through the lungs, tends to an improvement in the quality of the blood, both by diminishing its volume, and increasing its concentration. Proportionately to its bulk, it is easy to understand that its oxygen-carrying power is likewise increased.

Regarding the dietary, in the first place it stands to reason that only the smallest quantities of fat-forming elements (fatty foods and carbohydrates) must be permitted. If under these circumstances, owing to increased muscular activity, the combustion of non-nitrogenous elements in the body exceeds the amount supplied in the form of fat and carbohydrates in the food, the increased demand must be met from the fat already stored up in the tissues; in other words, the patient's obesity will be attacked, and he will get thinner. "If the fat destruction due to severe exertion be repeated at short intervals of time, the fat stores of the body will be encroached upon more and more and a minimum will be finally reached beyond which we cannot go."

On the other hand, the dietary must contain a large amount of nitrogenous food. This is necessary for the purpose of restoring the integrity of muscular fibres of the heart that are already in a weak or degenerated condition, as also for meeting the demands upon the muscular system in general decreased activity.

The amount of fluid ingested must be reduced to a mininum. This reduction alone exercises an influence of no considerable importance in the removal of fat. Oertel mentions two cases in which a considerable and rapid fat reduction was thus effected, no alteration whatever having been otherwise made in the patient's dietary or mode of life. Reasoning from the fact that the deposit of fat always take place in or upon the adventitia of previously formed blood-vessels, Oertel argues that its formation in quantity is dependent upon the occurrence of local vascular dilatations in which there is a considerable retardation of circulation. Owing to the diminution of the watery constituent of the blood, the total quantity of fluid circulation becomes reduced, the circulation is quickened, venous stasis is removed, and the conditions favorable to fat accumulation being thus altered further deposition does not take place. In addition it seems probable that the imbibition of a considerable quantity of fluid favors the absorption by the lacteals of the products of digestion, and thus indirectly aids fat formation.

The strengthening of the heart muscle it is easy to understand, must necessarily follow upon the course of systematic exercise, as already explained; the improvement in the quality of the blood at the same time by increasing its nutritional value aiding in the building up of an improved quality of muscular fibre. The additional assistance to be gained by the administration of such cardiac tonics as strychnia, digitalis and strophanthus is at the same time by no means to be despised.

SURGERY.

THE TREATMENT OF OBSTINATE SCIATIC PAIN BY SPLINT-REST AND COLD.

Dr. S. Weir Mitchell states (*International Clinics*, Vol. I) that in cases of sciatic neu-

ralgia—slighter forms, without marked organic changes—recovery, as a rule, occurs after rest for a few days, dry cupping, sinapisms, care as to gouty or other constitutional state. But even these cases may become chronic, and end in a true congestive and inflammatory condition.

Generally sciatica is not a functional disorder, but an organic disease from the first, and is represented by inflammation of the sheath of the nerve, the connective tissue, and neurilemma. It is these cases of grave sciatica or sciatic neuritis which Weir Mitchell specially considers in his paper. The symptoms are described briefly. The long duration of the disease, for months or years, the affection of nutrition of the leg and of its sensibility in variable degrees, are pointed out. Generally old sciatica is single; pain in both nerves may be due to spinal or caudal disease. After eliminating rheumatism, gout, syphilis, trauma, and pelvic growths, and deciding that the case is one of neuritis, Mitchell considers the most certain indication is to secure rest; not simply by keeping the patient in bed, but by means of a long splint. An old fashioned long splint from the axilla to the foot may be used, or a roughly moulded anterior splint, with a wooden attachment carried up laterally to the waist or axilla. The ankle must be so sustained "that the heel does not carry the weight of the leg." The knee must be gently flexed, and the angle of flexion changed a very little at each dressing. After a few days of undisturbed rest all the joints must be carefully and slowly flexed and extended to a slight extent, to prevent too great stiffness, the common evil which follows the use of a splint. Only sufficient bandage to keep the splint in position ought to be used. If the patient cannot bear a long splint, an anterior suspension splint may be of some service.

By this simple treatment, many cases of chronic sciatica may be overcome, which have defied more elaborate treatments. But if the case be not cured thereby, Mitchell recommends the daily use of Paquelin's cautery button at the pain points. If still obstinate, he employs *dry cold*. An ice bag of caoutchouc is kept on the painful nerve tract, day and night, for two or three weeks; or the leg is placed on a tin or copper gutter, on the under part of which is an ice case three or four inches wide. This method of treatment by dry cold, though described by Mitchell many years ago, has been little used by others. As the pain disappears, the use of cold is diminished until it is only applied at night, or, for an hour or two, twice a day. If any pain-points remain, the use of the cautery is often valuable, but is apt to interfere with massage treatment, which is so helpful at this time. At this state Mitchell employs kneading of the muscular masses of the leg, and also a gradually deeper surface rubbing in a downward direction over the nerve trunk, for half an hour twice a day. When the pain has disappeared, "it is wiser for a while that at first the patient stand aided by crutches, and then walk with them, and not sit up long, as this brings pressure on a nerve which may still be sensitive."

Often the patients are thin and anæmic, and *general* massage is of service after the rest treatment has been employed for some time; but at first it must be avoided in order that the resting limb may not be disturbed.

As regards general treatment, iron and cod liver oil are given, and milk or soups between the meals.

Strong galvanic currents may be of service in the milder forms of sciatic neuritis, but this treatment is as painful and less efficient than the cautery. If the wasted limbs do not gain in size and tone at the close of a treatment, the stimulation of the induction current may aid in producing a more rapid result. Mitchell states that he has never met with a case of sciatica in which he was obliged to resort to nerve stretching. He has seen nerve stretching cure sciatica, but prefers to see what medical means will do first, and points out that nerve stretching is liable to fail like all other means. In double sciatica, probably due to caudal disease, he is more willing to think of surgical aid.

The treatment of chronic sciatica by splint-rest and dry cold, as above described, is more apt then other means to effect permanent cures, and Mitchell has many times seen it triumph when all else had failed.

THE TECHNIQUE OF SUTURING IN OPERATIONS UPON THE STOMACH AND INTESTINE.

H. Braun (*Deutsch med. Woch.*) asserts that by far the greatest number of fatalities in operations upon the gastro-intestinal tract is due to the inefficiency of the means employed to prevent leakage into the peitoneal cavity. The following modification of the usual method employed by B. for the past six years is brought forward: Those portions of the digestive tract that are to be united to each other or to the abdominal wall are secured to each by a single row of

sutures through their serous surfaces. The serous and muscular coverings of each portion are now incised at a slight distance from the first row of sutures, the depth of these incisions corresponding to the submucous cellular tissue. The incised portion of each loop is now made to approximate its fellow and the suturing completed. The object of the incision of the wall of the stomach or intestine is to enable the surgeon to determine the exact depth to which the needle may be passed in order, on the one hand, to avoid penetrating the lumen of the organ, and on the other to secure as firm a hold upon the tissues to be united as possible. In cases in which communication is to be established between two portions of the intestinal tract, or between stomach and intestine (intestinal anastomosis—gastroenterorrhaphy), the mucous membrane is incised after placing the above-mentionad sutures in situ, and before tying the same a portion exercised if necessary and a separate row of sutures placed therein.

EXCISION OF THE APEX OF A TUBERCULOUS LUNG.

La Gazetta Médica de Granada reports a case of the successful excision of the apex of a tuberculous lung by Dr. Tuffieri, who, prior to the operation, had satisfied himself of its safety by a series of experimental operations on the lower animals. Cutting through skin and some fibres of the pectoralis major, Dr. Tuffieri laid bare the intercostal muscles of the second intercostal space, and cutting through these he exposed the parietal layer of the pleura which he detached from the thoracic parietes. Opening the pleura, he found the lung apex studded with tubercle and slightly shrunken. Round the apex he passed a ligature, which he attached to the second rib, and then excised five centimetres of the tuberculous mass. The patient was on his recovery exhibited before the Surgical Society.

FOREIGN BODIES IN THE LARYNX, ETC.

Dr. Schoyler, of Berlin, extracted (*Journ. of Lar. and Rhin.*, August, 1890) from the trachea of a girl of nineteen a needle attached to a feather. It had been aspirated, and could not be removed by traction on the feather. Laryngoscopic examination showed that it was fixed with one end in the bifurcation of the trachea and with the other on a tracheal ring. The needle was liberated by the aid of a probe introduced between it and the trachea.

A case of sudden death from escape of milk into the air-passages is reported by Dr. Emile Müller (*Gaz. Méd. de Strasburg*, April 5, 1890). A child, five months of age, had no other indisposition than slightly difficult respiration when lying on its back. One morning, after having been nursed and laid down, it made a grimace as though sick at the stomach, became blue, and died in a few moments. At the autopsy the thymus gland was found larger than is usual, and the larynx, trachea, right bronchus, and all its divisions were found filled with milk. The size of the thymus explained the difficulty of respiration alluded to.

Mr. Lennox Browne reports (*The Medical Press*, December 17, 1890) an instance of supposed laryngeal cancer or phthisis in a lady thirty-five years of age, from whose larynx he had removed an impacted plate of artificial teeth which, from the history, had been aspirated into the larynx twenty-three months previously, probably during an epileptic seizure. Six weeks after its removal the patient had regained twenty-three pounds of her lost weight. It is remarkable that laryngoscopic inspections had been made by four gentlemen who had failed to detect the presence of a foreign body.

Dr. William Macewen reports (*Glasgow Med. Journ.*, December, 1889) a case in which a nutshell lodged in the trachea for thirteen days was removed by tracheotomy during impending suffocation. It was found buried in the posterior wall of the trachea just under the cricoid cartilage, lying obliquely, and covered to a great extent with granulative tissue, one thin layer of which was spread over the surface of the nutshell. When removed with forceps its concave surface was found to contain a mass of granulation tissue surrounding a portion of the kernel.

An interesting case from the practice of Prof. Sonnenburg is reported by Hermes (*Deut. med. Ztg.*, June 23, 1890). A girl, aged seventeen years, had swallowed a needle the September previous, and had since suffered with intense gastric pains, compelling her to keep the body bent forward. The parts were cut down upon and a projecting point was found in the posterior edge of the transverse fascia. The peritoneum was incised at this point and the needle was found in a mass of connective tissue in which it had beeome engaged after

having perforated the stomach.—*Amer. Jour. Med. Sci.*

SPINAL SURGERY IN POTT'S DISEASE.

Chipault, (Arch. gén. de Méd.) says that Surgical intervention in spinal caries may have one or two objects which are often combined, viz.: (1) The discovery and removal of the focus of bone disease, and (2) the relief of pressure upon the cord, due to a sequestrum, an intra-spinal abscess, or the tubercular fungosities of external pachymeningitis.

I.—*Discovery and removal of the bony lesion.*—Occasionally the disease is localized in the arches of the vertebræ. If there be no suppuration this will often do well with fixation and expectant treatment, but if there be an abscess or a sinus the diseased parts should be scraped away (Lannelongue). These cases are, however, few. Six examples of such operations are recorded, all of which were successful except one, in which paralysis supervened from causes apparently unconnected with the operation.

For disease of the vertebral bodies Treves' operation (*vide Med. Chir. Trans.*, 1884) is cited, and reference made to certain technical modifications by Delorme. In regard to this operation the following anatomical points are noted: (1) The extensor muscles in children rarely extend far to the outer side of the transverse processes of the lumbar vertebræ. (2) The incision should be made about a quarter of an inch nearer to the middle line than is the outer border of the muscular mass. The muscle when exposed shrinks towards the middle line, and this incision brings us to its outer border. (3) Certain varieties in the position of the lumbar vessels are discussed. (4) The psoas should be separated from above downwards, when access to the anterior surface of the lumbar vertebræ is obtained without injury to important structure. (5) The peritoneum is perfectly safe. This operation of exploring lumbar caries from the back, and of thus scraping carious bone or removing sequestra, is commended in cases in which there is suppuration, and four cases are quoted in which the abscess passing towards the iliac region was thus successfully opened in the loin (in two others the iliac abscess proved not to be of vertebral origin, but the operation did no harm). In cases where the abscess points in the loin, this is naturally the method of evacuation. A few cases are recorded in which a similar operation has been applied to caries of the bodies of the dorsal vertebræ, but the indications are rare, as we must have an abscess pointing backwards. Altogether there are collected fourteen operations upon the vertebral bodies (eleven in the lumbar region), with eight recoveries, one death, and five cases relieved.

II.—*Relief of pressure upon the spinal cord.*—In these cases the above-considered indication for treatment can also be fulfilled when the bony lesion is in the arches, and the removal of one of these simultaneously frees the cord and excises the disease. Very rarely both indications are also fulfilled in cases of disease of the body, as in a solitary case of Israel's, in which a cold abscess having burst into the spinal canal, operation relieved the pressure on the cord, and allowed of removal of half the body of the twelfth dorsal vertebra. The patient died.

Of cases of true laminectomy the author collects 35 instances, two being original, 22 published, and the remainder obtained by personal communication. In twenty there was improvement or complete cure. In all of these the improvement began within a few days or hours of the operation, and proceeded steadily. As a rule sensation returned first, and from above downwards, motion later, and from below upwards; the sphincters recovered early. The fifteen cases not improved divide themselves into two groups—(*a*) those in which primary improvement is followed by return of symptoms, and (*b*) those in which the operation is without effect. In the first group the cause of recurrence may be the supervention of acute curvature, or the re-growth of granulations. The second source of failure is, in some cases, an incomplete removal of granulations; in others, possibly, a too great destruction of the cord tissue. Of ten deaths three were due to injury to the cord at the time of operation, four to generalized tuberculosis, and two to the severity of pre-existing complications.

The author concludes that we should operate only when the general health is good, and when the spinal symptoms are severe and do not yield to other treatment. Children do much better than adults. Of bad prognostic import are a high position or extensive distribution of the disease.

The technique of the operation is fully discussed, but without addition to our previous knowledge. The paper contains the most complete recent account of this branch of surgery with which I am acquainted.

GYNÆCOLOGY.

THE INFLUENCE OF THE CLIMACTERIC UPON FIBRO-MYOMATA.

Müller (*Archiv. f. Gynäkologie*) has made a careful study of this subject, based upon 109 cases. He found that while in many cases the tumor evidently diminished in size after the menopause, in nine instances it was clearly proved that the neoplasm continued to grow; such an increase in size was noted in women aged fifty-six and seventy-nine respectively. He infers that it is not safe to trust too much to the curative influence of the menopause.

In opening the discussion Werth took occasion to differ from Hofmeier regarding the effect of castration. The removal of the ovaries had, he believed, a direct atrophic influence upon the tumor. When menstruation ceases its vascular supply is diminished, but if the hemorrhages continue, atrophy does not take place. Tait's statements on this question were valueless.

Benckiser stated that in examing a fibroid uterus removed three months after castration had been performed, he found the same atheromatous changes in the vessel walls which were so often observed after the climacteric. This was a form of obliterating endarteritis which Thoma had described as a result of extensive arrest of the capillary circulation of an organ.

Veit said that he had seen large myomata increase in size in elderly women. He did not expect retrograde changes to take place in the tumor before the age of fifty or fifty-four. Progressive increase of the neoplasm after the climacteric must be due to some unusual source of blood-supply.

Fritsch had found that the occurrence of both the artificial and the natural climacteric arrested the growth of the tumor. If it continued to grow, it was usually due to cystic degeneration of the neoplasm.

STENOSIS OF CERVIX FROM CAUTERIZATION.

Dr. Fraisse, of Roubaix (*Nouvelles Arch. d' Obst. et de Gynéc.*, July, 1891), owing to a terrible case in his own experience, warns the gynæcologist and practitioner against unskilful and meddlesome treatment of uterine disease. A similar case was recently reported by Fochier, of Lyons. A robust woman, aged 27, was taken with labor pains at the end of her fifth pregnancy (exclusive of three abortions). The first stage was very lingering. On examination the os was found to be smaller in circumference than a sixpence and perfectly undilatable, being almost completely surrounded by cicatricial bands of woodlike toughness. Only one quarter of the border of the os was healthy. It transpired that about three months before this pregnancy the patient's cervix had been freely cauterized, and caustics of all kinds had been applied to the uterine cavity. Not only did impregnation occur, but the pregnancy went on without complication until labor. Drs. Godefroy and Fraisse found that the child could not be delivered until either the cervix was divided or Cæsarean section performed. Division of the cervix was almost impracticable owing to the high and backward position of the os. As the cicatricial bands often involve the lower part of the uterus itself, section through them might produce deep rents into or even through the substance of that organ. The patient was left alone for a few hours, the attendants hoping that the os might yield. Violent labor pains came on for an hour in the night and suddenly ceased, the patient appearing collapsed. Dr. Godefroy detected rupture of the uterus, with expulsion of the fœtus into the peritoneal cavity. The fœtal head no longer pressed on the cervix. The os was as rigid and undilatable as before. On the healthy quarter of the cervix—the portion free from cicatricial bands—the lower angle of a laceration could be felt; no doubt this represented the starting point of the uterine rupture. The laceration ran obliquely backwards and to the right. The patient, who was completely collapsed, felt no pain. Porro's operation was at once performed by Dr. Fraisse without anæsthetics. The fœtus was alive, the peritoneal cavity full of liquor amnii, liquid blood, and clots. The child died within a few minutes. The mother lived fifty hours. The previous cauterizations were the direct cause of the disaster. The rigid cauterized tissues of the cervix would not yield, so that the softer healthy tissue gave way during a violent contraction. Dr. Fraisse hopes that this example will warn those who persist in applying caustics to imaginary ulcers, and induce them to abandon that antiquated and barbarous practice. Dr. Godefroy adds to the above report the note of a case where the patient had pains in the perineum, evidently due to fissure of the rectum. An *officier de santé* insisted that uterine disease was present; he freely cauterized the uterus, and the patient died from the effects.—*Brit. Med. Jour.*

OBSTETRICS.

THE USE OF ANTISEPTICS BY MIDWIVES.

Budin (*Le Concours*, February 15, 1890) makes reference to the part which has heretofore been played by midwives in respect to the propagation of puerperal fever, and this suggested the question—what antiseptic, if any, should be placed in their hands for use among parturient women? The use of boiled water would be perfectly safe for them, but on the other hand this would not destroy pathogenic germs, though it might have efficiently cleansed their arms, hands and nails. As to the choice of antiseptics, it is not to be expected that midwives will be acquainted with the relative value of all of them, and the different ways in which they should be used. First of all, too, one must overcome the prejudice which many of them have to the use of antiseptics, and this can best be done by reducing the methods of using them to the simplest terms. It was finally recommended that only one antiseptic be given to midwives, and this in such a form that the minimum of danger would result from its use both to their patients and themselves. It must also be cheap, and easily kept and carried. The merits of boracic acid, creoline, naphthol, carbolic acid and sublimate were all considered, and the last was chosen, notwithstanding the possibilities of poisoning in some cases. The author has had extensive experience with sublimate in midwifery practice since 1882, and has never seen any severer results from it than an occasional gingivitis or erythema. It is said that sixteen cases have resulted fatally from sublimate injections into the uterus, but in fourteen of these the solution was too strong, being 1–1000 or 1–2000. Also in two of them it must be admitted that there had been no injections into the uterus. In these cases the perinæum had been badly torn during labor, and irrigation with a 1–1000 solution was practiced while the wound was being closed. In some of the cases also there was nephritis or profound anæmia from hæmorrhage, or retention of the placenta, and thus intoxication with mercury was favored. Intra-uterine injections should not be made by midwives, and should parturition be followed by fever a competent physician should at once be called. The effect of sublimate solutions upon the newborn is far more favorable than is carbolic acid.

CÆSAREAN SECTION.

Dr. E. Fraenkel (*Deut. Med. Wochenschr.*, August 13th, 1891) publishes two further cases of Cæsarean section, and reviews the present aspect of Sänger's improved method of performing the operation, showing especially how greatly the at first complicated method has recently been simplified. Indeed, apart from the asepsis and the accurate suturing of the uterine wound, the numerous details, at first regarded as necessary, have been abandoned. Silk is now admitted to be the most satisfactory material for sutures, as well as in every way most convenient. For closing the uterine wound it is neither necessary to avoid the decidua nor to use sero-serous (symperitoneal) stitches. Great care, however, must be taken that the edges of the wound are very accurately united and that the sutures are sufficiently close together (not more than 1 centimetre apart). Fraenkel considers that Cæsarean section in its improved but the simplified form can quite well be performed in private practice with but a small armamentarium and three assistants. This being so, much less hesitation need be felt before resorting to the operation than formerly.—*Brit. Med. Jour.*

THE FAVORABLE TIME FOR IMPREGNATION, AND THE VITALITY OF THE SPERMATOZOA.

Prof. Bosse (*Archiv. Obstet. Gyn.*) has made some interesting studies on these points, about which considerable differences of opinion have prevailed among authorities.

First, as to the most favorable time for impregnation. His first series of observations were with women who became pregnant for the first time immediately after marriage, and wives of sailors where the date of intercourse could be definitely established followed by periods of long absence.

There were twenty-seven such cases, in all of which except one the date of confinement made it probable that impregnation occurred during the four days immediately following menstruation. In the exceptional case, intercourse took place seven days before menstruation, and not again for a month. There are two alternatives, either that the confinement was tardy, as it did not occur until the 285th day, or that as the author has shown is possible, the spermatozoa retained their vitality in the vagina

until after the menstruation, and impregnation occurred then.

His second series of observations is of cases of artificial impregnation. He reports eleven cases, of which nine were successful. In one the successful injection was made the day before the menstruation occurred. In the remaining eight, after several unsuccessful attempts at other periods, the successful injection was made in five cases in the twenty-four hours following the cessation of the catamenia; in two, on the second day; and in one, on the third day.

His third series of experiments was made to determine the length of time during which the spermatozoa retained their vitality in the vagina. His methods which should be studied in the original were apparently conducted with the most scrupulous care, and the results he arrived at were as follows:

1. Of eight cases where the semen was deposited in the vagina before the menstruation and examined for afterwards, in four no spermatozoa were found; in three they were found alive; in one dead.

2. Of twelve cases where the semen was deposited after the menstrual period, in four no spermatozoa were found; in eight they were found living at from three to seventeen days subsequently. These investigations justify the author in concluding that the favorable time for impregnation is immediately after the catamenia, that the spermatozoa may retain their vitality for at least seventeen days in the vagina and even through a menstrual period, and that cases of prolonged gestation may be explained by the fact that fecundation may have taken place a number of days after the last cohabitation.

While there is a great liability to error in investigating so delicate a subject as this, yet these observations seem to have been very carefully made, and are a valuable contribution to the subject.

PÆDIATRICS.

THE TREATMENT OF CHRONIC CONSTIPATION IN CHILDREN.

Certain errors in the treatment of this most troublesome disorder are pointed out by Dr. Cheadle in the *Pratictioner* for July. Three devices seem to be most commonly adopted. The administration of more or less active purgatives from time to time, the dose being repeated as often as the bowels become confined; the use of enemata with more or less regularity; and the use of coarse foods and fruit. The chief point of error in these methods lies in the fact that chronic constipation is a recurrent and habitual condition, while the treatment is intermittent and spasmodic. Purgatives thus given lose their effect after a time, frequent stimulation of the bowel rendering it less and less sensitive. Most cases, however, of prolonged and obstinate constipation require drugs in their treatment. The constant daily use of some mild laxative is essential to ultimate success. Treatment, to be effective, must be continuous. Spasmodic, intermittent, and excessive treatment will invariably fail.

COMMON ERRORS AND FALLACIES IN THE TREATMENT OF CHILDREN.

Cheadle, (*Practitioner*, July, 1891), writes that the chief points with regard to which faulty practices prevail are the following:

1. *The sudden weaning of infants onto fresh cow's milk and water.*—The large curds of cow's milk are often beyond the feeble digestive power of the infant. The undissolved clots under favorable conditons of heat and moisture ferment and set up colic, vomiting, or diarrhœa. Boiled milk with barley-water seems to be much more readily digested. In the case of very delicate children the milk should always be peptonized at first.

2. *Insufficient gross amount of nutritive material.*—For example, a child is found unable to digest a mixture of cow's milk stronger than one in four. The capacity of the stomach, however, is limited, and it is impossible for it to take a sufficient quantity of this mixture to supply the material required for growth and nutrition. The difficulty may be overcome by adding some cream or perhaps some of Valentine's meat-juice.

3. *The use of food deficient in fat.*—This is an element of especial importance in the food of children, but is almost wholly wanting in most artificial foods, and is deficient in most condensed milk.

4. *The use of food deficient in proteid.*—Most artificial foods are lacking also in nitrogenous matter. Children deprived of these two elements are often large and fat, but are anæmic, flabby, and rachitic.

5. *The use of diet deficient in antiscorbutic elements.*—This is a point that is frequently overlooked. All condensed foods, farina-

ceous foods, and dry artificial foods are lacking in this regard, and should be supplemented by some fresh element.

6. *The prolonged use of artificially-digested foods.*—These preparations do excellent service in the case of children just weaned, or with small power of digested cow's milk. If they are continued for months the power of digestion becomes seriously impaired, nutrition falls off, and the child becomes anæmic and rachitic.

In the management of diarrhœa numerous errors are prevalent, one of the most common and dangerous, perhaps, being the idea that a moderate amount of diarrhœa is beneficial. So far from diarrhœa being a safeguard against convulsions, it is precisely those children who have been reduced by diarrhœa and vomiting who are most liable to them. Young children bear purging badly. A diarrhœa which begins moderately is apt to develop dangerous proportions in a short period and reach a point beyond control of medicine. The younger the child the greater the importance of getting a diarrhœa quickly under control. As regards food, give nothing that is not sterilized, nothing that is not predigested or easily digested. Astringents are useless in the acute stage, especially the vegetable astringents. Opium is essential in severe cases, even in young children. Gray powder and Dover's powder in small and repeated doses should be given if there is vomiting. The most efficient remedies are bismuth in full doses with small doses of opium.

In the treatment of chronic constipation in children, as a rule, three devices only seem to be adopted. 1. The administration of more or less active purgatives from time to time, the remedy being repeated as often as the bowels become confined again. 2. The use of enemata, sometimes regularly. 3. The inclusion in the diet of coarse foods and fruit, oatmeal, cabbage, prunes, figs, and the like. If the constipation is chronic, and hence habitual, it cannot be cured by spasmodic efforts; but that is the criticism upon the treatment described. In most cases a drug is required, the constant daily use of some mild laxative being essential to ultimate success. Treatment must be *continuous*. Spasmodic, intermittent over-treatment will fail.

Night-terrors occur usually, but not invariably in delicate neurotic children. The direct cause is usually undue stimulation of the brain, or of the imagination, by exciting stories; unkind treatment; a visit to the zoological garden; or over-pressure at school. By far the most common cause, the author believes, is constipation, often slight but persistent, the stools being hard and dry and usually of light color. The error in the management of these cases is the use of sedative treatment, the constipation being neglected. The neurotic element alone being recognized, bromides are prescribed, often with good effect for the time. The cause being allowed to remain, the relief is, in many instances, temporary.

Among the drugs most heedlessly used at the present day are those which have the property of reducing bodily temperature, such as aconite, antipyrine, and antifebrin. These are powerful drugs, and are too readily resorted to. Pyrexia is a symptom, not the cause or essence of disease. Yet the temptation to reduce the temperature is strong. It must be remembered, however, that in addition to their antipyretic power these drugs have other active properties. They are especially cardiac depressants. In many of the diseases in which they are used the danger lies not in the pyrexia, but in heart-failure. High pyrexia is an element of danger, but is not the sole danger. This is especially true of pneumonia, and the results of decided antipyretic treatment of that disease has not been favorable. Children do not bear such treatment as well as adults. The mere forcing down of temperature by means of antipyretic drugs is futile as a means of curing the disorder which gives rise to the febrile state, and is, besides, often dangerous.

One of the most universal mistakes, although, perhaps, not one of the most serious, is that of relying largely or chiefly upon drugs in the treatment of diseases of defective nutrition. Children are apt to be dosed with cod-liver oil and other drugs without regard to the condition of their digestive organs. A delicate child is drenched with these drugs because it has a poor appetite, is ill-nourished and anæmic. The tongue is coated and the bowels confined, and the child is receiving improper food. Here the chief cause of the anæmia and defective nutrition is the disordered state of the functions of digestion and absorption. A few doses calomel, followed by a tonic with a mild saline laxative and judicious feeding, will do far more good than cod-liver oil, iron, and hypophosphites. They are most valuable drugs in their place, but in these states of disordered function, by intensifying digestive difficulty and impairing appetite, they do more harm than good. In rickets far too much reliance is placed upon drugs to the

exclusion of milk, cream, meat-juice, sunlight and fresh air.

The cruel and useless practice of swabbing out the throat with caustic applications in diphtheria has almost died out, but this method of applying astringents and solvents still survives. After long experience and observation the author unhesitatingly condemns the practice as injurious. Such applications probably do more harm than good, while the terror, excitement, heart-strain, and physical exhaustion are conditions most inimical in a disease tending to death by asthenia.

Other errors in treatment are briefly mentioned, such as oppressive poulticing of the chest in pneumonia; the administration of emetics in diphtheritic croup, which is utterly ineffectual except to exhaust and depress the patient; their frequent repetition in bronchitis and whooping-cough when there is no extreme mucous obstruction of the air-passages to justify it; and the too frequent purging of rickety children.

HYGIENE.

THE ACTION OF WINE UPON PEPSIN AND DIGESTION.

Without dwelling upon the known action of alcohol, which has been well studied by Petit, and upon that of cream of tartar, the novel results arrived at by L. Hugouneng, in some recent researches (*Bull. Soc. Chim.*,) are the following: 1. All wines, without exception, interfere with the action of pepsin, those richest in alcohol, cream of tartar, and coloring matter being most injurious, as it was easy to foresee. 2. Among the elements of natural wines the coloring matters act in concert with the alcohol and the cream of tartar to retard or arrest pepsic indigestion. 3. The acidity of normal wines is unable to excite the action of pepsin; in most cases it does not appear to exist. 4. Among the coloring matters introduced fraudulently into wines, methylene blue, azoflavine, solid blue, and especially magenta, interfere with pepsic digestion. The vegetable colors, black mallows, elderberries, and maki, like œnoline, exert an injurious action. 5. Plastering, by removing a part of the cream of tartar, eliminates an element of natural wines which retards the action of pepsin *in vitro*. Digestion is more rapid in presence of plastered wines, than of natural wines, but the advantage which plastered wines have in this respect does not conceal their other disadvantages.

THE HABIT OF WASHING.

No practice, no custom, however long established, has ever been allowed a permanent right to respect, or even to existence. Sooner or later its turn will come to be weighed in the critic's balance, and its quality will have to be proved. Let us quote, as a recent illustration, the habit of daily bathing, the utility of which has of late, though not for the first time, been seriously questioned. The reasonableness of doubt in such a matter, and under ordinary circumstances, does not, we confess, commend itself to our judgment. Whether the opponents of ablution fear the shock of cold immersion, or whether they dread the cleansing stimulation thus applied to the excreting skin surface, their objection must appear to most persons possessed of ordinary health and vigor to threaten impairment of both by fostering uncleanliness. If, on the other hand, it is the too free application of heat by Turkish and other warm baths which appears objectionable, we will not deny that there is here a possible ground for complaint. Let it not be supposed that we ignore the curative influence or the cleansing property of this method when used with judgment. It has undoubtedly its fitting time and places if rightly applied. It is no less true, however, that experience has often proved the mischievous effects of its misuse —in case, for example, of cardiac weakness or general exhaustion. Cold bathing in like manner is not without its occasional risks. It is not suitable for persons enfeebled from any organic cause, though mere nervous languor is often braced and benefited by it. It has no proper place among the habits of those who are subject to chronic visceral congestions. As regards one advantage derived from bathing—*i. e.*, its cleansing property—there is no reasonable ground for difference of opinion. Man, whether savage or civilized, appears as a rule to have no doubt on the subject. Wherever we find him with water accessible he is a bather. Less practiced by one people than another though it may be, there still is commonly recognizable a constant habit of ablution, and this fact in itself attests at least an almost universal belief in the necessity of ensuring cleanliness by means of washing. Nor can we find reason to doubt the general soundness of this belief. In bathing temperature is of course a chief consideration. For the robust, cold immersion followed by rapid friction is a valuable tonic of nerve, skin, and heart function. For less vigorous constitutions—those, for exam-

ple, which have been tried by disease, and those of young children—the addition of heat up to the temperate point is only judicious. With some persons a warm bath is a daily luxury. Notwithstanding its efficacy as a means of cleanliness, however, this custom is or ought to be discredited by its inevitable action as a nervous depressant, which places it in an unfavorable position compared with the more bracing practice of cold effusion. The benefit derived from bathing, therefore, is likely to assert itself in spite of all adverse criticism, and its mismanagement, which is only too common, should not be suffered to condemn it in the eyes of any judicious and cleanly person.—*Lancet.*

PURIFICATION OF DRINKING WATER.

The burning question of the present age is how to obtain pure drinking water. In reference to this subject I would refer to a paper recently read by Dr. O. Froelich before the Electro Technical Society of Berlin, May, '91, in which he says: "That the attempt to destroy bacteria by means of ozone has been effected with water from Berlin and neighborhood and always with the most complete success. The sterilization test takes place, as is known, in the following manner: A few drops of the water to be tested are placed by means of a sterilized platinum wire on sterilized nutrient gelatine, contained in a sterilized reaction tube closed with a plug of cotton wool. If the water contains bacteria their cultures become visible in the form of opaque grains and tubercles, which continue growing. Even if by such experiments the sterilization of ordinary water is established, it is still doubtful if the less common bacteria, viz., those generating disease—typhus, cholera, anthrax, etc—and their spores are destroyed. The question can only be determined by experts, although there is every indication that it will be solved in a manner favorable to ozone.

"The ozonization of water acts besides in destroying noxious or disgusting substances or transferring them into harmless ones. Sulphuretted hydrogen is separated into sulphuric acid and water, ammonia becomes nitrate or nitrite of ammonia, iron is precipitated as ferric-hydrate, and finally, bacteria which generate decay are probably all killed. We have also good reason to assume that even the worst ordinary water can be made drinkable by means of ozonization. Disinfection by ozone has properties not appertaining to other methods of disinfection. In contra-distinction to sterilization by boiling, ozonization is quicker and cheaper, and as opposed to disinfection by chemical means, such as sulphurous acid and chlorine, etc., it has the greater advantage of leaving no traces behind it in the water. Of course some ozone is absorbed by the water, but the amount is so insignificant that it is not perceptible to the taste. The ozone gas goes through the water, does its work, *i. e.*, kills the bacilli, probably completely, and leaves the water in the same condition in which it entered it.

"How much ozone is taken up by the water in passing through has not yet been established. Shortly, however, larger apparatus will be prepared which may be considered as models of water ozonization, from which can be determined the working power and cost of ozonization for any quantity of water.

"The solid earthy matter held in suspension by water is not affected by ozone; filtration will therefore be a necessity in the ozonization process. The filtering plants heretofore employed have served not only for the removal of the solid matter in suspension, but have also answered the purpose of collecting the greater part of the bacteria and this takes place generally by means of the coating of algæ which is formed on the layer of filtering material. The ozonization of the water, however, answers the purpose of the coating of algæ, but in a much more complete manner. The algæ cannot survive in ozonized water, as has been established by actual experiment, and therefore the laborious upturning of the filtering layer, which has hitherto been the practice in order to prevent the coating of algæ from becoming too thick, is done away with.

"The proper discussion of the ozonization of water can only take place after the cost of ozonization has been more exactly ascertained; nevertheless, so much is thus far apparent, that a fundamental discussion of this question cannot be avoided, particularly in cases in which good drinking water can only be obtained at great cost, bad drinking water, on the other hand, easily obtainable and by ozonization converted into good. The question further arises whether, generally considered, impure water, such as the waste water of towns and factories, cannot be fitly treated by means of ozone. In waste water the bacilli generating decay would in this manner be killed, the ammonia probably converted into nitrate of ammonia and the organic constituents further oxidized

as far as possible."—*Elektrotechnischen Zeitschrift*, 1891, *Heft* 26.

MEDICAL CHEMISTRY.

DETECTION OF BILE-PIGMENT IN FÆCES BY GMELIN'S TEST.

Dr. Rosenthal (*Deutsch. med. Wochenschr.*, August 6th, 1891) investigated the fæces of a number of persons in health and disease, in order to discover under what conditions the presence of unaltered bile could be demonstrated by Gmelin's test, namely, fuming nitric acid. In healthy fæces, or in those resulting from slight diarrhœa, no reaction was ever obtained. If, however, the attack was sufficiently severe for there to be six or more stools in the twenty-four hours, the sixth and subsequent stools almost invariably contained unaltered bile, and Gmelin's test gave rise to the well-known color reaction. In cases, morever, where diarrhœa followed the administration of aperients, if the first stool was delayed, and if several others were passed with a minimum interval of four hours, unaltered bile-pigment was occasionally found in an earlier motion than the sixth. Rosenthal found that it mattered little what pathological cause had led to the diarrhœa. The increased peritalsis—that is, the accelerated transit through the intestinal canal—was the factor which determined the presence of the bile-pigment.—*Brit. Med. Jour.*

A NEW REAGENT FOR ALBUMIN IN URINE.

M. and Ad. Jolles (*Union pharmac.; Nouv. Remêd.*, 1891, No. 7), propose the following method for testing for albumin: 8–10 cc. urine are mixed with an equal volume of concentrated hydrochloric acid and to this mixture are added from a pipette a few drops of a saturated solution of chloride of calcium in such a manner that the liquids will not mix. In presence of even traces of albumin the dividing line will show a distinct white cloudiness.

AUTOMATIC CARBON DIOXIDE REGISTER.

Prof. A. Wolpert, of Nuremburg, has prepared an automatic apparatus for the estima- of the purity of the atmosphere by means of the amount of carbon dioxide contained in the air. This air-tester is so regulated that by a comparison to a standard dial, one is able to determine at once the amount of carbon dioxide in a room, and thus judge if the ventilation is consistent with the standard of health. The great advantage possessed by the use of this machine, from an economic point of view, is the fact that there is no need of changing the air of a room if it be found by the air-tester to be pure, and thus the cost of extra fuel can often be saved.

Printed on the dial are the words *very pure, pure, passable, bad, very bad,* and *altogether bad,* and a table is posted telling the amount of CO_2 these words indicate in 1000 parts of air. On the back of the register is the following scale:

Very pure when less than	0.5	parts CO_2 per 1000 of air.
Pure when from	0.5 to 0.7	" " "
Passable "	0.7 to 1	" " "
Bad "	1 to 2	" " "
Very bad "	2 to 4	" " "
Altogether bad over	4	" " "

The apparatus is arranged as follows: Upon a bracket is placed a low flat vessel, filled with a standard solution of sodium hydrate, colored red with phenol phthalein. To this solution a few drops of oil are added. This prevents the liquid from coming in contact with the carbon dioxide of the air until the proper time. By means of a syphon, which is attached to a cork floating on the liquid, the fluid is dropped automatically into a tube, one-half meter in length. This tube is prepared of a white transparent glass, so as to show off the color of the solution to the best advantage. The syphon is so arranged that at a temperature of 68° F. one drop falls into the tube every two minutes. As the solution falls from the syphon to the tube, the carbon dioxide of the air has an opportunity of coming in contact with the liquid for a constant period of time. If the air is very pure, the coloration will be unaffected. If the air contains CO_2 the color of the standard solution will become lighter from contact of the solution with the air. It would therefore follow that the lighter the solution, the more CO_2 is contained in the air at that time. By reference to an attached color scale, an approximate, but sufficiently accurate, result for ordinary purposes can readily be obtained. The apparatus should not be placed near the fire or in the direct rays of the sun.—*Fortschritte der Krankenpflege.*

NEWS AND MISCELLANY.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The next meeting of the Medical Society of the State of New York, will be held at Albany, February 2nd, 3rd, and 4th, 1892,

and Dr. Seneca D. Powell, No. 12 West 40th Street, New York; Dr. James D. Spencer, of Watertown, and Dr. Franklin Townsend, No. 2, Park Place, Albany, have been appointed the business committee. Any communications regarding papers or any matter pertaining to the business of the Society which should properly come before the business committee, should be addressed to Dr. Seneca D. Powell, 12 West Fortieth Street, New York City.

A. Walter Suiter, President.
F. C. Curtis, Secretary.

THE PREDICTED RETURN OF RABIES AND HYDROPHOBIA.

It will be remembered that only a short time ago congratulations were freely expressed on the fact that London was practically free from rabies, in consequence of the beneficent action of the muzzling regulations, but when Mr. Chaplin yielded to the pressure put upon him by some of his political friends, and substituted for the very efficient muzzle the oft-exploded plan of a collar and inscribed address, we pointed out that, as the restrictive regulation was only applied to a part of the country and for an insufficient period, the disease would inevitably reappear and human beings die from this most painful and yet most easily prevented of diseases. Our forecast is, unfortunately, only too truly justified by facts. Isolated cases of rabies appeared within a couple of months of the cessation of the muzzling regulation, and by this time now we are of course beginning to receive intelligence of human beings falling victims in their turn. Last week an inquest was held at St. Thomas' Hospital on a commercial traveler who had been previously bitten by a dog, and a verdict was returned of "Death from hydrophobia." A couple of months ago another case occurred at Ealing in which there was no doubt that the patient died of hydrophobia, a verdict being returned to that effect, although there was considerable question as to the identity of the dog which had conveyed the infection; and we have heard of another case since. It is perfectly clear that the usual autumnal increase of the disease is now notifying itself as the commencement of a fresh epidemic. We hope very much that the Board of Agriculture will take this lesson to heart and that political considerations will not be allowed to intervene again in matters of public health. Mr. Chaplin surely will not prefer the false statements of a few bigoted sentimentalists to the statements of fact offered to him by his scientific advisers.—*Brit. Med. Jour.*

INDIAN OPIUM IN MEDICINE.

At the recent British Pharmaceutical Conference Mr. E. M. Holmes read a paper on "The Opium Used in Medicine," in which it is stated that Indian opium is not used in England. In one recent year only two cases of Malwa opium appeared to have been imported into this country, and it was unknown to retail chemists. He thought that there was no reason why India should not take the place of Turkey in supplying Great Britain and her colonies with the drug. It was true that the Indian opium differed materially from Turkey opium, as, from the process of manufacture at present employed, it contained 30 per cent. of water, was apt to ferment, and contained less morphia than Turkey opium. But he saw no reason why, if the necessity arose, some improvement could not be effected in the process of manufacture. The poppy grown in the higher altitudes in India yielded opium containing 50 per cent. more morphia than that gathered in the plains. He then proceeded to adduce reasons for anticipating that it may be beneficial for the Indian Government to look to Great Britain as an outlet for the opium produce, and these are: The Chinese are now cultivating the poppy to a large extent, with the result that the opium exports of India are on the decrease; as the interior of Africa is opened up a large supply of the drug will be required by the inhabitants of that country; and should Turkey become the seat of a European war our supplies from that country will fail, and then it would be that India might step in. He also referred to the manufacture of opium in Australia, and gave it as his opinion that opium could be manufactured in India, under proper English supervision, which would compete with the Turkey variety. Specimens of Indian opium were exhibited.—After *Pharm. Journ.*

JOSH BILLINGS ON DOCTORS.

Doktors are not all quaks; you hav got wrong noshuns about this. Doktors, lawyers, and ministers have a hard row to ho; they hav to deal with kredulity, knavery and fears ov the people—three ov the most difficult traits in human natur tew handle. If i was a doktor and understood my bizzness, i should doctor my pashunts, and let the disease take care ov itself. More folks are cured this way than enny other.—*Med. Times.*

TWO RECENT CONTRIBUTIONS TO THE SUBJECT OF PRE-HISTORIC SYPHILIS.

In an exhaustive discussion of the question of the existence of syphilis among the inhabitants of America before the discovery by Columbus, Hyde, after an elaborate historical review, revealing an epidemic in Spain, just about the time of Columbus's sailing, describes many instances of the discovery of bones bearing what has been supposed to be unmistakable evidence of syphilitic lesions. One element, however, he says, he has been wholly unable to establish beyond a peradventure, namely, that the bones, which he examined either directly or from photographs, were genuinely pre-historic; and, moreover, he does not think that any means exist of proving that the lesions found on the bones were prodnced by syphilis and nothing else but syphilis. Dr. Hyde says that until we are able to prove beyond a doubt that the burial places of these bones have never been interfered with since pre-Columbian times, we cannot be absolutely sure that syphilis existed among the Indians of those early days.

Contemporaneous with this article in this country, Proksch, writes about the probable existence of syphilis among the old Egyptians. In studying a papyrus containing instructions for the management of different manifestations of a disease known to the old Egyptians as *uxedu* (so spelt in the original article), Proksch traces out syphilis. The papyrus gives the treatment for *uxedu* in the anus, in suppurating wounds, in the mouth, in the eyes, in the bones, in tumors of the head, in the body, in pustules, etc., herein giving an almost complete history of the various situations in which syphilis may manifest itself. The author concludes that *uxedu* of the old Egyptians is our syphilis. —*Boston Med. Surg. Jour.*

A MAN BURIED ALIVE.

A curious fact is reported as having occurred at Saint Crépin, in the canton of Saint Sernin, near Rodez. In carrying a man supposed to be dead, from the church to the cemetery the pall-bearers, four young men, thought that they perceived a movement inside the coffin. The ceremony being finished they compared observations, and all agreed as to their sensations. Communicating their suspicions to the clergyman the coffin was ordered to be opened, and it was found that the man had, in fact, moved. The hands, which had been crossed upon the breast, were raised in front of the eyes. The man was taken from the coffin; he was addressed, but made no reply. A stimulant was administered and absorbed. He was transported to his home and means used to restore him to life. The following day he was living, looked about him, drank, and spoke a few words, but was extremely weak.—*Le Progrès Médical.*

THE ANTIQUITY OF RHEUMATISM.

A very valuable find of skeletons has been made in Egypt by Mr. Flinders Petrie, who has recently opened a number of tombs previously intact at Medum, belonging to the beginning of the fourth dynasty. This is the earliest known date of Egyptian remains, and that to which the Egyptians ascribe themselves. The skeletons are well preserved, but tender and friable. Some of them bear unmistabable evidence of rheumatic changes, and consequently indicate that at that very remote period man was subject to and suffered from this, as is now shown from its antiquity, venerable disease. No ornaments or objects of art, except occasionally some rough pottery or a wooden headrest, were found with these remains. The greater number were interred in a contracted position with the knees drawn up to the breast, even when the tomb was long enough to allow burial in the extended position, the body placed on the left side, wrapped in linen cloth, the head always to the north and the face to the east. A few, however, apparently the bodies of the highest class or race, were interred in the extended position along with vases of stone or pottery and headrests. At this period there is no trace of mummification. The essential difference in the mode of interment seems to point to difference of race, and it is probably that the contracted burials are those of the prehistoric race of Egypt, while the dynastic race were interred with the body extended. It is extremely interesting to find the these contracted burials common at so early a date in Egypt, as a similar mode was adopted by the earliest inhabitants of Great Britain. Mr. Petrie has brought the skeletons to England, and deposited them at the College of Surgeons, where they are being treated so as to strengthen them and render them available for the anatomical investigation which Mr. Petrie intends to have made in order to determine, if possible, their ethnographical affinities. When this is done we shall doubtless also have a full description of any pathological condition which may be present.—*Brit. Med. Jour.*

Clinical Lecture.

SCOPE OF ORTHOPEDICS—THE FORMS OF CLUB-FOOT—TENOTOMY.*

BY H. AUGUSTUS WILSON, M. D.,

CLINICAL LECTURER ON ORTHOPEDIC SURGERY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

SCOPE OF ORTHOPEDICS.

Gentlemen:—By way of introduction I desire to say a few words in reference to the word orthopedic. Unless we understand thoroughly what is embraced in this term, we cannot entertain a clear idea of the subject we have before us. The first part of the word is derived from the Greek *Orthos*, straight, or preferably, to make straight. This is plain thus far, but unfortunately there is a confusion in the minds of many as to the derivation of the final portion of the word. It is supposed by some to be derived from the Latin, *pes*, a foot, thus limiting the meaning of the word to the narrow scope of making a deformed foot straight. The correct derivation is to take it from the Greek, *pais*, a child, therefore making the word mean literally "to make straight a child," presuming that the child is deformed.

Now let us think for a moment of those diseases which especially give rise to deformity in children, namely rickets, tuberculosis, paralysis, etc. Were we to confine orthopedics simply to the correcting of deformity already existing in children, we would limit its usefulness to a very narrow scope. Many of the deformities of children require orthopedic treatment during adult life. Therefore, orthopedists define orthopedics in the broadest sense thus: Orthopedic surgery is that branch of medicine which has for its object the prevention and correction of chronic and progressive bodily deformities. Thus enters into the subject the important feature of rational medicine, the prevention of disease, and as well the prevention of deformity. This necessitates a familiarity with those conditions which will produce deformity, and in our clinics we will from time to time give our attention to this part of the subject. There are numerous deformities that although congenital are not classed as orthopedic cases. Cleft palate for example is a congenital deformity, but it is a condition which is not a progressive deformity, and can not be corrected or prevented by other than surgical measures. We must remember that the definition embraces *progressive* deformities. It is the prevention of progress as well as the cure of disease that orthopedic surgery has for its object. It is within the knowledge of your preceptors that patients suffering with diseases of the eyes were sent to the optician by their physicians to have their optical defects remedied. This practice was continued until the oculists occupied the field, recognizing the injury that was being done to the patients, by men without any medical knowledge whatever, and now the oculist prescribes and the optician makes the necessary glasses. What would you think of a doctor who would send to an instrument maker a patient with a fractured limb with instructions to please apply a proper splint for this broken bone; or of a physician who would send a fever patient to a pharmacist with the request that he give him some drug to allay his fever? You say this would be absurd. Yet this has been the practice with orthopedic cases which have been sent to mechanicians for the purpose of having some form of brace applied. In many instances the braces so procured concealed rather than corrected the deformity. The mechanician has been driven to occupying the false position of in reality practicing medicine without a science, because of the ignorance of physicians of that most important subject mechanico-therapeutics. The mechanician is thoroughly skilful in

*Two lectures; the second to appear in the next issue of the Reporter.

the manufacture, adaptation and fitting of braces and orthopedic appliances, but his training has not been that of a physician and he is not therefore fitted to prescribe an appliance for a disease any more than the optician or the apothecary.

The entire absence of knowledge on his part, of pathology, etiology, etc., renders him liable to apply braces for cosmetic purposes only, in other words to correct the appearance of a deformity rather than to apply mechanico-therapy to the correction or prevention of the deformity or the disease or condition tending to produce a deformity.

I consider it as important that you should have a knowledge of the principles of mechanics, as that you should know what drugs to prescribe. I would urge upon you a strict, careful study of progressive deformities, for, in order that you succeed in treatment of orthopedic cases, it is necessary that you start at the initial stage of the management of the various conditions, namely, the *prevention* of the trouble. I feel that it will be impossible for me in this course of lectures to follow out a systematic course, beginning with one subject and following it to the end, simply because the patients are often sent to us in the stage of their disease when it is important for you to see them at once. If I withheld the case until the appropriate time had arrived in the course of lectures, I should deprive you of seeing the case when most instructive, and would cause you to lose much valuable information. To show you that orthopedic surgery treats not only of deformed feet, but of other equally important subjects, I shall begin with the feet and draw you away gradually to the other portions of the body. A strong, firm foundation is necessary upon which to build any superstructure, and therefore we begin with the feet. Let us see how we can take a club-foot, and by mechanical means combined with surgery and therapeutical measures correct the condition. There are various kinds of deformed feet.

FORMS OF CLUB-FOOT.

First, we have the *Equinus*, derived from the Latin *Equis*, a horse, and indicating that in this form the patient walked like a horse. The foot is so deformed, that it is extended in a more or less straight line, the patient walking on the tip of its toes or on the ends of the metatarsus. Now suppose the patient's foot was in the reverse condition, the toes up and heel down, then the patient walks upon the os calcis. Therefore this form of club-foot is called *calcaneum*. Although these two varieties are among the rarer forms of the disease, still they exist and must be recognized. Now we have mentioned the bending forward and back, let us consider the bending to either side. If the patient walks on the outside of the foot, the condition is called *varus*. In this condition the foot is turned in. The reverse of this is *valgus*, that is the foot is turned outwards and the patient walks on the inner surface of the foot. The condition produced in the Chinese woman's foot has taught us another variety which we occasionally see produced, not by fashion, as in the case of the Chinese ladies but by disease. This form is the condition in which the normal arch of the foot is increased, and the anterior and posterior pillars of the arch are brought closer together, and there results a cavity of greater magnitude than normal. This is called *cavus*. If we have an increase of the arch, it would be natural to suppose that there may be also a diminution of the arch. If the arch gives away we have a condition of flattening, and this is called *plantaris* or flat-foot. As we proceed in our work, and bring cases before you, you will see that there is no such thing as a simple straightforward disease or deformity with no variations. Some of the names I have given you designate conditions which are known by other names, and often they are combined to describe mixed cases, but I will avoid confusing you by deferring reference to these mixed varieties until I show you cases.

This morning I purpose starting with the cases we have on hand, and I will show you this girl who came to us recently, presenting *valgus* form of club-foot. I must ask you to form in your own minds a conception of what a normal foot is, and I may astonish you when I say that I doubt if there is anything of the kind in this room to-day, as the shoemaker has deformed all of the feet here. In this girl the foot is everted, and the patient walks upon its inner surface. In this second case you see an exaggeration of this same condition. You will notice how the great toe is infringed upon and the other toes pushed out. In contra-distinction to these two cases of *valgus*, the treatment of which I will postpone to another time, I wish to show you another variety of club-foot occurring in an infant aged two months. You will observe here a congenital club-foot of the *varus* variety. If this patient could walk, it would be upon the outside of the foot. There is something holding this foot in this position which prevents a return to the normal posture. There is here a want of correlation of muscular force. If one side of the muscles

of a foot is paralyzed or so placed that the muscles cannot act, there will be a resultant deformity from a want of correlation of muscular action. If a man while rowing makes use of one oar more than of the other, the boat is turned. Just so it is in this condition. Now if we can correct the defect in the muscular action, the deformity will be overcome, as you see has been done in this boy, who was born with *varus* of one side, but who is now approaching a normal condition. In this baby's case, on whom we will operate to-day, the difficulty is that certain muscles are tight and contracted while others are relaxed. The anterior tibial is contracted, and I find its tendon firm and unyielding as soon as I endeavor to correct the foot. This if left alone will counteract all efforts to overcome the deformity and the bones will become ossified in their deformed positions. In addition the tendo achilles feels like a taunt steel wire, and it is adding to the defect. Bear in mind that the operation is not to be done simply to correct the deformity but to put the muscles into a proper relationship, and to place the joints in a normal mechanical position, so as to favor the development of a natural condition of the foot. This second baby is three months old and has double *varus*. The earlier the patient is placed under manipulation and treatment the better the result. The longer we wait, the more thoroughly the bones of the foot become ossified, and consequently the more difficult is the correction. I believe that the first day is none to early to begin manipulative and restrictive treatment of a congenital club-foot, and further, that by beginning thus early, resort to surgical proceedings is less frequently necessary.

TENOTOMY.

The operation of tenotomy for the correction of club-foot is a comparatively modern procedure. It was performed, I believe for the first time, by Sartorius in 1812.

Delpech in 1816, divided the tendo achilles by an open wound, but it is recorded that the wound did not heal for three months.

It remained for Louis Stromeyer to perform the operation subcutaneously, which he did for the first time in 1831.

I know of no better words to describe subcutaneous tenotomy than by saying it is made by a small hole in the skin, the better to conceal the unknown and often extensive amount of destruction beneath.

It is performed by a sharp pointed tenotome perforating the skin and opening a way to the tendon; upon withdrawal a blunt pointed tenotome is introduced and the tendon divided by a sawing motion. No attempt should be made to use force, for the tenotomes are entirely too delicate to permit of it. I have seen tenotomes broken many times and great difficulty was experienced in finding the broken ends.

The various methods of procedure recommended by advocates of each method are first, the simple transverse incision in which the tendon is divided at a right angle to its length. Transversely oblique incisions are made by drawing the knife from below upwards or from above downwards through the tendon as it is being cut.

It may be divided longitudinally obliquely by entering the tenotome at a point one inch and a half to two inches above the os calcis and passing the knife under the skin to the distal insertion of the tendo achilles. The incision begins on the side opposite to that of the skin puncture and in this oblique position is gradually withdrawn, cutting the tendon as it passes.

Then a tendon may be cut from within outwards or from without inwards. I prefer the former, for then you have the movement under the skin to guide the progress of the knife.

While I frequently use the subcutaneous method you will, I think, perceive from the definition I have given, that I do not favor it, on account of the uncertainty which necessarily must exist as to the extent of the severance of tissues other than of the tendon.

Modern aseptic methods has made it possible to resort to procedures that are accurate in the incision as well as in the results obtained, and now open wound tenotomy is freely and safely performed. Professor W. W. Keen has originated an accurate method of tenotomy through an open wound, which I have found of the greatest service. It consists of the longitudinal slitting of a tendon through its middle, and at the point of the origin of the incision to transversely divide one-half of the tendon and at the other end of the cut to divide the other half. The divided ends being retracted to the required extent, the portions in contact are sutured and thus held in exact position, and the skin wound stitched.

I invariably resort to the requisite mechanical appliances to over-correct after tenotomy, so that plasma which, is deposited, may unite the divided ends of the tendon and avoid the necessity of after stretching, which tends to attenuate the newly formed tendon.

In the correction of a club-foot, divide by clean incision at one sitting all soft structures that restrict the complete correction, rather than depend upon the possibility of their yielding or tearing upon the application of force. If the case before us requires it I shall not hesitate to freely divide the anterior tibial, plantar fascia, all the tendons of the flexors of the toes and the tendo achilles, but I invariably reserve the latter for the last, to increase the hold upon the foot at the time of correction.

COMMUNICATIONS.

A NEW APPARATUS FOR DETECTING AND MEASURING THE ANOMALIES OF THE OCULAR MUSCLES.*

BY S. D. RISLEY, M. D.,

LECTURER ON OPHTHALMOLOGY IN THE UNIVERSITY OF PENNSYLVANIA; ATTENDING SURGEON AT THE WILL'S EYE HOSPITAL; PROFESSOR OF OPHTHALMOLOGY, PHILADELPHIA POLYCLINIC, PHILADELPHIA.

The renewed interest which of late years has been awakened in the study of the ocular balance has served to demonstrate the necessity for some form of apparatus which would facilitate the work of the surgeon, and at the same time secure trustworthy measurements of the relative strength of the ocular muscles. The use of the series of prisms ordinarily found in our sets of test-glasses, was notoriously tedious, fatiguing both to patient and surgeon, and withal variable in results, so that the temptation to avoid a wearisome task constantly presented itself, since at the end there was placed but little confidence in the result.

It is not my purpose to discuss here the anomalies of the ocular muscles, but to describe briefly an instrument devised to meet the indications suggested above. In passing it may be said that not infrequently muscular defects parade themselves in a manner to deceive the observer, as to the real muscles at fault, or the defect may be wholly or in part concealed, but nevertheless the cause of ocular disturbance or reflected symptoms. To detect these latent disorders, or to unravel successfully the vagrant and confusing movements of the eyes, it is helpful to have the patient as far as possible in a position of general muscular rest, and the eyes placed under conditions which remove the ordinary inducements to binocular vision. It is furthermore desireable that these conditions shall be simple and readily understood, since for the most part our patients are not trained to habits of accurate observation. Then, too, the persons suffering from these anomalies are apt to be "nervous," are afflicted with headache, particularly with occipital pain, which is aggravated by any protracted examination. The occular muscles become irritable under the effort to measure their relative strength, so that the more persistent the trial, the less trustworthy are the results reached. Nothing could be more annoying to the eyes of an already suffering patient, than the heavy trial-frame resting upon the nose, and the placing and replacing in wearisome successions of the cumbersome prisms of the test-set. To avoid these annoyances and at the same time meet the requirements for a rapid and careful determination of any existing anomaly I have had constructed, by John L. Borsch and Company, of Philadelphia, the apparatus here described. With various modifications I have used it daily for more than three years, and now present it in the hope that others may find it an additional aid in the daily routine of office work.

At the meeting of the American Ophthalmological Society, in July, 1889, I presented a convenient form of the Cretes rotary prism, a description of which will be found in the transactions for that year. The wood cut of this instrument is here reproduced, Fig. I. The instrument now described is a fixed form of apparatus for the accurate use of the rotary prism and certain other accessories, *e. g.* the correcting-glasses for any existing defect of refraction, the stenoparic slit, the Maddox double prism and rod. The accompanying wood-cut, Fig. II, exhibits its details in a manner which will obviate any necessity for lengthy description. The essential part of the apparatus is the *holder* which can be mounted upon a stand designed to rest upon a table or desk—or as in the cut upon a floor-stand which is placed by the side of the chair occupied by the patient. At the top of this stand there

Fig. I.

* Read before the American Opthalmological Society at Washington, D. C., September, 1891.

is placed a strong horizontal arm, which is carried to the front of the patient and supports a second upright shaft, which moves up and down freely but is fastened at any desired height by a binding screw. On this shaft is placed a chin rest, N. and at its top

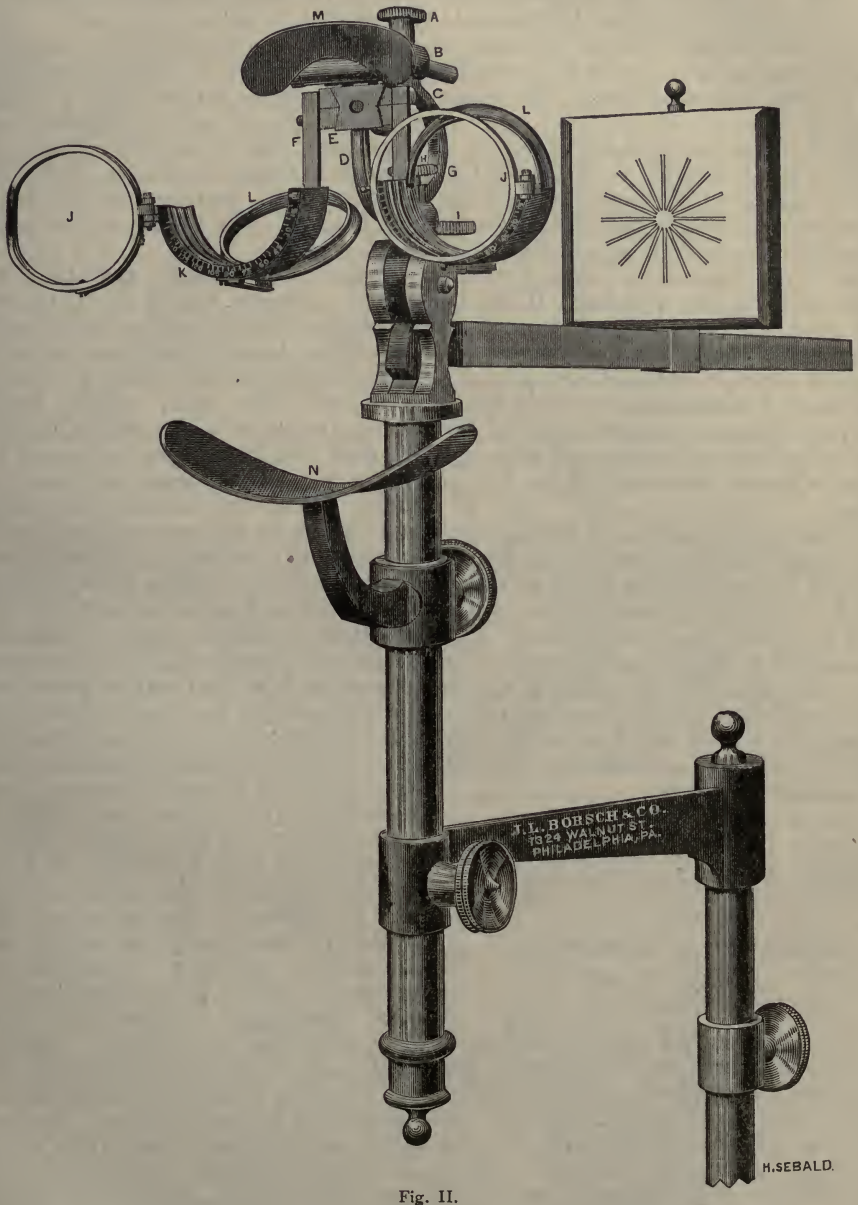

Fig. II.

the holders K. and accessories are supported. L. L. are a pair of rings or cells for the reception of the rotary prisms. These are hung on a spring hinge which permits them to be turned forward and downward below the line of vision, so that the prisms are out of the way when not in use, but are readily turned upward into place when desired. A rotary prism should be placed on each side for rapid working, the zero mark at 180° on one side and at 90° on the other. On the posterior surface of the holders, K. is seen the ring J. J. This is hung on a spring-hinge and on the left side is represented as turned outward, out of the line of vision, but *in situ* on the right side. These are designed for the reception of the Maddox double prism or red, each of which are

mounted in a cell which accurately fits these rings, and may be turned to any desired position, being checked at 90° and 180° by a stop-spring. These may be retained permanently in place, but are readily removed and replaced when desired, by other cells containing a stenoparic slit, a blank metal disk for excluding one eye, and a third with a central opening 2½ mm. in diameter to act as a diaphragm in correcting certain cases of high refractive error with widely dilated pupils.

M, is a brow-rest, adjusted by means of the screw A. Just below the border of this is seen a spirit level without which the triple images produced in using the Maddox double prism or the bar of light, as produced by the rod—are not easily maintained in a strictly vertical or horizontal position. When inclined they are confusing to the patient. The bar, with carrier on it containing the astigmatic chart is designed for work at a near point. The carrier moves freely to and fro on the bar and carries a series of test cards. The bar can be removed when not in use or turned down out of the line of vision.

The rotary prisms when in place as suggested above furnish a most ready and rapid method of determining the power of adduction, abduction and sursumduction at 6 m. or .50 m. At 6 m. a small point of light is used, while at the near point a small word of D = .50 is placed in the centre of a white card. In all these respects, however, the instrument lends itself to the preferred methods of the observer as readily as does his test set and trial frames.

SARCOMA OF THE DORSO-SCAPULAR REGION; OPERATION; RECOVERY.*

BY GEORGE N. LOWE, M. D.,

RANDALL, KANSAS.

In the formation of a sarcoma we have a neoplasm pathologically heteroplastic, predominating constructively over the type of the connective tissues in which, however, the cellular constituents predominate over the intercellular substance. In this respect they resemble the immature connective tissues; so that the comparison of sarcoma to embryonic formative tissue is perfectly apt.

*Read before the Mississippi Valley Medical Association, October 14, 1891, in St. Louis, Mo.

Sarcoma originates invariably in a structure belonging to the connective tissue group, *i. e.*, in formed or unformed fibrous tissue, in cartilaginous, bony, mucus, lymphoid, neuroglia, or adipose tissues. The transformation of these into tumor tissue is effected by the growth and multiplication of the constituent cells.

Of these there are several varieties, depending upon the size and configuration of the cells, and the nature of the intercellular substance. They include what have generally been known as fibro-plastic, fibro-nucleated, recurrent fibroid, and myeloid tumors. Many growths formerly described as "cancers" also belong to this class of new formations.

Structure.—Sarcomata may thus be defined as tumors consisting of connective tissue which throughout its growth more or less retains the embryonic type, in so far at least that cells predominate over intercellular substance. The cells, which constitute nearly the whole of the growth, consist for the most part of masses of nucleated protoplasm, and rarely possess a limiting membrane. They vary much in size and form, and though in a tumor one form predominates, all may generally be found by search (Cornil-Ranvier). Often the different forms are much mixed in the same growth. There are three principal varieties—the round, fusiform, and myeloid cells. The case now in question is of the round or giant variety.

Case.—Angle E., aged 18 years, American by birth, a farmer of healthy parents, no history of tuberculosis, carcinoma, or sarcoma so far as I could ascertain of either parentage. In the latter part of May, 1889, while lifting a heavy weight, using his language, he "felt something kind of give way on the left shoulder blade." No swelling, no redness of the parts could be detected; yet there was a dull aching pain at the seat of the lesion. Sometimes it apparently subsided, but occasionally the patient experienced a rather sharp darting pain at the site of the injury. At first the pains were at long intervals, from four to five days or a week; as time advanced they returned at shorter intervals. During the winter of 1889 and 1890, while attending school he was struck with the fist of a comrade two or three times while boxing, in the same region of the first lesion. He also stated that later he was struck with a hard ball with great force at the same region. Those contusions increased the suffering of the patient; yet there was none of those

blows sufficiently severe to produce a discoloration or swelling.

About the middle of February, 1890, the obtuse pains were deep-seated and almost constant; the acute sharp pains recurring at shorter intervals. At this time his condition was such that he consulted a physician of ability. As there was no discoloration, heat, swelling, or marks of any lesion, although there was some tenderness (deep-seated) on pressure; as there was nothing visible, his physician, not suspecting anything serious or malignant, diagnosed rheumatism and prescribed accordingly without benefit. About the first of March, 1890, the young man discovered a slight enlargement, seemingly solid and deep-seated, on the scapula about two inches posterior to the scapular notch, on and above the spine of the scapula. This neoplasm assumed a slow but steady growth, which, on pressure, produced a deep, sickening pain. No heat or redness over the parts affected.

On the second day of April, 1890, the young man and his father came to my office in search of relief, and gave me the above history of the case.

On examination I found a solid growth, deep-seated on the dorsum of the left scapula, but was not attached to the periosteum, measuring two inches in diameter, producing a fainting, sickening pain on pressure. I diagnosed sarcoma, and stated the facts in the case to the father and son, and told them that the only means for relief and cure was an immediate operation, removing a sufficient amount of tissue beyond the cell proliferation. They persisted in not having an operation done at this early stage until other means failed, and begged me to use my best judgment in directing some other course of treatment. I applied iodine injected with glycerine of various strengths, without reaction, and with iodide of potassium internally, and would have injected the virus of erysipelas for reaction if I could have obtained it. The only benefit obtained from the injection of the tr. iodine with glycerine was that it seemed to retard the growth. As there was no improvement up to July, the patient passed from under my observation to a new field of treatment. I insisted upon an operation. I did not see the patient again until about the middle of February, 1891, at which time he returned with a double neoplasm about the size of an ordinary cricket-ball, which he stated had grown rapidly for the past two months. As before, I pressed the matter of operation, but he refused. He begged for the iodine treatment again. I told him and his father that it was perfectly useless to waste time, as it would shortly terminate the boy's life. On the second day of April, 1891, the tumor measured 11½ inches in length by 6½ inches in width, perfectly adherent to the dorsum of the scapula, extending upward across the upper part of the dorsal and cervical vertebræ, and also extending downwards below the scapula, with an elevation above the surrounding surface about three inches. On the second day of April, I presented the young man to the members of the Republican Valley Medical Association in session at Concordia, Kansas, at that time. The majority of members present corroborated my diagnosis. The formidability of the growth now became a serious matter. About the 15th of April the young man and his parents consented to an operation, and I prepared the patient for it. On the 23d I operated, being assisted by Drs. B. T. Trublood, of Grand Island, Nebraska, and G. B. Morse, of Formosa, Kansas. At this time the growth measured 12 inches vertically and eight inches transversely. Palpation indicated a firmly adherent neoplasm. Fifteen minutes previous to the administration of the anæsthetic, I gave the patient gr. ⅓ morphia sulph. hypodermatically; brandy ℥jss. Dr. Morse administered the anæsthetic. Patient was ready for operation in fifteen minutes. Every antiseptic precaution was taken. I made the incision in the line of the vertex of the growth, commencing one inch from the summit over the cervical vertebræ down to one inch of the lower portion of the tumor. The growth was beneath the trapezius muscle. With a dissector I loosened the trapezius on each side of the tumor, and it was held back by retractors while I enucleated the entire mass, which was bound down by strong fibrous bands. The whole growth was deeply embedded on the scapula, the thoracic wall, the fourth, fifth, sixth and seventh cervical, and the first, second, third, fourth, fifth and sixth dorsal vertebræ. It was attached to the spine of the scapula, the sixth and seventh cervical, and the first, second and third dorsal vertebræ. The sixth and seventh cervical spines were removed with bone shears, the remainder of the spinous vertebræ being liberated with curved shears, also the spine of scapula. The wound was thoroughly irrigated with 1–5000 bichloride of mercury, then thoroughly dusted with iodoform, packed with 1½ yards of borated gauze, a drainage tube inserted, wound

closed with deep and superficial sutures, dressed with borated cotton and gauze, all completed in one hour, this at noon. The patient rallied nicely with but slight shock. Six P. M., temperature 100°; pulse 72, strong and full; respiration normal; patient complained of some pain. I gave morphia sulph. gr. ⅛, quinine sulph. gr. iij, brandy ℥ss in a little syrup and water, which soon gave the patient rest until my next visit, April 24th, 8 A. M., when I found his condition good, with temperature 100½°; pulse 74; respiration 19. He had taken milk and soup in sufficient quantity and said he felt all right. I left morph. sulph. gr. ⅛; quinine sulph. gr. iij; brandy to be administered *pro re nata*. At 10 A. M. the patient complained of pain, when the morphia, quinine and brandy were given as directed. He rested well the remainder of the day. I saw him at 7 P. M., when the temperature was 100.01°; pulse 72; respiration normal. He stated he was feeling quite comfortable. He had taken milk and soup in sufficient quantity. April 25th, 9 A. M., temperature 100°; pulse 70; respiration normal. Had rested quite well during my absence by taking morph. sulph., quinine sulph. and brandy at 2 P. M., April 26th. All conditions good. 6.30 P. M., condition the same as in the morning. April 27th, 10 A. M., temperature 100°; pulse 70; respiration normal. Had rested well during the previous night by taking quinine sulph., morphia sulp. and brandy at midnight. At 7 P. M. I found his condition unchanged.

April 28th, A. M., Dr. Morse present; temperature 99¾°; pulse 70; respiration normal; had rested well the past night; condition good. As drainage had been profuse, I redressed the wound, first removing the gauze packing, then irrigating the wound thoroughly with carbolized water, reinserting ¾ yard borated gauze, and dressed the wound as before.

April 29th, 6 P. M., condition remaining good; temperature 99½°; pulse and respiration normal. April 30th, 10 A. M., temperature, pulse and respiration normal. Had rested well since my last visit; appetite increasing; asked for a more solid diet than milk and soup, which was granted. May 1st, temperature, pulse and respiration normal. I removed all packing and sutures, re-irrigated wound as before; external wound had healed by first intention, and things pointed to an early convalescence. I redressed the wound as before. From this time on the patient improved rapidly. On the 14th day (May 9th) after the operation, he came a distance of 3½ miles to my office for a redressing of his wound. At this dressing I found that the wound had completely healed internally as well as externally without any apparent disfiguration in the region operated upon. At this dressing I discharged the patient.

From this time on he gained strength rapidly, and was able to be in the fields ploughing corn in five weeks after the operation. From this on he enjoyed excellent health up until about the first of August, 1891. At about this time he noticed a small elevation or nodule on the left side of his neck, just posterior to the sterno-cleido-mastoideus muscle. Although I had made positive injunctions to the patient and his parents that if they discovered a return of the growth to report to me immediately, they failed to do so up to the last of August, when I found the growth about the size of an ordinary goose egg deeply embedded in the left side of the neck, beneath and posterior to the sterno-cleido-mastoideus muscle, with the indications of other regions being affected. The weather was extremely hot, and his general outlook was unfavorable. He had now consigned himself to a faith cure quack, whom he was persuaded to go and see, who induced him to believe without a doubt that she could cure him by words. His parents entertained the same belief, and they refused to have another operation done until the faith cure was exhausted, alleging that they could not pay for an operation every few months.

September 20th, the young man again came to my office, having now a growth on the left side of his neck, which measured 8 inches vertically and transversely, deeply embedded beneath the sterno-cleido-mastoideus muscle and clavicle—in fact, the entire field across his back was involved, heaving up *en masse* with the neoplasm; also two nodules on his breast. At this time they fully realized his sad condition, and wanted quieting powders so that he could rest. They also wanted me to intercede for him that he might go to some institution for treatment. I sent him to an institution at Topeka, Kansas, on the 20th of September, 1891. He is still there. As the prognosis is unfavorable, the surgeons in charge refused to operate, but they are resorting to injections into the tumor growth in the hope that they will break down the cell proliferations and thus prolong life.

My object in this paper is to show the necessity:

1. Of an early operation in all cases of

malignant growth.

2. That some species of sarcoma are more rapid and destructive in their course than carcinoma, especially the spindle and giant-celled variety.

3. The necessity of having a law to enforce patients so afflicted as soon as a correct diagnosis can be made, to an early operation, thereby preventing great suffering and prolonging life.

4. That in the case of a sarcoma which has grown to enormous extent, infiltrating the surrounding tissues to any considerable extent from the main growth with cell proliferation, an operation is almost useless as regards a permanent cure.

DIET AND THERAPY OF TYPHOID FEVER.*

BY CHARLES F. J. LEHLBACH, M. D.,

NEWARK, N. J.

It cannot be denied that, far from unanimity of professional opinion, regarding the dietary and therapeutic treatment of typhoid fever, there has rather been a tendency during the last ten or fifteen years to wider divergence in the choice of agents to meet supposed indications. The causes which have led to this unsettling of theory and practice are mainly due to: first, the close, and more systematic observation of the clinical history of the disease by means of exact thermometry; and, second, the discovery of its infectious germs, their origin, growth and relation to previously known pathological lesions and complications; third, to the advance of organic and synthetic chemistry, followed by many additions to the list of dietic and remedial agents. With these new armaments, the thermometer, the microscope, the culture tube and the chemist's apparatus, the warfare against disease has entered into a new stage of experimentation. It is no reproach to physicians that in this almost wilderness of newly established facts, they should often strike out in seemingly opposite paths, apparently falling into contradictions and irreconciliable extremes. Sooner or later these seemingly opposite paths will meet, the apparent contradictions will be reconciled, the extremes will be welded together by the strong band of experimentally established truth.

It is not intended, were it possible, in this paper, to enter into a systematic criticism of the various dietetic and therapeutic modes of treatment of typhoid fever, but to point out a few fundamental facts which should be borne in mind, else we go adrift without rudder or compass.

The first point to be emphasized is the fact that typhoid fever is a wasting disease, that from the first day of its incursion to the last day of pyrexia there is a loss of weight of the body. This waste occurs more or less in every case and probably under many different modes of treatment alike. The curve of weight-decrease during typhoid fever has been made the subject of careful examination in numerous cases by Prof. Ernst Kohlschütter (Volkmann's *Samlung. Klin. Vortr.* No. 203—1887 Schmidt's *Jahrbücher.*) and it has been found that this curve takes an exactly uniform course. It sinks, at first rapidly, then, from week to week slower until complete freedom from fever. After complete apyrexia has occurred, it begins to rise. The fever alone therefore seems to be the cause of the decrease in weight, not as might be supposed, and has indeed been often assumed, the diminished supply of food. Probably all organs and tissues are equally involved according to Kohlschütter in the decrease of weight. Increase of weight, after apyrexia, follows more slowly, but also according to fixed rule.

Based upon some unique spectroscopic investigations, Henocque and G. Bandouin *Gaz. Hebdom,* 1888, 37, 38, 39), have attempted to prove that the activity of reduction of oxyhæmaglobin, *i. e.,* the energy of oxygen—waste in the tissues stand in opposite relation to the height of fever temperature. While it is certain that no particular dietetic or therapeutic method of treatment can prevent this waste entirely, it is only logical to conclude that this waste will be lessened in proportion to the reduction of the fever.

Undoubtedly basing himself upon the former consideration, we have been advised by Dr. R. F. Licorrish (*Medical Record,* March 8th, 1890) to subject the patients in the first stage of typhoid fever to absolute starvation. He recommends to withhold all nourishment until the patient calls for it, but to give water whenever required. At the same time absolute rest in the recumbent position is insisted upon, in order to reduce the waste of the heart's strength to a minimum. These are the conclusions which Dr. Licorrish deduces from his statements:

"1. That typhoid fever may be aborted.
2. That to be so aborted the patient must be

*Read before the Practitioner's Club, Newark, New Jersey.

seen and treatment begun within the first few days of its onset—initial chill. 3. That our chief aim should be to restore the appetite, so that the patient may be nourished and rendered able to throw off the disease. 4. That to create an appetite the patient should be deprived of food until nature demands it, or if any be given only in very small quantities at a time. 5. That the maintenance of the horizontal position, so retards or prevents heart weakness as to enable us to starve the patient without any risk. 6. That great care should be taken in feeding the patient after he has regained his appetite, for should it be again lost, the temperature rises and a relapse occurs."

The chief difficulty that presents itself to the adoption of Dr. Licorrish's starvation method, is the fact that, as we generally meet typhoid fever, in this part of the country, it is no longer in the incipient stage to which alone it is claimed to be admissable. The cases which we are called upon to treat both in private and hospital practice are generally from one to two weeks under way, and beyond any possibility of abortive treatment.

Again, may, we not justly suspect that numbers of these so-called aborted cases, in which the starvation method was apparently successful were not real cases of typhoid infection, but simply forms of malarial or ephemeral fever?

Another view which is taken by some, tending to a similar nihilism in practice, is that typhoid fever, being a self limited disease, the less interference with its natural course the better; that the typhoid bacillus during its growth and development evolves certain ptomaines or chemical putrefactive poisons which at last prove self destructive to the microbe. As an example the yeast cell is pointed to, which during saccharine fermentation, keeps on developing and multiplying until sufficient alcohol is produced to kill its own vitality, after which not even the addition of new yeast cells or sugar will be capable of revitalizing the fermentative process.

But it does not appear in accordance with the principles of truly conservative medicine to rely entirely upon the self limitation of morbid processes and to limit ourselves to the role of passive clinical observers. The eventual ptomainic self-destruction of the microbe is not the important element in its pathogenic history. The structural changes in the various organs, which accompany the invasion and the development of the bacilli and their interference with the normal performance of the physiological functions of the organs invaded are the main concern of the practitioner. What becomes of the bacillus, whether he is finally starved to death, or dies in his own venom, is of far less importance to us than the question of how to counteract the destructive processes in the localities of invasion, in the tissues and in the blood.

If by the supply of a proper amount of food, the tissue-waste can be rendered less, or compensated for, or if the same end can be accomplished by the reduction of excessive pyrexia, we certainly leave the patient at the end of the fever in a better condition for more rapid convalescence and repair, and, by having kept his standard of vitality at a higher level, less liable to yield or succumb to the complications and after effects, which so often follow the disease.

That there is a possibility by proper alimentation to compensate to a certain extent the waste effects of the fever, is conceded, I think, by all modern clinical writers. The question: what is the proper alimentation in typhoid fever? is one not so easily answered.

Let us take the natural division of foods and examine into their adaptability to the demands of nutrition under the conditions of fever, according to physiological laws. First, the nitrogenized or albumenous foods, the proteids, including milk, eggs, jellies, strong meat-broths, etc., while easily digested by the stomach and made ready for absorption and assimilation during a state of health, are far from undergoing the digestive changes with facility, in typhoid fever, and for very good reasons. The secretion of the digestive juices throughout the alimentary tract depends largely, if not entirely upon the rapid and normal growth, casting off, and renewal of the epithelial cells. Epithelial cell-life lies at the bottom of digestive energy and of digestion and assimilation, from insalivation down to gastric and pancreatic digestion and lacteal absorption.

It needs neither much clinical study nor investigation in the autopsy room to teach us that in cases of typhoid fever the mucous membranes of the alimentary tracts, from the mouth down to the rectum are in a condition of very sluggish epithelial cell-growth and renewal, and as a result unfit to furnish the digestive juices needed for proper nutrition. Hence, in whatever form albumenous food may be supplied to the fever patient and in whatever quantity, only a very small fraction thereof will meet the normal physio-

logical conditions, for digestion and assimilation, and thus help to repair the fever waste.

The introduction of peptonized meats and pancreatinized milk may, to a certain extent, assist and facilitate the process, but even here, in the mere process of absorption the epithelial and lymph cells also play a primary role. It is an entirely wrong view to look upon the absorbent surface of the alimentary canal as simply a filter, and to consider absorption as a quasi mechanical process of osmosis or dialysis, and to suppose that by putting in a quantity of artificially digested and dissolved albumenous food it will filter right through the absorbents into the blood. The action of live epithelial cells is needed here as well as in normal digestion, and where this epithelial cell activity is deficient, as it is unquestionably in typhoid fever, even peptonized proteids cannot be claimed to compensate for more than a part of the activity of the secretory epithelial cells, and they furnish no more of supply to cover the waste than the crippled epithelial cell-life of the absorbent machinery can accomplish. This, to some, who may be over-enthusiastic in regard to the immense value which is claimed for artificially digested foods, particularly by their manufacturers and venders, may sound like medical heresy, but let me call attention to a simple fact. No less an authority than the eminent Berlin clinician, Prof. Ewald, has published his observation on the value of the use of peptonized eggs administered by the rectum. (*Zeitschr. für Klin. Med.* Bd. XII. 5 and 6 p. 407), and he found that these peptones as far as resorption by the rectal mucous membrane is concerned are entirely irrevelant. Enemata of non-peptonized eggs were as readily absorbed and as efficient.

There is no particular form of diet which has found more advocates and is more commonly relied upon in typhoid fever than the milk diet. In Germany its use is almost exclusive, being supplemented only by gruels and thin soups. At one time in England and in the United States, the homes of the two principal beef-eating nations, the beef-tea, and beef-juice fever held the same relative important as the milk diet in Germany.

The abundance of meat supply in the former countries and its restriction in the latter undoubtedly explains the difference in popular opinion as to the relative values of milk and of meat juices for fever foods; for I venture to say that in the modes of cutting, of cooking and utilizing meat food in the United States, as much is thrown away as waste, as is used for the population of the whole of Germany. Of course it is not intended to compare milk as a physiological nutriment to beef-tea, or beef-juice, but to me it is doubtful whether the casein and albumen, representing the nitrogenous parts in the milk, perform even a fractional part of expected alimentation in the peculiar pathological state of typhoid fever. I have seen typhoid fever stools of patients under milk diet, largely consist of curd in various states, in flakes and grumous masses, and in a recent autopsy the stomach was found to contain a large quantity of a sticky, pasty, pulpy mass of curd. It is not the amount of nutritive material which any particular article of diet contains, physiologically considered, which is at question in this discussion, but how much of the amount can be rendered contributary to waste supply, under the peculiar pathological conditions of the digestive tract—how much can be digested. It is the writer's conviction that very little of the casein of the milk given in typhoid fever is really digested and that its other constituents, the milk serum with its salts, and its sugar and its cream form the essential elements of nutritive value in these conditions.

There is one reason why, in the alimentation of fever patients, less stress need be laid upon the introduction of proteid food, namely, the fact that whatever tissue waste there is in consequence of the normal elevation of temperature, it is the conversion into heat of the food introduced, that is of primary importance. We must reduce as far as possible the general tissue waste, or prevent it. Can we expect tissue repair, particularly of muscle, tendon and the fibrous structures as long as the combustive process exceeds the normal? The conversion of albumenous food into caloric is a much more complicated chemico-vital process than the conversion of the simple hydro-carbons or carbo-hydrates into the same. It gives rise to the formation of a larger amount of side products to clog up the channels of excretion. Does it not seem reasonable then that we should attempt to regulate the food supply in fever so as to restrict it to the simplest kind of food which can, without complicated processes of vital chemistry, be converted into heat and thus save to the extent to which they may be utilized the combustion of the living tissues.

This brings us to the use of the hydro-carbons and the carbo-hydrates in fever—fat, sugar and starch. The same cause which has been mentioned as interfering with the digesting of proteid,—low activity

of epithelial cell life—also comes into play here. The cream of the milk which the patient drinks, is, in ordinary physiological digestion, readily fitted for absorption through the emulsifying action of the pancreative juice. But in typhoid fever this gland partakes of the same general sluggishness of its epithelial cell-life as do the other secretory glands. As far as the lacteals are concerned we must not forget that they are not merely filtering apparatuses. It had been supposed that the leucocytes, the wandering lymph cells as the Germans call them, were the active elements in the fat absorbent processes of the intestines. According to Zawarykin they were presumed to wander between the epithelial cells to load themselves with the fine fat granules of the intestinial contents and then, penetrating the deeper layers of the mucous membranes, to return to the lymphatic vessels. But investigations made by A. Grünhagen, (*Arch. f. mikrosk. Anat.* XXIX 1 p. 139, 1889, *Schm. Jahrb.*) seem to have conclusively shown that the lymph cells are not at all concerned in the absorption of fat, but that this process is connected with the cells of the cylinder epithelium. These are found to be permiated by little clusters of fat, imbedded in various shapes, globular or radiating, in the cell protoplasm, whence they reach the lymph vessels of the mesentery. Bearing in mind that the glands particularly involved in typhoid fever, the solitary and agminated glands, are absorbent glands, we can readily understand, how fat absorption and consequently nutrition must be interfered with when large surfaces of these glands are deprived of their epithelium. Fortunately, however, this class of food can be introduced directly into the system by inunction through the skin. To the extent that this may be done we have a means of supplying a certain amount of caloric-yielding fuel, which may save a certain amount of the living tissue from combustion and waste. It must not be expected that we can thus compensate for all the waste, but whatever waste of tissue may thus be saved, be it ever so little, is so much gain. As a matter of clinical experience I may say that I have resorted to this feeding through the skin in a number of cases of wasting disease with good results. There is one fat, particularly well adapted on account of its easier absorbability to this purpose—the sheep wool fat, or lanoline.

I am aware that the absorbability of lanoline and of other fats through the skin has been denied or questioned, except in cases where the skin is broken; yet as far as my experience, clinically, justifies me to form an opinion decidedly in the affirmative. In a very severe case of neurasthenia with hysteria and extreme leucocythemia in a girl fifteen years of age, who had almost absolutely refused food until her weight had gone down from over 125 pounds to below 100 pounds, lanoline inunction-massage was systematically resorted to. On two occasions, when the blood was submitted to microscopical examination to determine the relative number of white and red corpuscles, the former being found in abnormal ratio, incidentally the blood was found to contain large numbers of very minute fat granules, and as the blood had been taken from a part of the body not subjected to the inunction-massage, there can be little doubt that these fat granules had entered the current of blood through the skin.

Of all the foods the easiest of digestion, as far as simplicity of conversion into heat is concerned, of course starch and sugar stand first. The carbo-hydrates, starch and sugar, are more digestible than the hydro-carbons or fats. If then, we are able to introduce this class of foods in a state that they can be readily digested without giving rise to much detritus and without provoking mechanical irritation along the intestinal tract, we have a ready means to counterbalance to a certain extent the loss caused by the fever temperature. The food thus converted into caloric saves so much of the living tissue from being burned up. It is not necessary to dwell upon the processes of the conversion of starch into glucose or maltose, or of cane sugar into glucose, in order to render them fit for assimilation, nor need we go into a lengthy discussion as to the production of glycogen, the product of the carbo-hydrates in the liver. Suffice it to say that we possess at present, various preparations in the form of malt extracts which speedily, when mixed with the food, or given immediately afterward, cause conversion of starch and sugar into glucose and maltose.

One of the most distressing conditions in typhoid fever is the dryness of the buccal cavity. This is only increased by an exclusive milk diet. Starchy food, like boiled rice, either with milk or without it, is very grateful to the patients, as they are able in a moderate degree to exercise the pleasurable function of mastication. During my January service in the German Hospital about a dozen cases of typhoid fever were put upon partial rice diet, the rice being given with a proper amount of one of the malt extracts, and I must say that the result was gratify-

ing to me and the patients themselves. During the February service the same plan was followed with equally satisfactory results.

Hence, I do not hesitate to call your attention to the propriety of enlarging our fever dietary by the more liberal use of starchy food, and of curtailing the excessive, if not exclusive use of the milk diet, which contains too large an amount of undigestible and unassimilable proteids under the conditions of typhoid fever.

In regard to the therapeutic treatment of typhoid fever, I must limit myself to only a few general points. I am no believer in any routine treatment, and a firm advocate of individualism in disease. The lowering of excessive temperature so as to reduce the bodily waste to the minimum point attainable, is certainly one of our chief indications. Whether in one case it is accomplished by the cold bath, in another by ablutions or the sponge bath, or in other cases by any of the various antipyretics, are questions to be decided by the physician, after due consideration of the surroundings and of the individual history of each case. As a rule I think we should not allow the temperature of our patients to rise much above 103° F. nor should we interfere when it is at 102° F. or less. Of the intestinal antiseptics we have our choice in naphthalin, salol, bismuth and others; with some, however, i. e. carbolic acid, much caution should be used on account of the risk of inducing nephritic complications. When there is excessive peristalsis and the heart becomes weakened after the second week small stimulating doses of opium, say 3 grains of Dover's powder, are useful as far as my experience goes. I have been in the habit of resorting to the acid treatment in most of my cases, from the beginning to the end of the disease. The sulphuric acid is preferred by me for various reasons. In the first place, properly diluted with water and sweetened, it is more palatable than nitromuriatic, or simple hydrochloric, or phosphoric acid, which latter is mostly used by the Germans. Secondly, laboratory investigations as to the action of the acid as a germicide place it at the head of the list of acids as shown in a table in Kitasato's paper of results obtained in experiments in the Hygienic Institute, at Berlin, (*Schmidt's Jahrb.* 1888, No. 1, p. 8). In addition, as we all know, sulphuric acid added to a solution of cane sugar assists in converting it into grape sugar or glucose thus aiding digestion of the carbo-hydrates.

Finally, attention must be called to a practice which has recently come in vogue and with good results, namely, the washing out of the lower bowel with warm water once a day, irrespective of the presence or absence of diarrhœa. The object accomplished thereby is the more speedy removal of infectious material from the intestinal tract.

I will conclude with the good old maxim, nearly two thousand years old: "Prove all things; hold fast that which is good."

PATENT NOSTRUMS.*

BY L. W. FLANDERS, M. D.,
BURLINGTON, VT.

I have ventured to bring this subject before you because I have never heard it discussed at a medical meeting, and, it seems to me, that it is an evil too apparent and wide-spread to be passed over without comment. So far as I know, there has never been any decided movement made on the part of the profession towards exposing the patent medicine frauds with which the country is filled. There have been one or two journals started with this object in view, but they have failed for lack of support on the part of the public, and the violent opposition of the manufacturers of these secret preparations.

We all know how much faith the general public has in patent nostrums. As practitioners we find them every day, not only in the hands of the ignorant, but, also, among those whose educational advantages have been of the highest order. I well remember my surprise upon seeing a gentleman of my acquaintance, a man of more than ordinary ability in business matters, bring forth a bottle of Warner's Safe Cure and take a huge potion before breakfast. I asked him if he had any "kidney difficulty" and he replied, "No, but there is a great deal of Bright's disease going about and I don't propose to have it creep on to me if I can help it." This would lead one to think that he was an enthusiast in prophylactic medicine, but he was not; for, he had a cesspool within ten feet of his well, and no amount of patient argument would convince him that they were dangerous neighbors.

The people from whom patent medicine men reap their richest harvests are those who are suffering with chronic and long-

*Read before the Vermont State Medical Society, Oct. 15–16, 1891.

continued diseases. Wearied with continual suffering and disappointed in the efforts of their physicians they grasp eagerly at anything that affords a prospect of relief, and the knowledge of these "Cure-alls" comes in spite of the most strenuous efforts on the part of the doctor. Our mails are loaded with circulars from the so-called "Dispensaries" carrying masses of corruption, lies, and impurity into the very hearts of our families. Our daily papers are full of advertisements designed to frighten the weak and timid into trying some celebrated nostrum. A large head line, "*Mother's don't let your child die!*" is followed by a description of the case of some little one who heard the "Death Angel," in large capitals, fluttering over his head and was saved by a timely dose of Somebody's Sarsaparilla. Then follows a list of trivial symptoms common to every growing child, declared to be the forerunner of frightful disease, which a dose of the aforesaid Sarsaparilla will surely prevent. The mode of approaching chronic invalids is crafty but not flattering to the profession. "You have suffered years; you have tried various physicians who have given you nauseous drugs and subjected you to needless operations," then in large black type, "What benefit have you received at the hands of your physicians? None!" (I quote literally.)

So much for advertising. Now let us see if these men give an equivalent for the money paid and if their printed labels are true or false.

A fashionable journal which comes to my notice frequently, has a column devoted to correspondence with ladies. Every week comes an inquiry for something to improve the complexion. The answer is invariably, "Recamier Preparations, which are harmless and endorsed by the leading ladies of the country." Recamier Balm when analyzed contains, according to good authority, corrosive sublimate and oxide of zinc. It costs, at the highest estimate, ten cents; it is sold for one dollar and a half a bottle.

Dr. Herrick gives a description of his famous plaster; tells us that it has been the labor of years to bring it to perfection; and calmly informs us that the holes had to be cut in it to allow the deleterious matter drawn from the body by the plaster to escape.

Some time ago I had a case of neurasthenia in which the patient had contracted the morphine habit in trying to get relief from insomnia. This I was endeavoring to break him of, and, upon the occasion of one of my visits, he placed in my hands a bottle of Scotch Oats Essence; warranted to cure all nervous disorders and to be a specific for the opium habit. This he was anxious to try and was very indignant because I would not consent to it. The composition contained as I have since learned one eighth of a grain of morphine in every teaspoonful.

Again, I had a case of heart disease in a lady seventy-two years old. There was marked cardiac dilatation, a weak impulse, and, of course, the general œdema was very great. The patient received from a friend a package of "Dropsy Balls" with many recommendations as to their efficacy. They were fully three-quarters of an inch in diameter, a dark, pasty mass, looking like tar and molasses. The directions were to take one at night, and in the morning to follow with a teaspoonful of Epsom Salts every hour, until there had been fifteen or twenty movements of the bowels. The fee to begin with was fifteen dollars, and if a cure was effected, fifty dollars. It is needless to remark that the "Balls" were a blind and the patient paid fifteen dollars for the advice and a pound of Epsom Salts.

The latest monstrosity I have met with is "Wm. Radam's Microbe Killer." The trade-mark consists of a picture of William armed with a metaphorical microbatic club, if you will allow me to coin a word, endeavoring to knock the skull from the gentleman upon the "Pale Horse." This delightful medicine comes not in bottles, but in gallon jugs; two gallons in a case. Of course, it cures everything; but phthisis is the specialty. The patient is to drink it, bathe in it, inject it into his rectum and in short fairly luxuriate in an atmosphere of this wonderful compound. According to the Druggists' Circular this remedy appears to be composed of oil of vitriol, four drachms; muriatic acid, one drachm; red wine, one ounce; spring water, one gallon. The manufacturers print scores of testimonials of the wonderful cures effected by its use, setting forth how this one was nearly dead with phthisis and that one crippled with chronic rheumatism, but after taking a few gallons of Microbe Killer were permanently cured. Think of it gentlemen! medicine taken by the gallon, and yet there are those who claim that the Homœopathic school with its minute dosage is increasing in popularity.

What are such testimonials worth?

Some physician has claimed that he could get testimonials of cure as the result of a medicine composed of pounded brick, and

I have no doubt but that he could. We have all performed miracles with brown bread pills. A gentleman of my acquaintance consulted a doctor as to the advisability of putting a patent plaster upon his back. "You might just as well bind on a book-cover!" was the reply. Taking this literally the sufferer went home and actually bound on the cover of an octavo volume and returned in a few days to report a cure and to express his surprise that so common-place a remedy should be so efficacious.

Who can estimate the harm done by these unreliable preparations?

The most powerful and dangerous drugs are placed in the hands of the ignorant. Some of us have seen dead infants who were soothed into their last sleep by Mrs. Winslow. I, have seen an old lady upon the verge of collapse from using Athlophoros too zealously; presenting the toxic effects of salicylic acid and colchicum. If the red label for poisons was faithfully carried out what a gorgeous array we should have upon the patent medicine shelf!

What can we do as physicians to remedy this great evil?

As a rule we are too luke-warm in the matter. We utter a feeble remonstrance occasionally but that is about the extent of our efforts. In many instances postmasters are paid to send lists of chronic invalids to the proprietors of "Dispensaries." See that it is not done in your town. Enforce the law against traveling quacks and venders of secret nostrums. Attend to our chronic cases more faithfully. In many instances the patient resorts to quack remedies because his physician takes no interest in his case and does not visit him unless sent for. Above all, encourage analyses of these preparations and acquaint ourselves as far as possible with their constituents. The patient may say, "How do you know whether Warner's Safe Cure is good for my disease or not? you don't know what is in it," and he has the best of the argument. But if you can show him that he is paying a dollar for ten cents worth of salt-petre, you have a powerful argument on your side; you appeal to a most tender spot—his pocket. Most of us have access to the Druggists' Circular, in which is published from time to time analysis of the more important patent preparations; so that with a little care we may be prepared to show our patient that his celebrated remedy has been used for years by physicians, and can be purchased in the regular way at half the price he paid for it.

Special Correspondence.

THE TENTH INTERNATIONAL MEDICAL CONGRESS, AT BERLIN, AS I SAW IT.

BY GEORGE DOUGLAS, M. D.,
OXFORD, NEW YORK.

DELEGATE FROM THE AMERICAN MEDICAL ASSOCIATION TO THE WORLD'S MEDICAL CONGRESS AT BERLIN, GERMANY, 1890.

(RESUME.)

Place of meeting.—Officers.—Some of the distinguished delegates of the Sections.—Some of the papers read.—Social festivities.—Koch; biographical sketch; his researches, aims and efforts.—Great desirability of a remedy for tuberculosis.

One of the events which crowned the decennial year of 1890, and made it memorable, was the International Medical Congress which convened in Berlin, Germany, August 4th. The largest gathering of representatives of the medical profession the world has yet seen, and probably the largest the present generation will ever see.

The first gathering of the Congress on Monday morning, 11 A. M. was in a grand amphitheatre, called the Circus Renz, resembling in shape the Coliseum at Rome, seating upwards of eight thousand persons, but on that occasion every inch of standing room was occupied and filled and crowded by at least ten thousand persons, among them army officials and representatives of Government in conspicuous dress with imperial decorations and honorary badges of many beautiful and striking designs; and delegates not only from every country of Europe and from America, but from Asia, from Africa, and from South America, from Australia, and from the islands of the sea,—scientists and scholars from every portion of the globe, who had come there to submit to the world's tribunal, the results of their truest thoughts and most patient labors.

The beautiful amphitheatre was draped with the flags of all nations, festooned with flowers, and made brilliant with flashing lights and amplitude of colors.

After the organization of the Congress, there was first the address of welcome and the reply; when came the able, and most fit

and timely address of the President, the distinguished Virchow, the great teacher of cellular pathology, who, crowned with the knowledge of three-quarters of a century of research, honored and almost idolized by his own countrymen, still survives in a most remarkable grandeur of physical manhood. After the address there was presented before the large audience, from each of the principal nations represented by delegates, one, as the medical representative of such country,—Sir James Paget, of London, the representative of England, and Surgeon-General John B. Hamilton, of our country, but to Sir Edward Lister, of England, was recorded the most enthusiastic reception of them all, evidently indicating the unanimity of the profession in according to him very high and universal honor for his introduction of the antiseptic treatment in surgery, which has given to that branch of our profession such an increased percentage of success, and with it so much greater confidence and respect with mankind at large.

There were but three general sessions of the Congress in this amphitheatre, most of the time being devoted to the reading of papers and to discussions in the sections of the Congress, their place of meeting, a very large and commodious building in the Ausstellungs Park, a famous place of resort with the pleasure-seeking Germans, with halls of entertainment, musical and theatrical, picture galleries and beer gardens, and the surrounding buildings were utilized as places for the extensive exhibits of everything pertaining directly and indirectly to the profession,—not only instruments and appliances of every kind known to surgery,—medicines and chemicals from the largest firms of almost every city in Europe, with some from our own country, but systems of gymnastics, health-lifts, hygienic baths and hygienic beds, improved modes of ventilation, hygienic foods and drinks, seemingly all in all an immense world-wide collection.

This beautiful park was made approachable from almost every portion of the city by public tramways, and from the central part of the city by an elevated railroad, far more commodious, substantial and magnificent in its structure than anything we can boast of in this country.

It was in these eighteen sections of the Congress, embracing all the different departments of medicine and surgery, that the greatest interest was centered. The official languages used at all meetings were German, English and French, but in discussions other languages were permitted, but reported by some one of the secretaries in one of the three official languages, and in this manner ten tongues and twice as many dialects were spoken in the course of the numerous discussions.

Each of these sections were presided over by a President, also a Vice-President, and usually not less than three Secretaries reported papers and discussions.

In the section of surgery in which I registered myself, there were upwards of 1200, and 15 sessions were held in the six days' time of the Congress, which, with the social events of the occasion, filled up almost every moment of time during the eventful week.

I did not, however, strictly confine myself to this section, but went about at will to other sections and especially where and when a paper was to be read by any one of the distinguished members, or celebrities that I felt a special desire to see and hear; and it was to me the fulfillment of a much desired opportunity and a life-time event to look upon such faces as Virchow and Koch and Pasteur and Lister and Esmarch and Tait and Billroth and Oppingheim, Sir Spencer Wells, Sir James Paget, Apostoli of Italy, Barbour of Edinburg and a host of others,—where Canada and the United States met Brazil and the States of South America; where Mexico met Russia; Great Britain met Italy; Spain met Japan; and Belgium and Holland and Sweden met Asia and the islands of the sea; where France only partially represented, but by the noblest and most large-hearted of her sons, was most cordially greeted by Germany, and grew cheerful and fraternal; and America with her 157 delegates, was cordially met and greeted by all, and when the number was given at the first gathering in the Circus Renz, the announcement was greeted with cheers long and loud.

In some of these sections, complaint was made by certain delegates from our own country, England and other representatives, not German, of a lack of courtesy and of proper recognition, and perhaps with reason, for there was somewhat evident the same "animus" as possessed the little lad, who said to his sympathizing playmate, "*You* have no right to cry, for it is my grandma's funeral," and the Germans appeared to some extent to consider it their Congress, appropriate the front seats, and monopolize the time.

The Germans as a nation are fond of social festivities, and there was not any lack of arrangements in this direction, although,

differing in some respects from the usual American style, with invited guests. I was asked on my return if I did not find the Germans a very hospitable people. My answer was—"That depends much upon your definition of hospitality!! If you call it hospitality for a friend to invite you to dine with him, and then he requires you to pay an equal share for the viands, and the wines, then they are truly hospitable." The only free entertainment given was the first, on Monday evening, by the Burgomaster, or Mayor of the city, at the Rathaus or Town Hall, with no ladies present, the expenses of which were paid by a Government appropriation by the Reichstag or Parliament at the recommendation of the German Emperor, who also gave a court reception at his palace in Pottsdam, just before the close of the Congress. At this reception the invitations were limited to four hundred—Germans mostly excluded, and the American delegates remembered at least a *pro rata* share.

Each section had their respective banquets, with speeches, toasts, etc. In the surgical section only 700 of the 1200 registered purchased tickets to the banquet held in a large and beautiful hall of the Hotel Central, perhaps the most magnificent hotel in Berlin, and was presided over by the Royal Court Surgeon, Von Bergmann, with Prince Carl Ludwig present, and at the tables, Sir James Paget, Sir Joseph Lister, Von Esmarch, Billroth, Oppenheim, and on the right of the President, in place of honor, our representative Dr. Billings, of Washington. On the next evening several large balls were given in different parts of the city. I attended the one given in the beautiful winter garden of this same hotel, at which was present the Princess of Germany, eldest sister of the present Emperor, and led with a prominent German official, the first dance of the evening, which was much after the order of the stately minuet of the olden time. After the dance, I had the opportunity of meeting her, and was most favorably impressed with her kindly as well as courtly air, her appearance of good sense, and truly lady-like and considerate manners—a model and a pattern for many of the simpering, vain snobs in our own country, who can boast much more of money than of brains, or intelligence. The Emperor did not return as was expected in time to be present at the Court reception at Pottsdam, and without his presence it lacked point and interest, and the palace itself is one of the least imposing of any of the royal palaces of Germany.

The "Farewell Banquet" and reception was given at Kroll's Garden in the Royal Platz, when upwards of ten thousand were fed and wined and supplied "*ad libitum*" with lager beer, in a way that was highly German, and quite incomprehensible to an American. The eighteen special sections of the Congress were each made centres of special interest by the scientific papers read, containing the latest researches and investigation in these respective departments of medical science.

In the section of Surgery, a very able paper was read by the distinguished surgeon, Oppenheim, on the subject of brain surgery, describing the successful removal of a sarcomatous tumor from the brain, and Professor Gluck, with one of his patients, demonstrated the use of the articulated ivory pegs, in a case of excision of the knee-joint, introduced into the medulla of both bones so as to give support and motion to the joint.

In the section of neurology, the subject of brain surgery at the present time attracting so great attention in the profession, was extensively discussed, with a citation of many unusual cases. Victor Horsely, of London, led in the discussion upon cerebral hæmorrhage, and contrary to my preconceived ideas, it was decided that the ligature of the carotids was of no service in this class of cases.

In the section of obstetrics and gynæcology, Professor Barbour of Edinburgh, read a very comprehensive and exhaustive paper on the stages of labor with consideration of the after conditions and complications which most frequently attend this class of cases.

In this section Dr. Parvin, Professor in Jefferson Medical College, Philadelphia, also read a masterly paper, listened to with much attention, on artificial premature labor, its indications and methods. A long discussion followed, in which many took part, and in particular the question canvassed as to which procedure was the most advisable in deformity of the pelvis, where premature delivery is demanded, whether by the Cæsarean section at or before the full time (which had many advocates) or by enforced labor at the seventh month. The majority of opinions was, however, that the Cæsarean mode was the most hazardous both to mother and child.

On the topic of uterine fibroids, or myomata, Dr. Apostoli, of Italy, distinguished

in galvanic treatment of diseases, read an able paper advocating electrolysis instead of the curette and other surgical measures, and, when advocating his most advanced and radical ideas, was a little hissed by the French, but applauded by all others. In the history of cases treated by electrolysis as given by himself and by others, there was certainly the most satisfactory results shown in this method of treatment.

Dr. Kaltenbach, of Halle, Germany, read a paper upon extirpation of the uterus, in which he cited 82 cases of total extirpation by himself, for cancer and other diseases of this organ, with the result of only two cases of death. After the reading of this paper there was a very interesting and animated discussion participated in by physicians from London, from Prague, by Pozzi of Paris, by Olshausen, by Landau, and by A. Martin of Berlin, the first distinguished operator of extirpation of the uterus, by Czerny, of Heidelburg, and by a gynæcologist of national reputation with an unpronounceable name from Moscow in Russia.

In the section of state medicine and hygiene, Dr. J. Hutchinson, of London, gave a very able and thoroughly exhaustive lecture without notes on the non-contagiousness of leprosy, in which he took still more advanced and positive ideas than in his articles published in the early part of the year,'89, in the British Medical Journal, that leprosy is absolutely not contagious, and that it is by a special kind of poison taken into the system in connection with food, that this loathsome disease is induced. A certain specific kind of "bacteria" has been found in the blood of lepers, and this is found only in a certain species of fish, and it is by the eating of this kind of fish that the once healthy individual or person becomes a leper. This species of fish is found to be common in leprosy districts, and as the varieties of leprosy are the same the world over, in hot and cold countries alike, this fact would indicate that the cause must always be the same. In Norway, India and the West Indies, nurses and surgeons do not fear to come in contact with lepers, so far as contagion is concerned. Hundreds of surgeons daily encounter the same risks that Father Damien, the Catholic Priest, did, but he exposed himself to other dangers as well, partaking bountifully of all kinds of fish and food in use in that country of lepers.

In England the most intimate possible contact with lepers has not been sufficient in itself to communicate the disease. A striking illustration and proof of this is the instance of the colony of lepers from Norway that located in the northwestern portion of Minnesota, not one of the wives, or children being, or becoming lepers.

These advanced ideas by Dr. Hutchinson were given more especially in the interests of humanity, and to prove how needless the oppressive regulations in almost all countries, of making this unfortunate class outcasts, expelled from society and forbidden to mingle with the rest of mankind.

Dr. French, of Brooklyn, led with an able paper in his specialty—the throat, and Dr. Wood's address on anæsthetics was a state paper and was assigned a place of honor—that of the closing session.

I will not attempt to give you an idea of the subject matter of all the papers heard, for that would be impossible, but every delegate will remember so long as memory lasts, the scene when Koch stepped forward to read his "Researches"; the ovation which he received, most strongly disproving the old adage that "a prophet is without honor in his own country."

Those salvos of applause were received with no gratified look of vanity, though courteously acknowledged, it was with almost a perceptible manner of annoyance, and when the cheers had subsided and he commenced the reading of his paper, his gentle yet decided bearing, saying so plainly, that he was giving us the truth, as he had found it, his deep-set eyes, so true and steady, you could not but accept his deductions and conclusions without a question. Not being able to follow his paper, which was in German, I watched with feelings akin to awe, the lines and shadows on the faces of those listeners who, gathered there from the ends of civilization, hung upon his words with breathless interest.

I have many times seen men and large audiences profoundly moved by passionate orations and stirring appeals from forum and pulpit, but never have I seen an audience of intelligent, educated, cultivated men, listen with such intense interest as to this man, who stood there, striving to give to dying humanity a respite from a disease, which in all its varied, hydra-headed forms, has swept to an untimely grave far more than any other; I had almost said than all others.

In this Medical Congress, so largely represented from all civilized countries, while listening to the papers of these intellectual and professional giants, one could seem to divine that there was a pervading presentiment and belief that a great tidal wave in science was imminent, and that it centered

on the discoveries of Koch. His name was upon almost every lip, his researches the absorbing topic of the hour.

Bacteria was in the air, and in its many forms or names of bacilli, microbes, micrcosma, was spoken of and speculated upon, as the cause of almost every disease that flesh is heir to. The prominence of this distinguished investigator and scientist will be my excuse for giving a brief history of the man, from such and various sources as I have been able to collect them.

Professor Robert Koch, as we are told, was the third of thirteen children, the first nine of whom were boys. He was noted as a studious lad, and early in life developed a fondness for the microscopical study of lichens and mosses, and when his mates and companions were out hunting and fishing, he was making such minute investigations at his favorite pastime. He completed his course in the High School at Clausthal, Hanover, at the age of seventeen, but was unable until he was eighteen to enter the University of Göttingen, where he finished his studies.

In his second year at this University he wrote a thesis which won the first University prize. We next hear of him as a physician at Wollstein, a Polish country town, in the district of Bomst in the Grand-Duchy of Posen, and while there received the government appointment of district physician of Bomst. It was at this time that he made his researches and investigations and performed his experiments relating to anthrax, and its characteristic bacilli, and in 1875 published his first work on anthrax, giving to the world the results of his discoveries, and the etiology of that destructive disease, and also published some treatises on wound infection.

In the summer of 1879 he was appointed to the position of medical expert in the law courts in connection with the University at Breslau, but this position was not satisfactory to him, neither scientifically nor pecunarily and he returned after a few months to Wollstein, where his place as district physician had been kept open for him. He was, however, soon after, in 1880, called to the newly founded "Imperial Office of Health" in Berlin, where he has since been pursuing his wonderful researches on the tubercle and cholera bacilli, which we earnestly hope, believe and trust, will prove not only a great honor to the German Government, but of great advantage to science and to all mankind. The distinguished Professor Ferdinand Cohn, of Breslau University, the famous botanist and scientist says: "When Koch came to my Institute on April 30th, 1875, I can truly boast that in the first hour of our intercourse, I recognized in him an unequalled master of scientific investigation. His method, his experiments, the classic clearness of his statements, were all as perfect in his first as in all his later researches." He further says: "All Koch's works have been so complete in form, and contents, that nothing remained for those that followed but to confirm them for it was not possible to add anything essential."

But in this medical Congress, notwithstanding that none doubted the sincerity of this new prophet, there were not wanting those possessed with a spirit of skepticism which inclined them to mock at the arguments of Koch. Against Koch was Virchow, unwilling to abandon his long cherished biographical doctrines, and Mr. Lawson Tait, the distinguished anatomist, surgeon and controversalist, always vivacious, and somewhat reckless in manner, facetiously, almost derisively said that, "if ever he got together enough bacteria to make a poultice, he would slap it on the next wound he had to dress."

There were others, who with greater candor and sincerity, willing to accept whatever might be truth, asked the question, "Have we yet struck the right trail?" and "Have we not been too much swayed by our hopes?" Time and still further investigations can alone answer these questions. This man is no charlatan, but an earnest seeker after truth. Look on his earnest face, his deep-set truthful eyes, and you will not doubt that.

By the ignorant and obtuse, he is not understood, and consequently misrepresented; by the envious maligned; by many of the conservative class, doubted; by the cynical class, sneered at; descried by the egotistical, who claim themselves the only fountains of knowledge; but to the earnest seekers after truth, who believe there are more things in heaven and earth than has yet been found in philosophy or science, he will be accorded at least respectful attention and a candid hearing. The superior effects of the treatment of many diseases by hypodermic injections are already very well known. As example, hemoptysis by injection of ergot; of syphilis by hypodermic injections of cyanide and bichloride of mercury, and chloride of gold and sodium; the prompt effect of Sammter's treatment of erysipelas by carbolic injection; strychnia and quinine in typhoid conditions. The experience of Tyndall, in New York, in the vaccination process, for the cure of tubercu-

losis, promises favorable results, and Dr. Landerer has obtained beneficial effects in phthisis from hypodermic injections of balsam of Peru, which he says goes at once to the diseased part, thus stimulating the animal fluids. That certain chemicals have a *selective* action on tissues cannot be doubted; as, for example, the hypodermic injection of cantharidin, resulting in the production of inflammation of the air passages; ard, coline, a volatile liquid, alkaloid, from the areca nut, has a selective action on the heart, digitalis upon the cells and vascular system. This would seem to show that there must be a sort of antagonism or isomerism between animal and chemical and vegetable poisons; and why may not more universal application be made of this principle, with a view of obtaining more therapeutic agents and effects.

The great hopes and expectations formed at the first publication of the methods and discoveries of Dr. Koch, have resulted in decided disappointment, but the most recent statistics obtained by the German Government, from fifty-five hospitals would indicate that the reaction that has set in against his treatment, is beyond what facts would justify, considering the utter hopelessness of this class of diseases as treated by other and former methods, these statistics showing that while less than 13 per cent. of cases of internal tuberculosis, were cured, 30 per cent. were improved, leaving only a little less than 60 per cent. of unimproved and fatal cases.

Of cases of external tuberculosis about 15 per cent. were cured, upwards of 40 per cent. improved, leaving less than 50 per cent. of fatal and unimproved cases, in this, as it would seem, more curable form of tubercular diseases. Koch himself, while believing that his remedy "Tuberculin" is a cure for incipient tuberculosis of the lung, does not claim there is yet established the fact of its being a permanent cure, and fears that in advanced tuberculosis, its use will no more than prove beneficial. The first marked change by its use in tuberculated lung affection is that the expectoration becomes non-purulent, and this change greatly retards the rapid wasting of strength and vitality so marked in advanced tuberculosis of the lung.

Thus far the most striking and rapid cures have been effected by its use in lupus, where recovery has repeatedly followed a single injection. The investigations of Robert Koch have unquestionably opened up the way to discoveries into new and valuable ways of diagnosis and treatment of diseases, where microbes play an important part in the inception and progress of disease, and out of it may finally come more certain and effective measures, prophylactic and curative. It was from Robert Koch that the illustrious Pasteur obtained his idea of his present treatment of hydrophobia, from a demonstration made by Koch in King's College, London, of his then new method of cultivating microbes, during the International Medical Congress in that city in 1881. It is in the same line of investigation, discovery and treatment, as that by which the immortal Jenner gave to the world the methods of restraining and preventing what was less than a century ago, one of the most dreaded and terrible of the diseases that scourged the human race, and gave to the physician that almost omnipotent power by which he can lay his hand on that loathsome disease (the small-pox) and say to it, "Thus far shalt thou go, and no farther, and here and now shall thy devastating progress be stayed."

If this can be done to tuberculosis, in all its manifold forms and complications, what a boon it will be to poor, suffering humanity, and how well worthy our greatest efforts, our most diligent and patient study and research. In my heart are no cynical sneers, no ridicule or contempt for Koch, or any other earnest worker in all and every rational method which may tend to mitigate and limit disease and suffering. Consumption, in its comprehensive signification, as generally used, classes among its victims more of those who are refined by nature, beautiful in person, intellectual, brilliant, and attractive in social life, than any other, perhaps all other diseases. How often do we see of the weaker sex (I mean physically, not mentally) those whose beauty and loveliness make even their very presence a benediction and a blessing, long before life has reached its meridian, fade away from family and friends, leaving hearts and homes sorrowing and desolate, some going in the morning of life, and seeming only like beautiful visions, sent for a little time to cheer and bless us, and then taken away.

How well do I remember one such, who, for five brief years was the light and joy of a happy home, filling its very walls with sunshine and music, but who, after only eight weeks of what is not inaptly termed in common parlance "galloping consumption" immediately following the birth of her first-born child, one morning in the early springtime, just as the sun was breaking over the Eastern hills, folded the white hands across

the peaceful breast, which soon ceased its throbbings, bade me farewell and then the gentle, loving spirit went away.

The fragrant and beautiful rose that blooms under our window, or in our gardens, gladdening our senses with its sweet perfume, our eyes with its exquisitely blended colors, sometimes fades prematurely; some untimely blight causes its lovely petals to droop and fall, and our hearts sadden with disappointment at the sight of the destruction of what we had thought would cheer us for many a long summer's day, but we have consolation in the thought that at another spring-time it will bloom again. But when disease and death comes into our homes and takes from us the loved and cherished ones, we know that no coming spring-time will ever bring them back to us, we bury them out of our sight, and so much of the light and joy of our life has gone out forever.

God grant that the day may not be far distant when this class of diseases which have so long been the *onus probandi* of medicine, shall, by investigation and research be made as curable and controllable in the hands of our profession, as the once-dreaded small-pox, that marred and decimated the human race. And with this desire in my heart, this prayer on my lips, I bring to a close this poor attempt at portraying "as I saw it" the Tenth International Medical Congress at Berlin.

Selected Formulæ.

ECZEMA.

Hollopeter has used with great success the following:

℞
Ac. salicylic.....gr. xx.
Zinci. oleat.....ʒij.
Cocaine.....gr. v.
Pulv. amyl, q. s.....ʒij. M.
Sig. Use as powder, externally.

The salicylic acid prevents fermentative changes in the skin; oleate of zinc adheres very closely to the skin, and protects it; the cocaine may be put in or left out, conditionally as to whether there is pain or not.

If, on the second visit, there is little pain, and the scales are drying up, the cocaine may be discarded; later, the zinc may be left out, then the acid, so that finally only the starch is left. After this, alcohol may be used.—*Times and Reg.*

TREATMENT OF CROUP.

Dr. Betz (*Revista de los Hospitales*, No. 30, 1891), in a desperate case of croup, used inhalations of the following with success:

℞
Ether.....grammes iv.
Ether acetic.....“ ij.
Menthol.....gramme o.6.
Inhale every fifteen to twenty minutes.

In one day the symptoms had disappeared. The child recovered.

Inhalations of ether diminish congestion, tumefaction and œdema of the laryngeal mucous membrane.

NEW MEDICATIONS AS HYPODERMICS.

Of late, advantage has been taken of the bland qualities of certain hydrocarbons, as also of their solvent properties, to prepare a variety of hypodermic solutions. Several of these have received the names of their suggestors as Picot's, Pignol's, Morel-Lavellée's solution, and in answer to inquiries from some correspondents we give them below:

Picot's Solution.

Guaiacol.....	5 grms.	75 grains.
Iodoform	1 “	15 grains.
Olive oil.....	48 c.cm.	14 f ʒ.
Liquid vaselin q.s. to make.....	100 c.cm.	to make 3½ f ʒ.

Pignol's Solution.

Eucalyptol	14 grms.	216 grains.
Guaiacol.....	5 “	75 grains.
Iodoform	1 “	15 grains.
Almond oil, to make.....	100 c.cm.	3½ f ʒ.

Morel-Lavallée's Solution.

Eucalyptol	12 grms.	180 grains.
Guaiacol	5 “	75 grains.
Iodoform	4 “	60 grains.
Olive oil, to make..	100 c.cm.	3½ f ʒ.

Besides the above: Creosote, 1; almond oil, 15 c.cm.; eucalyptol, 4; almond oil, 10, are in use. The hypodermic dose is from 3-12 c.cm. (50-210 minims) in 24 hours.

In preparing these solutions the aid of the water bath is needed to effect the solution of the iodoform, after which the other materials are added. The bottles and materials should be sterilized in the usual method.—*Pharmaceutical Record.*

MISTURA ANTACIDA.

℞
Cretæ præp.....ʒss.
Sodii bicarb.....ʒj.
Tr. cinnamomi.....ʒss.
Aquæ.....ʒss.
M. Sig. Teaspoonful every two hours.

℞
Liq. potas.....ɱ xx.
Mist. cretæ.....ʒj.

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO, (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

IS GENIUS A DEGENERATIVE EPILEPTOID PSYCHOSIS?

A very interesting paper has recently been translated by Dr. James G. Kiernan, from Lombroso's "Men of Genius," entitled "Genius a Degenerative Epileptoid Psychosis." The author, Cesare Lombroso, contends that genius is a degenerative manifestation and supports his views by quoting many men of undoubted genius who exhibited also symptoms of psychical degeneration. Among others he mentions Tasso, Rousseau, Swift, Poe, Southey, Haller, Lenan, Kleist, Gerard de Nerval, Musset Murget, Mailath Praga, Lorani, the Chinese poet Li-To-Kai, Pascal, Ampere, Walt Whitman, Letzman, Dostoyewski and many others, all of whom exhibited, in addition to the genius which has perpetuated their names, various abnormal mental symptoms. Accordingly, Lombroso concludes that their genius was also the outcome of degenerative processes of the mind.

The author of this startling theory says: "From anatomico-biological analysis of the careers of sane geniuses, and those neurotic or insane, of their geographical distribution of the causes (often pathological in character) of their appearance, and of the evil inheritance discernible in their descendants, naturally arose the suspicion that genius has a degenerative origin. This suspicion, whose audacity at first repels, becomes more and more justified by the phenomena exhibited by genius. If the lives and works of the historically great morbid minds be examined, it is found that they, as well as the men who have passed through the glorious parabola of genius without demonstrable mental taint are distinguished by many traits from ordinary men." Succeeding this statement, Lombroso goes on and quotes extensively the lives and works of the men whose names we have mentioned to prove that they exhibited in various forms the symptoms of degenerative psychical changes, or, in other words, that they dif-

fered from ordinary men sufficiently to render their mental operations pathological. The author, we think, has, in many instances, forgotten to take into consideration the environment of those whom he thus brings forward as examples of *pathological genius*, and has unconsciously measured them by the standards of our own times, thus characterizing as pathological mentality many who merely expressed ideas, which, in their age, were universally believed. For instance, he cites the belief of Pascal, that the contact of a relic was able to cure lachrymal fistula as an evidence of unbalanced mentality, but in his time such ideas were very common, and even in our own times, as the translator aptly remarks, not a few persons entertain the same kind of ideas. Another example adduced by Dr. Lombroso we would with Dr. Kiernan object to as inadequate, viz.: Newton is called insane for writing to Bentley as follows:

"By the law of attraction the elongated orbit of comets is explained, but God alone can explain the lateral difference of the almost circular planetary orbit." Lombroso characterizes this as a very singular argument, as has been said by Arago, which places God at the limits where science has not penetrated, and Dr. Kiernan in a footnote justly remarks that this does not differ "from the placing of God in modern times as the limits of the knowable." Many other instances the author has collected from the great geniuses of the world's history seem to poorly support the ingenious and very taking theory which Lombroso has formulated definitely in his very interesting paper. If space permitted we think it possible to enumerate from historical literature a large majority of men of genius, in whom genius was not an expression of morbid mental action, and until better proof than Lombroso's sweeping statements is forthcoming, we prefer to regard genius as a physiological, and not as a pathological manifestation. For opposite views regarding this subject we would refer the reader to Lombroso's paper (*Alienist and Neurologist*, July, 1891), and to a paper by Dr. Kiernan (*Alienist and Neurologist*, Vol. VIII), in which he says: "Genius is not a product of morbid mind. In the exceptional instances where the two co-exist the genius is evidence of a healthy, conservative element, struggling with the incubus of disease."

Book Reviews.

A MANUAL OF HYPODERMATIC MEDICATION: THE TREATMENT OF DISEASE BY THE HYPODERMATIC OR SUBCUTANEOUS METHOD. By Roberts Bartholow, A. M., M. D., LL. D. Fifth Edition; Revised and Enlarged. J. B. Lippincott Company, Philadelphia, 1891.

It is almost a matter of supererogation to review this work, which has already been so favorably received by the profession, and whose author is so widely and favorably known. However, the increased knowledge and practice of the methods described by the author must advance the cause of scientific medicine, and if the time is coming when additional accuracy in the diagnosis and treatment of disease shall demand the more frequent use of the active principles or concentrated preparations of individual drugs, then the study of this book will hasten that day's advent.

By the hypodermatic method the characteristic action of single remedies is manifested, and the observant physician gains both in the study of his cases and the accuracy of his subsequent dosage. It would often be of undoubted advantage to many of us if we were more familiar with the subcutaneous use of remedies, and our success in many cases would often be the more apparent.

The present edition has been enlarged to the extent of about two hundred additional pages, and many of the articles in the preceding edition have been revised or entirely rewritten. As the author remarks: "The additions had become the more necessary because of the increasing importance of the hypodermatic method since the germ theory has so closely occupied the etiological field. It is by means of the injection instrument that in so many instances pathogenic organisms can be reached and effectively treated."

Picrotoxin for Night Sweats.—Picrotoxin is one of the best remedies for *night sweats* of consumption; one dose of $\frac{1}{60}$ or $\frac{1}{80}$ grain taken at night generally prevents perspiring for several nights.

PERISCOPE.

THERAPEUTICS.

TREATMENT OF TYPHOID FEVER.

M. Hayem (*Concours Médical*) gives, in one of his lessons on therapeutics, a new method of treatment of typhoid fever, which he has used with excellent results for several years. It consists in the exhibition of lactic acid as an intestinal disinfectant, and as a means of controlling the diarrhœa. He rejects all internal antipyretics, but reserves the use of baths. Lactic acid, with or without baths, according to the indications, is the regular treatment followed by M. Hayem. He prescribes the acid in the form of lemonade:

℞ Acidi lactici.....ʒiv--vj.
Syrupi simplicis.....ʒvjss.
Aquæ.....ʒxxvij. M.
Sig. To be taken in the course of twenty-four hours.

If there is gastric intolerance, the lemonade may be diluted with seltzer-water.

In slight cases, M. Hayem prescribes 15 grammes (ʒiv) of lactic acid daily. When the evening temperature reaches 40° C. (104° F.), the dose is increased to 20 grammes (ʒv). In grave cases, with hyperpyrexia, 20 to 25 grammes (ʒv to vj) of lactic acid are given with cold baths (20° C. —68° F.), or baths in water gradually made cold. Brandy is given if adynamia is present. When the fever declines, the daily dose of lactic acid is gradually diminished, but is given in daily doses of 5 grammes (gr. lxxv) even during the first days of convalescence.—*Journal d'Accouchements*, Aug. 15, 1891, p. 191.

TREATMENT OF MIGRAINE.

In the *Archiv. für Psychiatrie*, Band xxi., Heft 1, Dr. Neftel has a paper on this subject, of which an abstract appears in the *Neurologische Centralblatt*. He regards the condition as a vaso-motor neurosis, but has nothing new to say about the etiology. As to treatment between the attacks, the circulation must be carefully attended to and kept active. Constipation must be got rid of, which is best effected by the use of diminishing doses of mineral waters and by the use of electricity to the abdomen. Muscular exercise must also be prescribed, and subsequent temporary rest, and nothing should be eaten or drunk until at least half an hour later. Then a cup of freshly boiled water, he says, will be found wonderfully refreshing. The systematic use of electricity to the head is strongly recommended, and Dr. Neftel finds that in some cases the constant current, in others the interrupted, is beneficial. For the attacks themselves electricity also is recommended, together with ergotin for plethoric patients and salicylate of soda for anæmic sufferers, or a large dose of quinine for either class.—*Lancet.*

BROMIDES IN EPILEPSY.

While bromides remain the sheet-anchor of physicians in the treatment of epilepsy it cannot be said that success always results, a circumstance probably due to the fact that the course of epilepsy is often neglected. But according to Poulet better results are obtained by combining bromide with calabar bean, as in the following formula:

℞ Bromide of potassium .....ʒij.
Tinct. of physostigma (1 to 10)..... ....ʒss.
Water to.....ʒviij.
Mix.

The dose of this is a tablespoonful daily, gradually increased to two tablespoonfuls. The best plan, however, is to give a teaspoonful three times a day gradually increasing the dose. Cases which have been treated consistently with the remedy for several months to a year have completely recovered, the only change in the treatment being that in cases where the heart was affected, digitalis was combined with the bromide.

TREATMENT OF ACUTE TORTICOLLIS.

According to Professor Phocas, of Lille (*Rev. des Mal. de l'Enf.*, October, 1891) acute torticollis is far more common in childhood and youth than in adult or old age. He recognizes two main varieties: (1) acute torticollis following immediately a sudden movement of the head, and due to sprain of one or more articulations of the cervical vertebræ—acute traumatic torticollis; (2) acute torticollis following exposure to cold, and due to slight cervical arthritis or to muscular rheumatism—acute rheumatic torticollis. In a few cases the acute traumatic variety may be due to partial rupture of muscles. In either of the two above-mentioned forms clonic contractions may be superadded to the tonic contracture. The muscle involved primarily is usually the trapezius. As to treatment, hot applications are the best anodynes; massage of the contracted muscle is a more effectual remedy, and often gives immediate relief, but M. Phocas recommends

particularly the application of a collar in the following manner. The patient is placed in a Sayre's suspension apparatus as for the treatment of cervical caries; he is then very slowly suspended partially. In this way the muscles are uniformly stretched, and their resistance gently overcome with little or no pain. A collar of moistened millboard is now applied and retained in place by a few turns of bandage. The patient remains in the apparatus about ten minutes more, and when liberated is free from pain. In one case the collar was removed on the next day, and the symptoms had all disappeared.—*Brit. Med. Jour.*

ANTICYLIC ACID: A NEW ANTIPYRETIC.

Müller (*Correspblatt f. Schweizer Aerzte*, August 15th, 1891), of Tokio, recommends anticylic acid as an active antipyretic. It is a white, fragrant powder, with a refreshing, acid taste, readily soluble in water, alcohol and glycerin, and is non-toxic. In a solution of 1: 10,000 it is destructive of even the most resistant organisms. The solutions are clear and do not injure instruments. Administered internally in doses of gr. $\frac{1}{100}$, anticylic acid proved exceedingly useful is cases of pneumonia, typhoid fever and articular rheumatism.

A CASE OF LOCOMOTOR ATAXIA SUCCESSFULLY TREATED BY SUSPENSION.

There seems to be a tendency in the profession, when a new therapeutic measure is introduced, to make it the fashion, and to use it in almost every disease which flesh is heir to. Thus often, because not all of these various conditions are benefited, we lose sight of the one for relief of which the measure was originally introduced and for which it may have proved beneficial, and it falls into more or less disrepute. Such has been the case with suspension as a remedy in posterior sclerosis; for, while originally introduced for the relief of that affection, it was not very long before it was used in almost all forms of nervous disorder. Now it is scarcely used at all. On reading the papers of Mendel, Weir Mitchell, Charcot, Dujardin-Beaumetz and others of like repute, we find that, while the cases of paralysis agitans, neurasthenia, myelitis, etc., were not benefited, those of posterior sclerosis were to more or less extent.

It is the opinion of the writer that when men, such as above mentioned, report successes with a remedy, it must possess merit, and his experience at the Dispensary for Nervous Diseases of the University Hospital confirms such opinions, in support of which he wishes to report the following case:

J. P., aged 39, married, and a member of the Philadelphia Fire Department, presented himself at the Dispensary on May 27, 1890, and gave the following history:

He had never had any illness, excepting syphilis, acquired thirteen years ago, but has suffered from exposure and a rather unusual series of accidents incurred in the line of his duties as a fireman. In 1876 was knocked from a roof to the ground by being struck in the back by a falling flagpole. In 1878 fell from a third-story window to the ground, and in January, 1885, fell through three floors, striking upon his back, and was buried in the débris for twenty minutes. The next was in June, 1889, when he sustained severe burns, in addition to a fall of about twenty feet.

It was after the fall in 1885 that he first noticed anything wrong with himself, suffering for some time after from tingling and numbness in the legs and arms, and some difficulty in walking. This improved somewhat for a time, but he has "never felt right since." About two years ago, considerable difficulty in coming down stairs quickly or in going up ladders was noticed. This kept growing worse until, at the time of his first visit, he was afraid that he would be obliged to give up his position. He then felt as if he were walking upon cushions, and his greatest difficulty in walking was at night. Upon examination, the knee-jerks were found to be absent; sensation delayed in the legs; gait ataxic, but not markedly so; station with eyes closed very poor. There was also some loss of co-ordination in the upper extremities. There were no typical ataxic pains, but had been troubled for some time with what he termed dull rheumatic pains in the legs. Sexual power was not impaired. The eyes were, unfortunately, not examined.

Suspension, by the means of the Weir Mitchell apparatus, was at once begun, being practiced every other day, commencing at first with two minutes, and gradually increasing to three and a half. No disagreeable symptoms were ever experienced. Improvement was noticed in the course of a month, and continued slowly until January, when he had an apparatus put up in the house where he was stationed, and continued the suspension, employing it daily. I saw him again about a month ago, and found him in the following condition: He had

gained in weight twenty-five pounds, and felt considerably stronger; station and gait were much improved, and he was able *to run at quite a fair rate of speed;* was also able to walk a chalk-line drawn upon the floor; the knee-jerks were still absent. His comrades informed me that, before commencing the treatment, they were often obliged to wait a time to enable him to get upon the apparatus when answering an alarm, but that now he was almost as quick as the best of them. It is proper to add that at first he was placed upon anti-specific treatment, but he would not take the medicine, and it was discontinued in a week's time, since which suspension has been the only treatment employed.

Other cases have been also thus treated at the Dispensary, always with some benefit; but as internal remedies were also used, there is, of course, some doubt as to which was the effective agent.—Dr. Chas. S. Potts, in the *Univ. Med. Mag.*

THE TREATMENT OF SYPHILIS BY DEEP INJECTIONS OF CORROSIVE SUBLIMATE; REFERENCE TO INFLUENCE OF MERCURIAL INJECTIONS ON BODILY TEMPERATURE AND WEIGHT.

Dr. Zëlëneff, of Kiev, publishes (*Meditzinskoië Obozrenië*, No. 3, 1891, p. 290,) a careful report on 104 cases of syphilis treated by him in Professor M. I. Stükovenkoff's clinic with corrosive sublimate after the formula: ℞.—Hydrargyri bichloridi corrosivi, vaselini, ana. M. f. ung. cui adde olei vaselini ut f. 1. a. emulsio contin. 22 per cent. hydrarg. corr. subl. D. S. To inject from one-half to two grains of the sublimate. In some cases the following "suspension" was employed: ℞.—Hydrargyri bichloridi corrosivi gr. xxxvi.; olei vaselini 1 oz. M. D. S. To inject one grain of the sublimate. In either case the emulsion was warmed in hot water, and then thoroughly shaken just before using. In the case of half grain doses the injections were repeated once every four days; in that of one grain doses every six; and in that of two-grain every ten. In all, 915 injections were made; 31 patients being treated with half-grain doses, 33 with one-grain ones, and 40 with two-grain ones. The following are the principal deductions from the clinical inquiry:—

(1) In the case of two-grain injections all syphilitic manifestations disappear on an average after five or six *séances:* in that of one-grain ones after eight or nine; and in that of half-grain doses after twelve or fourteen.

(2) A local reaction (at the site of the injection) is mostly but trifling, in which regard the sublimate injections closely resemble those of salicylate of mercury (*vide* the *British Journal of Dermatology*, June, 1889, p. 276). Some pain was observed only in 32 per cent. of cases treated with half-grain doses, in 19 of those treated with one-grain ones, and in 27·5 of those treated with two-grain ones. Only once a two-grain injection caused a rather vivid pain, which appeared on the third day, being accompanied with some rise of the temperature (37·7° C.). Infiltrations occurred only on eight occasions (twice after half-grain injections, twice after one-grain ones, and four times after two-grain). They were always but slight, and speedily underwent resorption.

(3) As to the influence of the injections on the bodily weight, the latter fell in 39 out of 74 patients examined, while in 35 it increased during the course. Of the former 39 cases, in 10 some complications (stomatitis, diarrhœa, etc.,) were simultaneously noticed, while in the remaining 29 (39 per cent.) the fall proceeded without any concomitant phenomena of the kind. For the sake of comparison, the author also examined (*a*) 21 cases treated by injections of suspended yellow oxide of mercury or benzoate of mercury; in 11 cases (of which one was complicated) the weight sank, while in 10 it increased; and (*b*) 60 cases treated with injections of solutions of mercurials (corrosive sublimate, succinimide, or benzoate of mercury); of them, in 32 the weight decreased, of which number in nine some complications existed, but in the remaining 23 (38 per cent.) no such cause could be made out. The comparative observations showed further that (*a*) injections of mercurial solutions gave rise to a more considerable loss in the body's weight than mercurial "suspension"; (*b*) gain in the weight was generally lesser than the fall; (*c*) in the beginning of syphilitic eruptions the patient's weight sank but rarely, and then mostly in the presence of such complications as fever, subjective disturbances, etc.

(4) As to the bodily temperature, in 40 per cent. of cases the first injection of the sublimate "suspension" is followed by a rise varying from 37·6° to 38·5°C. (mostly up to 37·7°C.) and disappearing on the next day. Subsequent injections do not make any impression on the temperature. The

febrile rises do not manifest any influence on the intensity of syphilitic lesions.

(5) Of toxic phenomena there may be sometimes observed gingivitis (it occurred in seven patients, one of whom was treated with half-grain doses, three with one-grain ones, and three with two-grains); salivation (one case of three days's duration treated by two-grain doses), stomatitis ulcerosa (one case of seven days' duration, the affection developing after fifth injection of two grains); abdominal pain and diarrhœa (twelve cases, in three of which half-grain doses were employed, in three one-grain ones, and in six two-grains; in one of the latter cases blood-stained stools occurred.)

(6) The elimination of mercury through the kidneys proceeds much in the same way as in the case of yellow mercurial oxide (*vide* Dr. Zëlëneff's paper in the *British Journal of Dermatology,* June, 1890, p. 190). That is, distinct traces of the metal appear in the urine in about twelve hours after the first injection; after each subsequent dose the proportion of mercury markedly increases for from one to three days.

(7) On the whole, injections of suspended corrosive sublimate in large doses afford a convenient and energetical method of treatment of syphilis. Its only drawback is constituted by occasional irritant effects on the gastro-intestinal tracts.

THERAPEUTIC USES OF INTRAVNEOUS INJECTIONS.

The therapeutic uses of intravenous injections has been ably discussed by M. Mayet before the Lyons Medical Society (*Lyon Médical,* May 10th, 17th, 24th, 1891). Intravenous injections may be useful for three distinct purposes: (1) To make up a deficiency of the quantity of circulating liquid, the result of a considerable loss either of blood as a whole (hæmorrhage) or of its fluid portions (cholera, etc). (2) To favor the elimination of certain toxic principles—namely, to wash out the organism—by largely increasing the quantity of liquid passing out by the kidneys. (3) To introduce various drugs into the circulation, in order to obtain a prompt action. M. Mayet considers that injections employed in the first manner act principally by re-establishing the mechanical conditions of the circuiation, whether transfusion be employed or an artificial liquid injected. In cholera the blood loses a large portion of its watery constituents, and becomes highly concentrated; the introduction of liquid acts here in two ways, by increasing the fluidity of the blood, and by restoring its bulk. Undoubted successes have been in many cases obtained by adopting this method. As to the liquid to be employed, there has been much difference of opinion. What is least likely to be harmful to the corpuscles or the organism generally? Water does not appear to be highly suitable, owing to its known poisonous effect on proteid material, and an "artificial serum" has not in the author's hands yielded better results than simple saline solution. The use of defibrinated blood is doubtful, it being very uncertain whether the foreign corpuscles, ferments, etc., may not exert a harmful influence. Probably the most satisfactory fluid in every way is water containing from 0.5 to 0.6 per cent. of sodium chloride; that has little action on the corpuscles or on the vessels, is easily prepared, and rapidly miscible with the circulating blood. The mode of injection is important. Theoretically, a given vessel should never contain at any moment a quantity of foreign liquid more than equal to that of the contained blood. Thus, if the median basilic vein be employed, this quantity would be about one ounce per minute. In practice, however, not much harm arises from the injection of as much as ten ounces in six minutes, and this should generally be the maximum quantity for a single injection, save in cases of extreme urgency, in which the relative emptiness of the vessels is the chief danger. The quantity injected in a given time should also be regulated by the extent to which the eliminative function of the kidneys is impaired, a point to be specially remembered in the case of cholera. Danger of phlebitis is inconsiderable if proper precautions be adopted in operating. The next use of intravenous injections—to favor the elimination of certain toxic principles—is one which has been much studied of late, especially in its application to uræmia. Its employment in man has been limited, but Dastre and Loye showed its practicability in 1888, and pointed out the necessity for extreme slowness in injecting and for regulating the quantity used by the rapidity with which elimination, which takes some time before commencing, is carried out. This application of intravenous injections is suggested by M. Mayet as a means to be adopted in poisoning by "blood poisons" such as arsenical compounds, arseniuretted hydrogen, sulphuretted hydrogen, chlorate and nitrate of potash, in acute poisoning by salts of mercury and lead, and with some

chance of success in poisoning by alkaloids and digitalis. It might also be successful even in conditions due to presence in the blood of toxines, ptomaines, etc., the results of bacterial growth, and in such conditions as uræmia. The action in cholera is probably of this kind, the products of the comma bacillus being dissolved and eliminated at the same time as the bulk of the circulating fluid is restored. The introduction of drugs directly into the circulation is more doubtful ground, and is a proceeding the advisability of which has been with some reason called in question. Without doubt this is the most certain and rapid method of administration, and the one generally preferred in physiological experiment, as one can be quite sure that the action of the drug will be quickly and surely produced. Of course the hypodermic method is generally sufficiently rapid, but some drugs are unsuitable either from the quantity required, or from the fact that they produce serious inflammation (for example, chloral). Occasionally, too, as after swallowing soluble poisons, it may be desirable to produce emesis by apomorphine more rapidly than it would occur after hypodermic injection, and in these circumstances M. Mayet would be inclined to inject the drug, in very weak solution of course, into the veins. The objections which have been urged against the method are that there is a risk of (1) unduly violent action, and (2) of the formation of clots in the vessel which may become carried as emboli into the general circulation. Both these dangers can, however, be obviated by using sufficiently dilute solutions, and by injecting very slowly. The method of injecting will be the subject of a future paper, as well as the advantage of the employment of chloral, etc., by intravenous injection in cases when swallowing is impossible.—*Brit. Med. Jour.*

MEDICINE.

SPASMODIC SCIATICA.

M. H. Lamy (*Le Progrès Médicale*) reports 2 cases of spasmodic sciatica. Charcot, Babinsky, and Ballet have taught us that deviation of the spine is a frequent result of sciatica; they tell us that these deviations always consist in scoliosis, with an inclination of the vertebral column on the side opposite to that affected with sciatica. However, Brissaud (*Archives de neurologie*, January, 1890) has demonstrated that the scoliosis may be homologous, that is, with an inclination toward the pelvis on the same side as the sciatica, and that this is observed in those cases where the sciatica is of a spasmodic nature.

The two cases recently published by M. Lamy are examples of homologous scoliosis following spasmodic sciatica. In both cases the patients had an apparent shortening in the affected limb, amounting in one case to 6 centimetres (2⅓ inches), and an apparent enlargement of the buttock on the same side. The apparent shortening of the lower limb was attributed by M. Lamy to the spasmodic retraction of the muscles supplied by the lumbar and sacral plexuses,—a retraction caused by pain. The enlargement of the buttock, the author thinks, may be explained by the rotation of the pelvis produced by muscular spasm; the rotation having for an effect the carrying backward of the trochanteric region of the affected side.

GRAFTS AND INOCULATION OF CANCER IN MAN.

La Practique Medicale, Paris, June 30, 1891, in an editorial, strongly denounces the experiments of certain foreign surgeons in regard to the grafting and inoculation of cancer in man. It claims that such experimentation should be as justly a criminal offence as a wrongly-written prescription, and advises that surgeons desirous of knowledge in this direction should make the experiments on their own bodies. In the same issue is published an account by M. Cornil of two experiments in cancer-grafting made by a foreign surgeon whose name is withheld. The first case concerned a woman with a large tumor of the breast, of which after it was extirpated, a very small slice was inserted under the skin of the opposite perfectly normal breast. The incision healed by first intention, but soon an indurated swelling about the size of an almond appeared and was removed. The original and the grafted tumor on examination showed exactly the same sarcomatous structure. The graft showed quantities of cells in the stages of karyokinesis. The second case was one of tubular epithelioma of the breast, also in a woman. The same experiment was tried, with the same result, but the woman refused a second operation. From these facts, Cornil draws the conclusion that grafting of cancerous or sarcomatous tissue is perfectly possible in persons bearing the tumors; that the graft will become fixed, will develop and invade the normal tissues.—*Univ. Med. Mag.*

CONGENITAL RICKETS.

At a meeting of the Section on Orthopedic Surgery of New York Academy of Medicine, Dr. T. Halsted Myers presented a case of marked rickets, in which it was stated by the mother that the greatly enlarged epiphyses of the tibæ, femora and radii were present when she first examined the child a few days after birth. The sternum at that time was also abnormally prominent. The mother had been in good health during the gestation; the father was also healthy. No specific history could be obtained. The child, six years of age, presented all the deformities of rickets in a marked degree, except that the head was well shaped and that there was a marked increase of the normal dorsal curve of the spine, rather than the dorso-lumbar kyphosis usually found in these cases. An unusual degree of permanent knee and hip-flexion also existed, and the patient, when resting, assumed the hand-to-knee position of Pott's disease. The epiphyseal tenderness seemed to indicate an active stage of the disease. After being nursed nine months, the child had a mixed diet, not especially starchy or lacking in animal fats.

ANTIFEBRIN BY BROKEN DOSES.

Dr. M. A. Favrat reports (*Inaug. Disser.*) on the use of antifebrin in broken doses at the *Medical Clinic* at Berne. He is opposed to the doctrine of the curative effect of fever, of which there are no positive proofs. The whole doctrine is based upon bacteriological researches on the influence of elevated temperature on bacteria-cultures. It has found one support in the lack of success had with the modern antipyretics, which have brought discredit upon medicinal antipyresis. But these failures are positively referable, for the greater part to the fact that the antipyretics are placed into the practitioner's hands without sufficient knowledge of their modes of action, their accessory effects, and their drawbacks. A conscientious investigation—the author continues—must determine to what extent the drawbacks of individual antipyretics can be eliminated by different methods of employment. How variously the action of antipyretics manifests itself, is shown in the case of Thalline, which, in large doses, is an entirely worthless medicament, while in repeated small doses, it is one of the best antipyretics we possess.

Dr. Favrat asserts that it is a universally valid rule to administer antipyretics which act rapidly, in fractional doses; those slow in action,—as quinine, for instance,—on the other hand, in large single doses. This it was which induced Prof. Sahli to employ antifebrin—a prompt and reliable remedy, but one which under certain circumstances manifests strong drawbacks—in small, frequently repeated doses, instead of the customary large single doses.

The experiments made at the *Berne Clinic* on 11 patients (8 with typhoid fever, and 3 with phthisis) with 1090 doses of antifebrin have shown that "continual antifebrinization"—as the administration of antifebrin in small frequently repeated doses is called—is an agreeable and mild method of antipyresis, possessing material advantages over the modes of employment hitherto in vogue. It was demonstrated that 0.05–0.1 gramme- [¾-1½ grains] doses of antifebrin, repeated hourly, completely suffice to materially depress the fever in both the acute period and the defervescent stage of typhoid fever. On the other hand, the action of the small doses administered at intervals of 2 hours, is not sufficient to effect a decided depression of temperature in the acute stage,; but in the defervescent stage, it may suffice. True it is, that the fever cannot be entirely dispelled by these small doses; but it is moderated, and the patient obtains relief, subjectively.

The hectic fever of consumptives can also be successfully combated and relief be afforded to the patient, by repeated doses of antifebrin. The remedy acts better the higher the temperature. In consumptives a dose of 0.05–0.1 gramme [¾–1½ grains] often suffices to reduce the temperature more than 2° C [3.6 F] within 2 hours.

In 2 cases, chills, slight cyanosis and perspiration (several times) survened from this medication: however, these symptoms were far less pronounced than is the case with the customary large doses. There is no danger connected with these small doses, because it is within our power at any time to discontinue the antifebrin upon the slightest appearance of untoward accessory symptoms. —*Merck's Bulletin.*

THE NERVOUS TROUBLES OF URÆMIA.

Lancereaux, who has written much and well on the nerve-intoxications, discusses the Nervous Troubles of Uræmia in his recently published "*Lecons de Clinique Médicale.*"

The nervous perturbations in uræmia have not the same significance as the digestive. The gastro-intestinal phenomena, in fact, are,

at least at their onset, compensatory. They present a character of utility, even to some extent of necessity, which must be recognized, and which regulates therapeutic interference. The nervous accidents, on the contrary, constitute always symptoms of ill omen, which must be combated as soon as possible. Moreover, the disorders of the first category result from an elective action on the digestive mucosa, the excretory function of which is solicited by the afflux excrementitious principles. There is nothing like this in the reaction of the nervous system, which is simply encumbered, like all the other tissues, by the products of disassimilation; only it reacts more energetically by reason of its special excitability.

Among the accidents purely nervous, we may first isolate and describe apart the group of *cardio-pulmonary accidents.*

In dyspnœic uræmia the thoracic organs are not directly affected. They only give expression to the functional disorders of the nervous centres.

Dyspnœic uræmia presents three principal varieties: Simple dyspnœa, paroxysmal dyspnœa and spasmodic dyspnœa. Simple dyspnœa is characterized by acceleration and variations of extent of the respiratory movement and by the breathlessness which follows the least effort, even walking. Examination of the mode of respiration always shows a predominance of the diaphragmatic type. This is, moreover, the characteristic of uræmic respiration in general; it is almost exclusively diaphragmatic. The costal type is seen only in uræmic patients who have at the same time material lesion of the lungs or heart. The simple dyspnœa of uræmia patients is sometimes accompanied with laryngeal phenomena, hoarseness of the voice and inspiratory sibilance, which may even simulate serious obstructive disease of the upper air-passages, so as to seem even to call for tracheotomy.

The paroxysmal dyspnœa of the uræmic has been long known as the *Cheyne-Stokes* respiration. It consists in the succession, regular and periodical, of a phase of apnœa or pause, and of a phase of dyspnœa in which the inspirations, at first infrequent, short and superficial, augment gradually in amplitude, become more and more frequent, profound and noisy, then decrease progressively to another pause. The period of apnœa is generally limited to thirty or forty seconds; the complete cycle has a duration of several minutes. The circulation is always more or less embarrassed, the lips are cyanosed; the pupils are contracted during the pause, to become dilated when the respiratory movements are resumed; psychical faculties are more or less obtuse. Apart from the probable influence of cardiac steatosis and certain organic cerebral affections in occasionally causing this form of dyspnœa, it is generally renal and uræmic in its origin, and one or two energetic purgatives often suffice to cause it to disappear for a time.

Spasmodic dyspnœa much resembles spasmodic asthma, and hence has been often described as uræmic asthma. It comes on suddenly, like an attack of purely nervous asthma, and generally without any appreciable exciting cause. It consists in the sensation of a distressing anguish, which obliges the patient to sit up in bed, to cling hold of surrounding objects, and to make painful efforts to breathe. The ordinary description of an asthmatic attack is here applicable only during the relaxation phase; expiration is slow, prolonged, but not wheezing; rarely sibilant and sonorous rhonchi are audible to auscultation, and the paroxysms are not followed by expectoration. Vomiting often precedes or follows the attack; the latter may last half an hour or even an hour and be repeated several times during the day and night.

Uræmic dyspnœa is, in general, much benefited by the exhibition of drastic purgatives.

The *circulatory disturbances* observed in uræmia consist in palpitations more or less intense of the heart or even of the blood-vessels. These irregular and intermittent palpitations are felt during rest, and are often aggravated by movement. They are a frequent cause of insomnia. The pulse is ordinarily accelerated during the crises of uræmia, although it may be preternaturally slowed, as before puerperal or scarlatinal convulsions; here we should interpret the phenomenon as due to a perturbation in the innervation of the vagus.

The *cerebral accidents* of uræmia affect the three great functions of sensibility, movement and intelligence, which are singly or simultaneously disturbed.

The sensory disorders consist in subjective sensations of pruritus, of numbness and of pain in different parts of the body; lastly, in temporary visual disturbances.

The pruritus is especially observed in patients whose renal lesions are dependent on generalized arterio-sclerosis, and as this latter alteration is always linked to troubles of the innervation, we may well ask if the itching is not rather the effect of the general morbid state which engenders the renal

affection than of this affection itself. These itching sensations have for their more special seat the genital organs.

Amaurosis sometimes accompanies the uræmic crisis, appearing suddenly at the onset, continuing through the attack, and disappearing with it. The vision is obscured or even almost abolished; objects appear as through a mist. It is the result of a simple functional disturbance. Diplopia, hemiopia and even hemeralopia have also been noticed.

Cophosis is also an occasional symptom of uræmic poisoning.

The *motor disorders* of uræmia are less complex than the sensory. They manifest themselves under the form of contractures, convulsions, and even of paralyses.

Contracture is relatively rare. In the majority of cases, when present, it is fugacious and associated with a transient paralysis or with eclamptic paroxysms. When isolated, it is generally localized in the muscles of the back of the neck, causing a stiffness and a slight bending backward of the head; this is frequently strongly suggestive of meningitis.

Convulsions represent the most common type of the motor disorders of uræmia. They are partial or general. Partial convulsions consist in muscular twitchings, subsultus tendinum and convulsive shocks resembling electric shocks. General convulsions strikingly resemble the epileptic seizure; they are known under the name of uræmic eclampsia, of which puerperal convulsions are the type. Uræmic eclampsia with general convulsions is exceptionally met with in interstitial nephritis linked to general atheromasia, while at the same time persons suffering from this form of nephritis form the majority of the uræmic.

Uræmic paralyses affect generally a great number of muscles, and are confined to one-half of the body (uræmic hemiplegia). They ordinarily appear in the course of nephritis dependent on arterio-sclerosis. This kind of paralysis succeeds pseudo-apopletic attack. The case is supposed to be one of cerebral hemorrhage; but if the patient dies, the autopsy discloses only atheroma of the vessels of the encephalon. When the patient survives the attack, he is found to be hemiplegic; but to the surprise of his medical attendant this "wears off" after a few days; the patient regains perfectly the use of his members! Later on there comes another attack on the same side or on the opposite side. Such pseudo-apoplectic attacks are not rare in aged persons affected with arterial nephritis. Raymond, Chantermesse and Tenneson, besides Lancereaux, have reported cases of the kind.

Other morbid sensations are those formications and pricklings of the limbs which are observed especially in arterial nephritis, and which may be due to an imperfect sanguineous irrigation. The only *articular* pains which it is possible to ascribe to uræmia are those erratic, flitting pains of the Brightic, and which yield to purging; these evidently originate in the nervous system, and not in any material disorder of the joint. To the same category belong those painful cramps of which some patients complain, and which are seated preferably in the muscles of the legs.

As for the *digitus semi-mortuus* phenomenon (the dead-finger sensation), which is by some writers ascribed to uræmia, it is a symptom common to the neuropathic and atheromatous.

Cephalalgia is an ordinary symptom of uræmic poisoning, and appears in the form of a simple headache, or of pains which bear a great resemblance to migraine. The first of these forms is continuous, with paroxysms which may come on in the daytime, but oftener supervene in the night. Moreever, nocturnal exacerbations are almost pathognomonic. The pain has for its seat sometimes the frontal region, sometimes the occipital, and reveals itself by a sensation of horrible discomfort, of weight, of pressure, rather than of painful lancinations. It is rarely located in the temporal region; oftener it occupies the entire head, and is compared to a hoop encircling and compressing the cranium, or a tight and heavy helmet.

The intensity of the headache (causing outcries), joined to the nocturnal paroxysms, reminds one of the osteocopic pains of syphilis. If in doubt, the result of treatment will sometimes clear up the difficulty; the antisyphilitic treatment (iodide of potassium, minute doses of calomel) will be found inefficacious, while a few purgative doses of Carlsbad salts will give speedy and magical relief.

The *migrainous* form is intermittent, and supervenes by crisis of a duration which varies from several hours to several days. Sometimes unilateral, it is oftener frontal. The pains are of a rending, grinding, crushing, compressing character; arterial beatings (aggravating the pains) and lancinations (so common to migraine) are rarely complained of. The pain is exceptionally accompanied with nausea and vomitings.

Vertigo is a symptom which is quite often observed in uræmia; it is not always, however, due to uræmic poisoning, being frequently dependent on a morbid state of the cerebral arteries.

Aphasia is rarely witnessed in uræmic poisoning; when supervening, it appears at irregular or periodical intervals, and is transitory.

Uræmic coma is relatively common. It is generally associated with other uræmic manifestations; it succeeds convulsions and frequently accompanies paralyses; but in some cases it remains isolated, constituting the sole disorder. There are all grades in the depth of the somnolence; sometimes the patient lies in a state of semi-consciousness for entire days, replying in monosyllables when spoken to in an earnest tone of voice. Seated in his arm-chair or lying in bed, generally a prey to a painful dyspnœa, the patient utters complaints or groans when he awakes, and speedily relapses into his hebetude.

At other times the coma comes on suddenly, and is much more pronounced. The patient is struck down with an apoplexy, and becomes insensible to all excitations; his face is pale, the pupils are immovable, the pulse is slowed, the respiration irregular sibilant or stertorous, sometimes puffing. Muscular resolution is then general, the limbs when raised fall back flaccid, as if they were paralyzed. Death may take place during a first attack. Œdema of the cerebrum is sometimes met at the autopsy, but it may be lacking; or the patient may come out of his coma, manifest some hebetude and obtusion of the intellectual faculties, but respond to questions and take nourishment; then, after a few hours, a day or two, or even several weeks, he again lapses into the same apoplectic inertia, and may have several such attacks before he dies.

The diagnosis is always difficult in cases of this kind. The absence of reflexes speaks in favor of uræmia. The examination of the urine and the state of the temperature have a great semeiological importance and a real value from the point of view of prognostic and therapeutic indications.

Uræmic madness or delirium is a rare symptomatic manifestation of renal insufficiency. When it makes its appearance it is generally in the course of interstitial nephritis, especially of that form which is dependent on arterio-sclerosis. Uræmic delirium has, however, been witnessed in scarlatinous nephritis, and it is probable that many observations of puerperal mania belong to this category.

When uræmic delirium is associated with other troubles, nervous or digestive, it is habitually mild, calm and transient, rather than noisy and persistent; hence it may pass unperceived, and generally it has but a secondary importance. If, on the contrary, this accident is the predominant phenomenon and sums up in itself all the uræmic disorders, it is more pronounced, and presents particular characters which it is absolutely necessary to know well. In fact, it is not enough that there should be delirium and a renal lesion to constitute *uræmic insanity;* this delirium should have a special behavior which distinguishes it from other forms of delirium.

Rarely it bursts forth all at once; almost always it is preceded by insomnia, change of disposition, by melancholy or by impatience, by headache or dyspnœa, or other signs of urinary insufficiency. It is active, boisterous, rather than depressive; hence its type resembles acute mania.

Hallucinations, when they exist, affect sight or hearing, and are rather terrifying than gay. The patients believe that plots are formed to injure them, to poison them, and in certain cases they refuse all food.

Uræmic delirium has remissions and paroxysms, rarely a uniform and continuous progress. It may last for months; but its duration is ordinarily shorter—a few weeks or only a few days—and, like the convulsions and coma of uræmia, it generally kills the patient unless it is met by the appropriate treatment. Patients affected with it have frequently been sent to asylums and put under restraint. This is bad practice, and may be followed by fatal results.

Uræmic delirium presents serious diagnostic difficulties, arising from the morbid predispositions which in an albuminuric patient, as in any other person, may be awakened by various exciting causes. It is conceivable that an alcoholic patient affected with renal lesion may be taken with a delirium absolutely foreign to this lesion. It is the same with an individual who has antecedents of insanity in his family; hence it is important to have clearly in mind the characters of uræmic insanity if one would arrive at a correct diagnosis. These characters may be summed up as follows: Appearance of the delirium generally after well-known uræmic phenomena; maniacal exaltation with general incoherence, which may disappear at the end of several days or end in a dementia of short duration, in

coma, or, lastly, in death. We have here, then, a grave disorder, which we should know how to diagnosticate in order to treat it properly and to avoid the disaster of committing to an asylum the unfortunate victims of this form of mental alienation.—*Jour. Nerv. and Mental Disease.*

SURGERY.

SURGICAL TREATMENT OF INTUSSUSCEPTION.

The following conclusions are reached by Dr. N. Senn, in an article in the *Canadian Practitioner:*

1. Intussusception of the bowels is a strictly surgical affection, and should be treated as such from the beginning, on the same ground as a strangulated hernia.

2. Immediately after the accident has occurred peristaltic action should be arrested by emptying the stomach by an emetic or irrigation, by suspending stomach feeding, combined with the administration of opiates in sufficient doses to procure rest for the bowel at and above the seat of invagination.

3. Prompt arrest of peristalsis procure for the affected part the most favorable conditions to arrest further invagination and to effect spontaneous or artificial reduction.

4. Artificial means to effect disinvagination should be instituted as soon as this form of intestinal obstruction is recognized or even suspected.

5. Rectal insufflation of hydrogen gas or filtered air is the most efficient and safest procedure in reducing the invagination, and, if employed sufficiently early, will prove successful in the majority of cases.

6. Inversion of the patient and complete relaxation of the abdominal muscles by the use of an anæsthetic are important factors in rendering the inflation efficient.

7. Enterostomy and colostomy, according to the seat of the invagination, are only permissible if the patient's general condition does not warrant laparotomy.

8. Laparotomy in all other cases should be done as soon as the irreducibility of the invagination has been demonstrated by rectal insufflation.

9. In acute recent cases the swelling of the intussusceptum, caused by the circular constriction at the neck of the intussuscipiens, often proves a serious obstacle to reduction, and should be removed as nearly as possible by manual compression made direct or over a large aseptic sponge before attempts are made to reduce the invagination by traction.

10. Reduction of the invagination is accomplished most readily by making traction in opposite directions upon the bowel, above the neck of the intussuscipiens, and upon the sheath below the apex of the intussusception, combined with pressure against the intussusceptum in a direction from below upwards.

11. If adhesions between the apposed serous surfaces of the inner two cylinders resist reduction, they should be carefully separated with a Kocher's director or a small pair of straight blunt-pointed scissors before traction is made.

12. After reduction has been accomplished the affected segment of the bowel should be carefully examined, and small patches of gangrene or rents of the peritoneal coat covered by stitching the peritoneum over them.

13. Recurrence of invagination is prevented most effectually by shortening the mesentery by folding it in the direction of the bowel, and fastening the fold in this position with a few catgut or fine silk sutures.

14. If the external surface of the bowel present evidences of gangrene, disinvagination should not be attempted, and in such cases a resection is absolutely indicated.

15. The resection, under such circumstances, should always include the whole intussusceptum, but only so much of the intussuscipiens as is threatened by gangrene.

16. If the continuity of the bowel cannot be restored by circular suturing, either on account of the difference in size of the lumina of the resected ends, or inflammatory softening the same object is attained in an equally satisfactory manner, and more safely, by lateral implantation or intestinal anastomosis.

17. If the invagination is not extensive, but irreducible, and the bowel presents no signs of gangrene, obstruction should be allowed to remain, and the continuity of the intestinal canal restored by making an anastomotic opening between the bowel above and below the invagination, by the use of perforated decalcified bone plates.

18. If the invagination is extensive, irreducible, and the bowel presents no indications of gangrene externally, the intussusceptum should be made accessible through an incision below the neck of the intussuscipiens and resected after securing the stump with an elastic ligature, after which the ob-

struction is permanently excluded by an intestinal anastomosis.

19. In irreducible colico-rectal invagination, or when this form of invagination has been caused by a malignant tumor, the intussusceptum should be drawn downward and removed by the operation devised by Mikulicz.

REMOVAL OF BREAST DURING HYPNOTIC SLEEP.

Dr. Schmeltz, of Nice, has recently recorded a case (*Gazette Medicale de Strasborough*) in which he removed a sarcomatous breast during an anæsthesia caused by hypnotism. The patient was a girl, æt. 20, who was easily thrown into the hypnotic state. The operation was performed in the presence of Drs. Lauza and Barriera, and the entire organ, together with the aponeurosis of the pectoralis major was removed by the oval incision. Five drainage tubes were inserted and the wound was closed with thirty-two metallic sutures. The operation lasted an hour. The patient remained absolutely insensible, in a condition of the deepest anæsthesia, such as is only seen after large doses of chloroform. Dr. Schmeltz says: "I operated very slowly and quite at my ease; the patient even tried to encourage by her words; she seemed very gay, and laughed loudly from time to time as if to show that she felt no pain. In order to make the operation easier for me, she turned herself about, so as to place herself in the most favorable position, keeping her right arm stretched out so that no assistant was required to keep it steady." She was kept under observation the rest of the day, and having been told not to feel pain and to have a good night she obeyed these instructions in the most docile manner. The wound was completely healed on the fifteenth day. The only symptom worth mentioning, which Dr. Schmeltz observed in the patient during the operation, was great pallor of the countenance, without any dilatation of the pupil or weakening of the pulse. The tumor weighed two kilograms.

THE USE OF PLATINUM INSTRUMENTS IN OPHTHALMIC SURGERY.

Gruening, of New York, in a paper contributed to the last number of the *Archives of Ophthalmology*, refers to the use of platinum instruments in ophthalmic surgery, which he regards as very advantageous. He has used for the last twelve months a set of instruments, composed of the following, a cystotome, an "iris repositor," a wire loop, a spoon, several straight and curved iris forceps, a fixation forceps, and a speculum. The platinum, alloyed, compressed by hammering, becomes very firm, and when polished is not blackened by the flame of a spirit lamp. The time, he says, required for the sterilization of a platinum instrument by imparting to it a white heat is but a small fraction of a minute, so that every instrument required for an operation can be prepared in a direct, simple, and thorough manner by the surgeon. After all, while admitting the certainty of completely sterilizing instruments by heat, a plan rendered possible by having them manufactured of platinum as suggested by the author, we are doubtful, in view of the satisfactory results which can be obtained in ophthalmic surgery, as far as suppurative processes are concerned, by the free employment of antiseptics, whether the necessity for using platinum instruments can be shown to exist.

A METHOD OF OPERATION IN POLYPI OF THE NASAL CAVITY.

Roman von Baracz, Lemberg (*Centralblatt f. Chirurgie.*) The author refers to the favorable results following the method introduced by Furneaux Jordan (*British Med. Journal*, May 2, 1885), the fundamental principle of which consists of clearing the anterior naris by means of the formation of a triangular-shaped flap from the upper lip and wing of the nose, in order to gain access to the nasal cavity. The steps of Jordan's operation are as follows: A curved bistoury is introduced beneath the upper lip at the side corresponding to the polyp, passed perpendicularly until its point emerges into the nasal opening, and the upper lip cut through from behind forward. The cut edges of the upper lip are compressed. A long and pointed bistoury is introduced into the nasal cavity and an incision made, continuous with that just described and passing out through the dorsum nasi. In this manner the soft parts of the nose are separated in a longitudinal direction. A few strokes of the knife suffice to lift the flap thus formed and permit inspection in the nasal cavity. Should the opening thus made prove insufficient for the removal of the growth, which is accomplished by the finger, aided by knife and scissors, this may be enlarged by the bone forceps.

In 1888 König (*Centralblatt f. Chirurgie*, No. 10) called attention to a method quite

similar to Jordan's. The only essential difference between the method of Jordan and that of König consists in the use of the large sharp spoon by the latter for the removal of the tumor. In B's operation a combination of the two methods is aimed at by making a formal osteo-plastic resection of the nasal bone and the nasal process of the superior maxillary bone, and the removal of the growth by means of König's sharp spoon. The operation is performed under cocaine anæsthesia. It is claimed that no deformity results, and that the cicatrix is almost invisible.

GYNÆCOLOGY.

BACKACHE AS A SYMPTOM OF LOCAL DISORDERS.

So large a proportion of the female patients who present themselves in our consulting rooms, suffering from pelvic disorders, complain of backache in the sacral region, that Dr. W. P. Manton, (*Jour. Gynæcology*) has interested himself in looking up the relation of this symptom to the conditions which physical examinations have shown to be present. At first, he attempted to arrange the results of these studies in a somewhat systematic order, but this he soon found to be quite impracticable. From a somewhat hasty scrutiny of the leading textbooks on gynæcology, he finds that but scant mention is made of backache as a symptom, some authorities ignoring it entirely, while others dismiss it with a few words. English specialists give it greater prominence than do Americans. The neglect of this symptom may be due to the fact that it is of but little practical importance, one of those minor conditions which are so frequently overlooked in our attempts to discover something new and startling. To determine the significance of backache, therefore, he took the histories of 100 cases from his case-book, omitting all conditions of the vulva, vagina and bladder, when uterine, tubal or ovarian complications were absent.

His table stands thus:

Whole number of cases	100
Of these were:	
Unmarried	17
Married	83
Of the unmarried suffering from backache were	12
Of the married suffering from backache were	60

Twenty-three more of the married women had the backache occasionally, usually at the menstrual period.

The cases of backache in the unmarried were:

Inflammatory conditions of the uterus	9
Chloro-anæmia	2
Sub-serous fibroid	1
Total	12

In the married the causes of backache were more difficult to determine, since in hardly a single instance was the local condition simple, but usually consisted of several diseased states, inseparable.

In the married there were:

Anteflexion	10 cases.
Retroflexion	8 cases.
Retroversion	6 cases.
Laceration of the cervix uteri	22 cases.
Inflammatory conditions, uterus	45 cases.
Fibroids	5 cases.
Prolapsed ovaries	8 cases.

The cases of unmarried women who had no backache were found to present the following physical conditions:

Interstitial fibroid with anteflexion and prolapsed and adherent ovaries	1 case.
Anteflexion, associated with epilepsy	1 case.
Anteflexion, with dysmenorrhœa	1 case.
Anteflexion with endometritis, anæmia and ovarian hyperæsthesia	1 case.
Right lateral anteflexion with endometritis fungosa	1 case.
Total	5 cases.

It will be observed that in those who were subject to sacral pain, there are no displacements of the uterus noted, while in those who had no pain, in all five cases, there was an anterior dislocation of the womb. That this is not invariably the rule he states he can prove by other records, in which simple, so-called congenital, anteflexion is associated with the most distressing sacral ache.

The following conditions were found affecting the married women who had no backache:

Displacements of the uterus in 6 cases, viz. anteflexion, 3; retroflexion, 2; retroversion, 1. The ovaries were prolapsed four times, inflammatory conditions of the uterus were present in 16 cases, 1 case suffered from general debility and in 4 cases there were lacerations of the cervix uteri.

By comparing this last set of cases with

the first set (married) which suffered from backache, we see that the physical conditions presented in each are essentially the same, a preponderance of the patients suffering from some inflammatory condition of the uterus, from dislocation of that organ or from lacerations of the cervix. In very many of these cases a combination of these conditions were present. A number of the patients were anæmic and several were neurasthenic.

Backache was a prominent symptom in cases where only a slight cervical catarrh was present, and absent in others where graver pathological conditions existed. From this superficial study of a limited number of local conditions associated with backache, it is quite evident that these alone are not entirely responsible for the pain, but that some other factor must be present as the determining cause. This he believes to be a nerve state dependent upon either a congestion of the pelvic viscera, more especially of the uterus, or upon an opposite state of anæmia. In the first instance the nerves of the pelvis or uterus are pressed upon by the distended blood vessels, or the uterine muscular fibers, under certain conditions, perhaps themselves taking part in the pathological states present. In anæmia the backache would only represent a phase of the general condition, a symptom of the general nerve starvation. Certain it is that in these cases a one-sided treatment almost invariably fails to afford relief, and it is only after we combine general with local treatment that we succeed in curing the patient.

He suggests that sacral backache is always a symptom of local disturbance, but that as it is a symptom common to nearly all pelvic disorders, it cannot be considered as diagnostic of any particular functional or pathological condition.

OBSTETRICS.

THE PROTECTION OF THE PERINEUM DURING THE PASSAGE OF THE SHOULDERS.

Couder (*Archives de Tocologie et de Gynécologie*, No. 7, 1891) has found it of advantage to unfold an arm when the shoulders present with folded arms after the expulsion of the head. When a hand presents before the shoulders, it should be drawn down and the arm entirely delivered. When this is not possible, the hips of the mother should be raised, and when the head has rotated externally, the head must be pulled down and the anterior arm freed to the elbow. The elbow is then to be flexed toward the back of the fœtus and the anterior arm entirely extracted. The head is then to be raised and the trunk allowed to emerge slowly.—*Amer. Jour. Med. Sci.*

DELIVERY OF THE SHOULDERS AND LACERATION OF THE PERINEUM.

Dr. Auvard (*Arch. de Tocol. et de Gynéc.*, Aug. 1891) differs from many obstetricians in his opinion as to the order in which the structures in the neighborhood of the shoulders are born, in labors where the head presents. The classical theory, at least in French schools since 1830, gives the order thus: (1) Escape of the prominence of the anterior shoulder (that which is turned towards the maternal pubes); (2) birth of the posterior or perineal shoulder and of the corresponding arm; (3) birth of the arm corresponding to the anterior shoulder. Dr. Auvard holds that the true normal order of birth, putting aside the action of great weight of the fœtus, is: (1) birth of the perineal shoulder and of the entire corresponding arm, whilst the anterior shoulder keeps fixed behind the pubes: (2) escape of the anterior shoulder and the corresponding arm. The circumference of the fœtus around its shoulders is greater than the circumference of its head, and the circumference of the fœtus around the elbows pressed against the trunk is yet greater; hence the perineum is in greater danger of laceration from the shoulders and disengaged arms than from the head. Therefore Dr. Auvard holds that in order to preserve the perineum, the arms must be disengaged before the birth of the trunk. If the hands are easily accessible, draw them down so as to bring out the corresponding arms. When neither hand can be reached, the head must be drawn aside so as to make the posterior shoulder project. The corresponding arm is next disengaged by pushing the humerus towards the back of the fœtus, and then drawing down the forearm. The anterior arm is delivered in the same way. If the posterior arm cannot be delivered first, the anterior must be brought down. In no case should the obstetrician leave the arms to be delivered pressed against the trunk, for this involves great danger to the perineum.—*Brit. Med. Jour.*

TRAUMATIC DETACHMENT OF THE PLACENTA.

Bogoroditzky (*Proceedings of the Tambow Medical Society*, Nos. 9, 10 and 11, 1890) reports the case of a healthy woman, twenty years old, in the fourth month of pregnancy, who, one night, "for amusement," threw a somersault in bed. Immediately after, she was conscious of pain in the abdomen, which moderated, and the woman fell asleep. On the next morning, however, she awoke with increased pain, a feeling of weight in the abdomen and general prostration. Soon there set in obstinate constipation (that did not yield to enemata or purgatives), violent vomiting, fever, dysuria and retention of urine. Two weeks later she appeared anæmic and collapsed; the pulse was quick and weak, the abdomen distended and tender, the uterus flabby, its fundus reaching about three fingers' breadth above the umbilicus, the cervix displaced backward, the os admitting a finger. Intra-uterine hæmorrhage being diagnosticated, hot vaginal douches were given, an ice-bag applied to the abdomen, ice, stimulants and ergot administered. At the end of four hours a dead four-months' fœtus was expelled; but the uterus remained as large as ever. On further examination, the organ was found to contain a smooth, globular body, of the consistency of the placenta. The membranes and placenta being ruptured, the finger entered an enormous cavity filled with an immense volume of fluid and clotted blood. After the removal of the membranes, clots and blood, the uterus contracted and hæmorrhage ceased. The after-treatment consisted in hot, disinfectant irrigations and the internal administration of ergot and quinine. Notwithstanding the formidable loss of blood, an excellent recovery followed. On the fourth day the temperature was normal; on the tenth day the patient got out of bed.—*Provincial Medical Journal.*

PÆDIATRICS.

HYPODERMIC INJECTION OF MERCURY IN INFANTILE SYPHILIS.

Moncorvo and Ferreira have reported in the *Revue des Maladies de l'Enfance* (T. ix, pp. 241 and 289) the results of an extended series of trials of the subcutaneous injection of mercurial salts in the treatment of infantile syphilis. The preparations used were calomel, yellow oxide, *huile grise*, salicylate, and corrosive sublimate. Of these, the *huile grise* and corrosive sublimate were found to be the most efficacious; neither gave rise to much pain at the time of injection, and there was little or no subsequent reaction. In making the injections, strict antiseptic precautions were observed. The treatment was exceedingly well tolerated, and in addition to the rapid amelioration of the cutaneous lesions and the somewhat slower disappearance of glandular enlargements, there was a very noticeable improvement in the general condition, as was evidenced by increase in weight and in the proportion of hæmoglobin in the blood. The dose of corrosive sublimate was 1 or 2 milligrammes; the ages of the children varied from 3 months to 14 years. The salt was simply dissolved in water. The dose of *huile grise* given is stated to have varied from "two-fifths to the whole of a Pravaz's syringe." The ages of the children ranged from 38 days to 12 years; the number of patients treated with the oil was 13; 5 were completely cured and 7 were much improved. The injections were repeated every third, fourth, or fifth day, according to circumstances. The authors consider that the hypodermic injection of one or other of these mercurial preparations should be a recognized form of treatment in congenital syphilis, and should be resorted to when an immediate and powerful effect is desired. [The following is the note on *huile grise* in Martindale and Westcott's *Extra Pharmacopœia*. "Injectio Hydrargyri Hypodermica.—*Syn.* Grey Oil. Mercury 3, lanolin 3, olive oil 4. Preferable formula: Mercury 39, mercurial ointment 2, vaseline oil 59. Dose, 1 to 2 grains daily."]—*Brit. Med. Jour.*

THE SUSCEPTIBILITY OF CHILDREN TO HYPNOTISM.

Berillon (*Gaz. Méd.*, July 25, 1891), has found that out of every ten children, taken indiscriminately from every class in society, eight may be put to sleep (hypnotized) at the first or second trial. But the singular part of the subject is that children who have the most marked hereditary nervous taint are the most difficult to hypnotize. It has also been demonstrated that hysterical persons are only sligtly susceptible of hypnotization, while epileptics are highly susceptible. Children without hereditary taint, who are active and vigorous, are usually hypnotized with facility. This author recommends that suggestion (hypnotization) be made use of in the treatment of such conditions as insom-

nia, night-terrors, kleptomania, onanism, and other vicious habits. If such practice is limited to ends which are strictly useful, and employed only for therapeutic purposes, it would appear free from danger and fruitful as to its results.

EYESIGHT—ITS CARE DURING INFANCY AND YOUTH.

Dr. L. Webster Fox, contributes a timely paper on this subject. In conclusion he formulates ten rules on the preservation of vision:

(1) Do not allow light to fall upon the face of a sleeping infant.

(2) Do not allow babies to gaze at a bright light.

(3) Do not send children to school before the age of ten.

(4) Do not allow children to keep their eyes too long on a near object, at any one time.

(5) Do not allow them to study much by artificial light.

(6) Do not allow them to use books with small type.

(7) Do not allow them to read in a railway carriage.

(8) Do not allow boys to smoke tobacco, especially cigarettes.

(9) Do not necessarily ascribe headaches to indigestion, the eyes may be the exciting cause.

(10) Do not allow the itinerant spectacle vendor to prescribe glasses.—(Paper read before the *Franklin Institute*, Phila.)

HYGIENE.

THE MECHANISM OF IMMUNITY FROM INFECTION.

Drs. Emmerich and Mastraum have published an interesting article in a German hygienic journal on the cause of immunity from infectious diseases and their treatment, especially of swine erysipelas, and a new method of protective vaccination for it. Emmerich published in the year 1886 his doctrine that the cause of immunity from infectious diseases is a modification of the chemical process going on in the cells, so that the new chemical compounds formed act as microbe killers without doing any harm to the cells themselves. In consequence of the results of a series of experiments, Emmerich concluded that this antibacterial poison acts destructively on all the microbes within a few hours after their introduction into the organism. The publication of this doctrine having met with a good deal of opposition, he repeated his experiments, and again arrived at the same result, showing that the explanation of immunity from infections diseases proposed in 1886 was justified. Granted the correctness of this, it follows that extracts from the tissue of any animal enjoying immunity are remedies against the corresponding infectious disease. Further experiments are now reported by Drs. Emmerich and Mastbaum which show that an extract from the various tissues and the blood of rabbits which have been made proof against swine erysipelas is an excellent remedy for the disease, and that a hypodermic injection of the extract can serve as a rational protective inoculation. A rabbit was inoculated by having injected into the posterior auricular vein the fifth of a cubic centimetre of a fresh broth culture of swine erysipelas, diluted with fifty times its volume of distilled water. In the course of the following week or two a series of hypodermic injections of the same liquid was administered. For the purpose of preparing a liquid extract suitable for therapeutic or prophylactic purposes, the organs of the rabbit were cut up and submitted to a pressure of from 300 to 400 atmospheres, and the expressed juice filtered into sterilized bottles. A large number of white mice as well as rabbits were now inoculated with the swine erysipelas, and at the same time, or very shortly afterwards, an injection of the liquid extract was administered to some of them. These remained alive, while all the others—that is to say, those which had not received an injection of the liquid extract of the organs of the infected rabbit—succumbed. Other experiments were carried out by which it was shown that this same liquid extract is capable of conferring immunity from the disease. Further experiments were made which showed that the bacilli were destroyed in six hours, and that in eight hours all were dead, or at least incapable of multiplication, but that the liquid extract produced extremely little effect upon the same baccilli outside the organism, so that the presence of living cells is evidently necessary for the destructive effect of the liquid extract to manifest itself. Another interesting result obtained was that bacilli taken fresh from the body were very much more active than their cultures in broth.—*Lancet.*

MEDICAL CHEMISTRY.

DERIVATIVES OF SALOL IN URINE.

Lacroix (*Répertoire de Pharmacie; Bull. de Thérapeut.*, 1891, cxx, 284) calls attention to the fact that patients taking salol internally or using it externally pass a urine having the property of reducing certain metallic oxides (copper, silver and bismuth) just as is the case with diabetic urine. The examination with the saccharometer can also not be depended on, the rotatory power of these salol compounds being opposed to that of glucose. The author gives an optical and a chemical method for distinguishing between the two. After treating the urine with subacetate of lead, a test tube holding 15 cc. is half filled with the same; to this is added ·05 gm. phenylhydrazin hydrochloride and ·2 gm. pure acetate of sodium. The test tube is then heated to 100° C. (212° F.) on a water-bath for half an hour. The contents are then poured into some water and allowed to cool. The precipitate formed is examined with the microscope. Glucose gives a crystalline precipitate while the salol compound gives an amorphous one. The other method is as follows: 100 cc. urine are shaken with 1 gm. sulphuric acid and about 50 cc. pure ether; it is then permitted to separate. The upper layer, containing the derivatives of salol, is evaporated, the residue dissolved in water and a few drops of perchloride of iron are added to it. This would give rise to a violet color in case salol were present. The lower layer, after separation from the ethereal solution, is treated with subacetate of lead, filtered, and the glucose then estimated in the usual manner.

EXAMINATIONS FOR ADULTERATIONS OF TOMATO PRESERVES.

Capdeville (*Bull. de Thérapeut.*, 1891, cxx, p. 277) divides the analysis into an optical or microscopical and a chemical portion. The adulterations which are looked for by the first method are carrot and pumpkin, and this is done by comparison with sections of these vegetables. The chemical method takes cognizance of the presence of coloring matters such as eosin, cochineal and grenadin. *For eosin:* 5 gm. of the preserve are treated in a test tube with a mixture of 25 cc. of distilled water, 1 cc. ammonia and 25 cc. amylic alcohol. The mixture is then filtered, and in case the filtrate is rose-colored, eosin is present which is also shown by the fluorescence. *For cochineal:* 5 gm. preserve are treated for 24 hours with 30 cc. alcohol of 95 per cent.; the liquid is then filtered and the alcohol evaporated on a water-bath. Should this residue, on treatment with ammonia, give a red color, cochineal is present. *For grenadin:* The preserve is treated with alcohol, the solution filtered and the filtrate evaporated to dryness. The residue is treated with water which dissolves the grenadin, and this aqueous solution is used for dyeing silk. Hydrochloric acid does not, while a solution of chloride of lime does, decolorize the silk even at ordinary temperatures.

NEWS AND MISELLANY.

THE POLYCLINIC COURSE OF EVENING LECTURES

Will be given on Tuesday and Friday evenings of each week, at eight o'clock, in the New Polyclinic Hospital, Lombard street, above Eighteenth street.

November 24—Dr. Edward Jackson—The Shadow Test.

November 27—Dr. B. Alex. Randall—Ear Diseases in General Practice.

December 1—Dr. S. D. Risley—The Diseases of the Choroidal Tract.

December 4—Dr. John B. Deaver—The Operative Treatment of Head Injuries.

December 8—Dr. Henry Leffmann—Recognition of Albumose and Peptone in Urine.

December 11—Dr. Edward P. Davis—The Use of the Forceps.

December 15—Dr. Henry Leffmann—Determination of Sugar and Urea in Urine.

December 18—Dr. S. D. Risley—The Diseases of the Choroidal Tract.

December 22—Dr. John B. Roberts—Fractures of the Elbow.

January 5—Dr. J. Henry C. Simes—Syphilis.

January 8—Dr. Lewis H. Adler, Jr.—The Physical Exploration of the Rectum.

January 12—Dr. Arthur Van Harlingen—The Contagious Diseases of the Skin; Their Diagnosis and Treatment.

January 15—Dr. John B. Deaver—The Radical Cure of Hernia; Umbilical, Inguinal and Femoral.

January 18—Dr. J. Henry C. Simes—Syphilis.

January 22—Dr. H. Augustus Wilson—The Mechanism of the Normal Foot with Reference to the Correction of Deformities.

January 26—Dr. Arthur Van Harlingen—The Antiseptic Treatment of Skin Diseases.

January 29—Dr. Lewis H. Adler, Jr.—Congenital Malformations of the Rectum and Anus.

February 2—Dr. E. P. Davis—The Treatment of Delayed Labor.

PERIODS OF GESTATION.

The periods of gestation are the same in the horse and ass, 11 months each; camel, 12 months; elephant, 2 years; lion, 5 months; buffalo, 12 months; cow, 9 months; sheep, 5 months; reindeer, 8 months; monkey, 7 months; bear, 6 months; sow, 4 months; dog, 9 weeks; cat, 8 weeks; rabbit, 4 weeks; guinea pig, 4 weeks; wolf, 90 to 95 days. Goose sets 30 days; swans 42 days; hens, 21 days; ducks, 28 days; pea hens and turkeys, 28 days; canaries, 14 days; pigeons, 14 days; parrots, 40 days.

DEATH IN THE JAM POT.

A correspondent of the *British Medical Journal*, in calling the attention to a danger that attends the use of glass jars for holding jam, writes: "Twice within the last two months have my children found pieces of glass in their mouths, and fortunately got it out again; one piece was half an inch long and very sharp. If this has happened twice in so short a time to me, how often must it occur to others, and how often must the children swallow a piece without knowing it? It makes one look back to the obscure case of enteritis one has met with, which could not be accounted for as to the cause. The jams my children had were from different makers, so the accident must not be uncommon."

THE COUCH.—A ROOM IS ONLY HALF FURNISHED WITHOUT ONE.

A room without a couch of some sort is only half furnished. Life is full of ups and downs, and all that saves the sanity of the mentally jaded and physically exhausted fortune fighter is the periodical good cry, and the momentary loss of consciousness on the upstairs lounge, or the old sofa in the sitting-room. There are times when so many of the things that distract us could be straightened out, and the way made clear, if one only had a long comfortable couch, on whose soft bosom he could throw himself, boots and brains, stretch his weary frame, unmindful of tidies and tapestry, close his tired eyes, relax the tension of his muscles, and give his harassed mind a chance. Ten minutes of this soothing narcotic, when the head throbs, the soul yearns for endless, dreamless, eternal rest, would make the vision clear, the nerves steady, the heart light, and the star of hope shine again.

There isn't a doubt that the longing to die is mistaken for the need of a nap. Instead of the immortality of the soul, business men and working women want regular and systematic doses of dozing—and after a mossy bank in the shade of an old oak, that succeeding Junes have converted into a tenement of song birds, there is nothing that can approach a big sofa, or a low, long couch placed in a corner, where tired nature can turn her face to the wall and sleep and doze away the gloom.—*Exchange.*

NO MORE ARTIFICIAL TEETH.

Old age is robbed of half its terrors and much of its deformity by the brilliant discovery of a Moscow dentist, Dr. Zuamensky, who, according to a possibly over-sanguine Russian contemporary, has delighted the civilized world by his skill in making teeth grow in toothless gums. After experimenting on dogs, he tried the effects of his method in human beings, and the success was complete. The teeth are made of gutta-percha, porcelain, or metal, as may be desired. The root of the false tooth has some holes bored in it. Holes are now bored into the jaw, and into the hole the false tooth is stuck as is a nail in the wood. In a short time a tender growth starts up the cavity of the false tooth, and this growth hardening, the tooth becomes fixed in position. These new teeth can, according to the inventor, be placed in the alveolus of a natural tooth, and thus, when a diseased tooth is pulled out a metal or porcelain substitute can be inserted in its place, without incurring any risk of transferring disease, as happened in Hunter's days, when the apparently sound teeth of poor persons, when transplanted, not infrequently conveyed disease. There are several minor inconsistencies in this statement, but it would be ungracious to look such a noble gift in the mouth, especially as, according to dentists of authority, our race is destined eventually to become edentulous. —*Medical Press.*

Clinical Lecture.

THE ETIOLOGY OF CLUB-FOOT—THE TREATMENT OF CLUB-FOOT—THE PLASTER-OF-PARIS BANDAGE.

BY H. AUGUSTUS WILSON, M. D.,

CLINICAL LECTURER ON ORTHOPEDIC SURGERY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

Gentlemen:—I have had this baby, who was operated upon at our last meeting, brought before us to-day in order that you might see the character of the dressing employed, the condition of the foot now, and also the character of the appliance which we shall put on. I have had the plaster-of-Paris cast cut in such a way that it will be readily removed. Remember that we are simply putting the parts in a mechanical relationship so that there may result a correction of the deformity. The feet, you notice, are placed in a position of extreme eversion. The scar here is very small, the greatest amount of damage having been done beneath the cutaneous surface. Union has taken place by an exudation of plasma, which will become organized to form a new elongated tendon. But little force is required now to correct the deformity, but as soon as this force is relaxed, the deformity returns. Therefore is indicated the adoption of a form of treatment which will hold the feet in the corrected position. Subsequently, then, to the operation, comes in maintenance of the corrected position and finally the treatment proper of the deformity.

Time did not permit me to operate upon this second patient before you last week, but I performed the operation immediately after the hour, and bring him before you now that you may see the two patients together. You will see here also that when this plaster-of-Paris cast is removed from the foot, the latter immediately returns to its former position. Just here there is one point I would have you bear in mind. You will observe in those children who have normal feet, a position of *varus* which they assume when at rest. You must keep in mind the fact that the position of repose is that in which the foot is slightly inverted.

ETIOLOGY OF CLUB-FOOT.

Since my last lecture I have been asked several very pertinent questions which I have felt called upon to answer publicly rather than individually. One of these is, What produces these congenital deformities, or why do some children present the deformity, and others in the same family not? More time, probably, has been spent upon the study of the etiology of congenital club-foot than upon that of any other subject in orthopedic surgery. I will endeavor to place concisely before you the various theories which have been advanced, notably by our German confréres, to explain the origin of the condition. Among these theories is that of *heredity*. It is well-known that a child inherits certain traces and peculiarities from its parents. A father or mother with a defective part of his or her body, may have a child with a similar defect, or a parent with a constitutional taint of consumption or syphilis will give to the child a similar disease. In my practice, however, over thirteen years now, I know of but one case in which there was an hereditary club-foot, the child inheriting the deformity from its father, and here is a suggestion worthy of remembrance, namely, that it is stated as a result of investigation in nearly all cases where the club-foot is inherited, it comes from the father. This theory, therefore, is proved to be an unimportant one, since so very small a number of cases may be explained by it. Equally unimportant is the theory of *maternal influence* or impression. When a mother cannot explain satisfactorily a condition in her infant in any other way,

she will go back to her period of gestation and recall some influence which she can bring to bear upon the production of the deformity. Thus nævi are frequently referred by the mother to seeing some object which in a general way resembled the appearance of the nævi or some other equally improbable occurrence. Another theory which approaches nearer to the truth and is more satisfactory in its explanation, is that of *mechanical intra-uterine pressure*—pressure exerted in intra-uterine life. If we can think of a condition in which there is a pressure being brought to bear upon the fœtus, as for instance when there is insufficient liquor amnii we can conceive of the possibility of the feet being held in this position so long as to result in the deformity. This theory will explain the formation of *varus* and *calcaneum*, but I do not think it will explain the other forms which are encountered. Another theory, is that which is known as the *musculo-nervous* theory, because it claims there is some central lesion of the brain or cord, whereby the muscles of the extremities are paralyzed, resulting in the deformity. This does not cover the large number of cases, however, in which there is no paralysis or atrophy of the muscles to be found.

The theory of *arrested development*, I believe, is the only theory by which we can explain the etiology of the condition. By arrested development we may explain not merely the various orthopedic conditions, but the various other congenital defects and anomalies, such as the case that I discharged from the hospital yesterday, who had congenital club-feet, club-hands, and defective knee-joints. Club-foot is frequently associated with spina-bifida, club-hand, webbed fingers, hydrocephalus and other evidences of some arrest of development. This theory is the most satisfactory because it will not entangle you with the other theories with which you will be brought in contact in considering the other deformities of the body. Those who advocate the musculo-nervous theory, found their belief upon false grounds. I cannot believe that the atrophy which exists in adult life in many of these conditions has preëxisted to the deformity, but I do believe that it has followed it as the result of the deformity. This urges me to impress upon you the possibility of producing deformity in the efforts made to correct an existing deformity. If we take a foot in which there is a *varus*, and so bind it to completely restrain muscular action that it becomes a mass of immobility, as in the case of a Chinese lady's foot, we are producing a condition of atrophy of the muscles which may result in a deformity.

In this boy, who I now bring before you, you see applied in another form, a means of mechanical restraint. This apparatus is doing here what was done in the other cases by the plaster-of-Paris splints, but has, however, a possibility of motion, while the other exerted an absolute restraining power. There are a large number of cases of so-called acquired *varus*, developing after birth. The argument advanced in these cases, is that if paralysis will produce *varus* after birth, why not apply the musculo-nervous theory to the prenatal cases. This child will illustrate the condition found in a great many cases of corrected club-foot. There is danger of atrophy from misuse. You notice the diminished calf on one side, and the shortened, narrowed foot. On measuring the ankles from the fixed points of the malleoli I find there is an atrophy of the bones also. If this atrophy has been produced by the central lesion which caused the club-foot it will be a much more difficult condition to treat; if, however, it is due to our means of mechanical restraint, we will be able to correct it, and improve the muscular development of the limb. The other leg develops more rapidly, chiefly because it is free from any form of restraint. I have now very briefly indicated the etiology and will now endeavor to lay down a principle upon which to base

THE TREATMENT OF CLUB-FOOT.

I shall ask you to divide all of these cases, following an arbitrary division, into three grades. The *first* grade will include all cases of congenital *varus* in which the deformity is easily corrected without operation, the foot readily placed in a proper position, and readily maintained in this position. Naturally, the *second* grade is a degree beyond this, where the deformity is corrected with difficulty, and the corrected position is maintained with difficulty. The *third* grade includes those cases where the foot is so firmly fixed in the deformed position that it cannot be corrected at all, that is, without the intervention of surgical or mechanical measures. If we accept these three grades we shall be prepared to take the next step and apply the treatment. This, likewise, is divided into three positions: first, the correction; second, the maintenance of the corrected position; and, third, the application of measures to restore the normal mechanical action of the foot. On the ear-

liest possible moment at which you correct the deformity will depend the ultimate success of the operation. After this, the subsequent treatment will consist in the application of such forms of manipulations, electricity and gymnastic exercise as will develop the muscles of the limb.

PLASTER-OF-PARIS BANDAGE.

I have shown you one form of operation, I will now show you one form of maintenance apparatus. One of the most important adjuvants of the orthopedic surgeon is the plaster-of-Paris bandage, but I would impress upon you the fact that you do not employ the plaster-of-Paris for any therapeutic action it may have but solely as a mechanical agent. Often have I seen a plaster-of-Paris bandage worn by a patient for a long time after it has become broken and useless with the apparent idea that it was keeping away the disease. In the preparation of the plaster-of-Paris bandage it is well to remember first the material you are going to use. If we use the ordinary surgical roller bandage made of unbleached muslin we will encounter two serious objections. In the first place its meshes are so close that we cannot get sufficient plaster-of-Paris into it; and in the second place, it is non-absorbent. We may place a surgical bandage in water for some time and it will not absorb any. A material which I am very fond of using is a form of cheese-cloth from which the sizing has been removed. It has, as you see, wide meshes. Ordinary cheese-cloth is yellow, being unbleached, and if we attempt to use it we will find that it is non-absorbent. The material I use is called butter-cloth, and has been passed through a process which has removed the sizing so that it readily absorbs the water from the plaster. Butter-cloth is even preferable to crinoline, which is somewhat stiffer and hence unpliable. There are all sorts of ways of preparing a plaster-of-Paris bandage but I will show you only the method resorted to here. The butter-cloth comes in fifty yard pieces, one yard wide. With an ordinary carving knife a bandage of the proper width is cut off the end of the piece as it comes from the store. We have adopted in this Hospital a method of rolling the bandage by means of a box of small size, which I devised some years ago and it possesses the advantage of simplicity. Resting on the edges of the box, at one extremity is a movable diaphragm, and on this, by means of a spring, is arranged what is called, for want of a better name a "distributor." This holds the bandage down and smears in the plaster as the bandage passes under it. At the other extremity of the box is a crank-pin attached, and around this the bandage is rolled. The plaster-of-Paris is then placed on the top of the diaphragm in a sufficient quantity and the crank-pin being turned, the bandage is rolled with its meshes filled with the plaster. It is not essential that the bandage should look pretty. The shop-bandages are nice to look at, but are not as efficacious as these which are roughly made, the real beauty consists of its utility and not its appearance. A plaster-of-Paris bandage spoils from being kept, because the gypsum possesses hygroscopic properties and will absorb water readily from the atmosphere. We can avoid this by wrapping the bandage in waxed paper, which will keep it for a long time without any damage whatever. In using these bandages two points of great importance must be borne in mind. The first is to have salt ready, and the second is to have something to cover the part of the patient upon which the bandage is to be placed. The use of salt is essential as a hardening process and is used in the water in which the bandage is to be soaked. The time occupied for the setting of the bandage should not exceed that of the time of application. If we use hot water the setting takes place far more quickly, but its use tends to make the plaster brittle and less durable. If you apply the bandage directly to the skin the hair will be caught and the patient will suffer as a consequence and any bony prominences are apt to cause abrasions of the skin covering. Plaster-of-Paris contracts in cooling, and if the bandage be applied too tightly it will constrict the parts and may produce sloughing. If some covering for the skin is used, all this may be prevented and I have found that for this purpose a prepared lint best answers the purpose. It absorbs the moisture from the inner side of the plaster-of-Paris bandage and thus makes it set more quickly. In conclusion, one point must be remembered, and that is, never cover an entire extremity in applying one of these bandages. If you are bandaging a foot leave the toes uncovered so that you may see whether or not too much pressure is being exerted. You can then have an indicator constantly before you and the nurse. Any tendency to constriction manifested by imperfect circulation would be sufficient reason for the removal of the fixed dressing and its reapplication.

TOOTHACHE may be relieved by naphthalin, 5 grains, dissolved in chloroform, 1 dram.

COMMUNICATIONS.

FURTHER CONTRIBUTIONS UPON TUBERCULIN.*

BY PROF. R. KOCH,

BERLIN.

(Translated by Henry T. Brooks, M. D., and Wm. Vissimann, M. D.)

Since I introduced the substance known as tuberculin to the world, many experiments have been made to isolate the active principles contained in it, and to free it from other matters to which it was believed disturbing extraneous actions were to be attributed. For some time past I have also busied myself with similar experiments and will state the results which I obtained in the following report. As yet only preliminary contributions upon the work belonging here are at my command, and, according to my own researches, the question appears to me not yet ripe for discussion. I shall confine myself to a description of my own observations, and leave the elucidation of casual contradictions and the discussion of the results obtained by other observers to a later time.

A few experiments showed that the active principles of tuberculin did not belong to the alkaloid ptomain groups, but that it is a substance closely allied to the albuminous bodies, and it was questionable whether it would bear the manipulations usually employed in isolating such substances without being changed in its composition. I, therefore, so proceeded that after every chemical reaction, I tried the action of the product on the animal organism in order to convince myself whether the active principle itself was still present and, if this was the case, whether a complete or partial separation had been produced. Without a control following the researches step and step, one very easily loses the thread and falls into error.

Since in this case almost everything depends upon experiments on animals and upon the proper interpretation of the same, it will be necessary to go into the details of these more closely. Healthy guinea pigs, as I have already shown, may be given very large quantities of tuberculin without any particular action. These are, therefore, not to be used as a medium for testing its active principles. Tuberculous guinea pigs, on the other hand, react in a characteristic manner after comparatively small doses. However, it is not sufficient to inject just enough tuberculin into the animals to cause them to react in a manner in which we are accustomed to see tuberculous persons react, for the temperature exacerbations and the local symptoms in a guinea pig are not sufficiently marked to permit of a certain opinion of the action of a single tuberculin injection. There remains nothing except to give the animal a large enough dose to kill it. In guinea pigs which are tuberculous in a high degree, *i. e.* 8 or 10 weeks after inoculation, 0.01 gram of tuberculin is very often enough for this purpose. In animals with less advanced tuberculosis, 4 or 5 weeks after inoculation, a dose of from 0.2–0.3 gram is usually required. A dose of 0.5 gram kills without exception. Now, if we take animals that have been inoculated at least 4 weeks and inject 0.5 gram of tuberculin, or a corresponding amount of the substance obtained from the tuberculin, which is to be tried as to its effect, then we can conclude as to the presence or absence of the active substance accordingly as the animal dies or lives. Here we have an infallible reagent which, in several hundred experiments, has not up to the present time disappointed me in a single instance.

Further, the phenomena under which the tuberculous animals killed with tuberculin, die, are so characteristic that they cannot well be mistaken for those arising from an accidental cause of death. The animal dies according to the degree of tuberculosis, in from 6–30 hours. If death takes place sooner or later it cannot be positively attributed to the action of tuberculin. In my experiments I could show in all of these cases that death was caused by pneumonia, malignant œdema and other infectious diseases.

On the cadaver of a tuberculous guinea pig killed by tuberculin the following changes are found. On turning back the abdominal walls, the place of injection is very much reddened by the injections of the vessels; it often has a dark, almost violet color. This redness spreads out more or less into the surrounding tissues. The lymphatic glands in the neighborhood of the inoculation-point are very much reddened. The surfaces of the liver and spleen show, beside the tuberculous changes, spots up to the size of a hemp-seed which are deeply reddened and look exactly like ecchymoses which are found in many infectious diseases. Microscopical examinations of these points show that they

* From the *Deutsche Medicinische Wochenschrift*, No. 43, Oct. 22d, 1891.

are not extravasations of blood but are due to enormous dilatation of the capillaries in the neighborhood of tuberculosis patches. The capillaries are packed so full with red blood corpuscles as to give the appearance as though the blood current had come to a complete stand-still at this point. Only in exceptional cases did we find a rupture of the vessels and a hæmorrhage into the tissue. Like changes are found in the lungs, but they are not so marked or so constant. The small intestine is often strongly and evenly reddened. The symptom which never fails and which is really pathognomonic, is the hæmorrhage-like spots on the surface of the liver. They are best seen in animals with tuberculosis 4 or 5 weeks old, whose livers show numerous grey nodules which have not taken on that peculiar, well known yellow and brown marbleized appearance as a result of distributed necrosis. If one has seen the above described changes, a few times, there will scarcely be any doubt whether the tuberculin action is present or not.

My first experiments for isolating the active principles of tuberculin were made with alcohol.

If the tuberculin is mixed with five times its volume of absolute alcohol, a brown rosin-like mass is separated out which adheres tightly to the bottom of the vessel. The brown mass, as well as the fluid above it, which can be poured off clear, show on testing, about the same strength of action as tuberculin. Therefore, a separation in this manner cannot be brought about.

If alcohol in excess is added we obtain, in place of the rosin-like mass, a fine, granular precipitate, which, on repeated washing with absolute alcohol and collecting on a hard filter and then drying in a vacuum over sulphuric acid, produces an almost white powder. In order to obtain this precipitate it is advisable to proceed as follows: The tuberculin is slowly dropped in 20–25 times its volume of absolute alcohol under constant agitation. After the precipitate has settled, the alcohol is poured off and the same amount of fresh alcohol is added. This is to be repeated several times and then the precipitate is dried in the described manner above. If we try to dry the precipitate wet with alcohol, warming on a water-bath, it runs together and becomes brown, while in a vacuum exsiccator it dries to a white, spongy mass which can be easily crushed to a powder. Tuberculin yields about 10 per cent. of a dry powder on treatment with absolute alcohol. The latter, however, is by no means, the active principle in a pure state, for it contains besides a number of extractive substances not soluble in alcohol. It is not possible to precipitate all of the active principles out of the tuberculin with alcohol absolutus. For, if the filtered alcohol be evaporated, a clear, yellow fluid remains which consists of the glycerin and the substances dissolved in it. Half a gramme of this fluid is not enough to kill an animal, yet in one experiment death followed the injection of 1.0 gramme, and in another 1.5 grammes.

Even if all of the active principle cannot be obtained by precipitation with alcohol, still a number of inactive substances can be removed in this manner and above all the glycerine, which has a great influence on the solubility of the substances contained in tuberculin.

It was necessary to bring about a separation of the mixture of substances in the alcoholic precipitate. With the help of Mr. Proskauer and Prof. Brieger, pretty much all of the methods in question were tried for this purpose. Of these I will only specially mention the following: Treatment with ammonium sulph., magnesium sulph., calcium carb., baryt., phosphomolyb. acid., phosphotungst. acid., ferrum acetat., plumb. acetat., tannin, animal charcoal. But none of these methods were successful. Either the active principle was contaminated with too many other substances, as in the case of ammonium sulph., or it lost the action altogether, or it could not be separated from the precipitating substance in an active form. For instance, with tannin all of the active principles could be precipitated and the precipitate, brought into solution through addition of sodium carb., still possessed all of its effectiveness, but we were not able to separate the active substance from the tannin. Perhaps, in spite of these obstacles, these experiments, if continued far enough, would have led to results, had we not succeeded in nearly accomplishing our end in another way, whereby the former methods were pushed into the background for the time being. I observed that, if the alcohol was mixed with tuberculin in a very much less proportion than in the former experiments, *i. e.* in proportion of about 2:3, the rosin-like mass was not separated, but that a white flocculent precipitate formed which readily subsided and, by washings with alcohol of equal concentration, could be easily purified [reinigen]. In these experiments a part of tuberculin (e.g. 10 c.c.) is poured into a beaker glass and under agitation 1½ times

of volume, or 15 c.c. of alcohol is added; the glass is covered and allowed to stand 24 hours. By this time a flocculent sediment forms on the bottom of the glass in the dark brown fluid. The supernatant liquid is carefully poured off and an equal volume of 60 per cent. alcohol is added; it is again stirred up and then allowed to settle. This is repeated (about 3 or 4 times) until the alcohol above the sediment is almost colorless when it is washed several times in absolute alcohol in the same way (generally three times is enough), the sediment is placed on a filter and dried and then put into a vacuum exsiccator where it is freed of all moisture. It then produces a snow-white mass which, after drying at 100° C. (whereby it loses 79 per cent. of water) has, in the powdered state, a light grey color. Small quantities of the precipitate may be freed of its alcohol on a water bath, without its appearance being changed, as was the case with the impure precipitate obtained with 100 per cent. alcohol.

This precipitate formed with 60 per cent. alcohol surpasses all substances produced in other ways from tuberculin so much in efficacy and is so constant in all the reactions made with it up to the present, that we can look upon it as nearly pure; perhaps it is in reality the perfectly isolated active principles of tuberculin. While at least 50 mg. of the precipitate obtained with 100 per cent. alcohol is required to produce the same effect as 0.5 gramme of tuberculin, 10 mg. of the precipitate formed with 60 per cent. alcohol is sufficient; in several experiments the animals died after injection of 5 mg. from marked tuberculin action, indeed in one case death ensued after 2 mg. The yield is about 1 per cent.† If we compare the effect of the amount yielded with the effect of the amount of tuberculin used we find that scarcely one-half of the active principle has been precipitated from the tuberculin with 60 per cent. alcohol, and this agrees with the examination of the filtrate which, after freeing it of alcohol and adding water to the original volume, produces death of tuberculous animals in doses of from 0.75 to 1.0 gramme.

The 60 per cent. precipitate, which has been termed pure tuberculin, has the following properties:

† The yield may be increased by adding more alcohol to the tuberculin, e.g. 65–70 per cent. Then not only large quantities of the active principle are precipitated but also other matters are thrown down and an impure product is the result.

It dissolves in water easily, easiest when rubbed in a mortar with water. This kind of solution does not retain its efficacy very long, for it has been repeatedly observed that after standing one or two weeks it had lost considerable in action. Evaporation seems to affect the watery solution considerably, but it suffers less at the beginning, if sufficient fluid is still present, than towards the end of evaporation when it becomes quite concentrated; then coagula-like flakes separate from it, which do not dissolve on addition of water. A specimen of the precipitate which had been repeatedly dissolved and evaporated to dryness on a water-bath had finally lost its action altogether. After protracted standing and drying at a high temperature, purified tuberculin becomes partially insoluble. At first, I assumed that the insoluble constituents were foreign substances mixed with the tuberculin which could be separated by cautious heating with dry heat, hot steam, etc. Even after it was proven that the insoluble substances (if they had not been altered by repeated heating) had the same action as tuberculin itself, it was still probable that they were coagulated albuminous bodies which had taken part of the active principle with them during precipitation. As we were not able to separate the active principle either by the addition of other albuminous substances, which had been added to the watery solution of tuberculin and then coagulated, nor by the addition of other precipitable substances, this view had to be abandoned. Since the questionable substance has the same action as tuberculin, I am inclined to consider it as a modification of tuberculin, insoluble in water.

If the pure tuberculin is not very carefully produced and preserved it always contains a small quantity of this insoluble substance, and we do not receive a clear fluid by dissolving it. The addition of a small quantity of sodium carb. until distinct alkalinity is generally sufficient to cause everything to dissolve.

Solutions of pure tuberculin in 50 per cent. glycerin are, on the other hand, quite permanent. A solution which I have had for four months has remained unchanged in its efficacy. If the solutions contain a small per cent. of glycerin they may be repeatedly evaporated and dissolved without detriment, and when they contain a large amount they will bear very high temperatures. Several experiments were made in which it was exposed to a temperature of 130° C. and 160° C. for hours without observable diminu-

tion in its activity occurring.‡ Glycerin, therefore plays an important role in the preservation of tuberculin.

If we carefully prepare a concentrated solution of tuberculin and pour a few c. c. of it into absolute alcohol, a precipitate does not appear as soon as we should expect, but a very weak opalescence takes place. The alcohol may now stand for weeks without changing its appearance or without a precipitate forming. Purified tuberculin is, therefore, not altogether insoluble. 80 per cent. alcohol will take up considerable quantities and 60 per cent. alcohol will take up large quantities. Now, how does it come that tuberculin may be precipitated from the crude fluid by alcohol? This problem is very easily solved in that the alcohol containing the tuberculin had received all the constituents of the crude fluid. The addition of glycerin permitted no precipitation. The extractive substances formed a precipitate, but after these had settled, the alcohol still retained its opalescent appearance. Only after the addition of salts did the tuberculin form flakes and separate completely as a precipitate. Of the salts sodium chloride proved to be the best precipitant for tuberculin in alcohol. One drop of a concentrated solution of sodium chloride is sufficient to precipitate the tuberculin in several hundred c.c. of alcohol. This relation of tuberculin to dilute alcohol is to be considered in its purification. As soon as the mineral salts which favor the precipitation of tuberculin are removed by washing with 60 per cent. alcohol the latter begins to become opalescent *i.e.*, it begins to dissolve the tuberculin, and in this way large quantities are lost. If this takes place, the alcohol must be cleared by the addition of sodium chloride and for further washing absolute alcohol employed.

Of the chemical reactions which characterize tuberculin, the following may be mentioned:

First, it produces all albuminous reactions, the biuret reaction, Adamkiewicz's reaction (glacial acetic acid and concentrated sulphuric acid), with Millon's reaction a white precipitate forms which becomes reddish on warming, etc. Phosphotungsten. acid, acetate of iron, ammonium sulph., and tannic acid completely precipitate tuberculin out of its solution; also plumb. acetate produces strong cloudiness but no complete precipitation. Glacial acetic acid also produces at first a strong cloudiness and even a slight precipitate in the watery solution of purified tuberculin, but these disappear on further addition. The substance precipitated by acetic acid showed neither more nor less efficacy than the pure tuberculin, and appears to be very much like the modification which is insoluble in water and may be identical with it. Aqueous picric acid causes a flocculent precipitate which chars upon heating but reappears on cooling. Dilute HCl, and H_2SO_4 produce no precipitate. These acids have the same action in the concentrated form. HNO_3 on the other hand produces a precipitate that increases on standing; by boiling it becomes yellow and on addition of caustic soda becomes brownish-red (xanthoproteic reaction).

Ash analyses and elementary analyses of purified tuberculin were made by Mr. Proskauer and Brieger and were as follows:

1. Ash analyses:

I. Ash from 0.4816 gramme of substance (dried at 100°c.) 0.0802 gramme=16.65 per cent. (Brieger).

II. Ash from 0.1410 gramme of substance (dried at 100°c) 0.0265 gramme=18.46 per cent. (Proskauer).

III. Ash from 0.1740 gramme of substance (dried in vacuum) 0.0350 gramme=20.46 per cent. (Proskauer).

The preparations I and II I made, each being obtained from 500 c.c. of crude tuberculin. Preparation III was made by Mr. Proskauer from 300 c.c. (washed 3 times in 60 per cent. alcohol, 4 times in 70 per cent. alcohol, 3 times each in 80 per cent. and 90 per cent. alcohol and 5 times with absolute alcohol, the latter displaced by ether and then dried). The ash consisted almost exclusively of potassium and magnesium phosphates and contained no chloride. The ash of sample II contained 59.84 per cent. of phosphoric acid.

2. Elementary analyses (calculated for substances free of ash):

	1. Brieger	2. Proskauer	3. Proskauer
Carbon.....	47.02%	48.13%	47.67%
Hydrogen.....	7.55%	7.07%	7.18%
Oxygen.....	14.45%	14.46%	14.73%
Sulphur.....	——-	1.17%	1.14%

For the elementary analyses the same preparations were used as for the ash analyses.

‡Prof. Pfuhl made several experiments at the same time: 1—crude tuberculin, 2—watery solution of tuberculin, 3—50 per cent. glycerin solution of purified tuberculin were exposed to a temperature of 160° C. for 2 hours and then corresponding quantities of each injected into tuberculous animals. The animal which had received the watery solution alone remained alive; both the others injected with the crude and purified tuberculin respectively died, and showed pronounced tuberculin action.

If we take all of the described properties of purified tuberculin into consideration we must assume that it belongs to the group of albuminoids. The high ash contents and the irregular course of a few reactions (plumb. acetate and glacial acetic acid) lead us to believe that the substance had not been obtained wholly pure, but that other matters, though in small amount, may be present and consist perhaps of traces of albuminous and mineral bodies similar to tuberculin, which, as far as the therapeutic value of the preparation is concerned, have no significance. Although tuberculin appears to be closely allied to the albumins, still it is distinguished from these and especially from the so-called toxalbumines, through its behavior toward high temperatures. It also differs from the peptones in many particulars, namely through its preciptability with ferrum acetate.

It is not improbable, that by further research in the field of the products of pathogenic bacteria still other substances will be found which will permit of this classification into a special group of albuminous bodies.

In the chemical examination of tuberculin the trials of the purified substance in regard to its physiological action were confined to experiments upon tuberculous guinea pigs. After we had succeeded as far as possible in isolating the active substance, it was naturally of great interest to learn how it acted upon man, *i. e.*, if the desired therapeutic effects of crude tuberculin took place in the use of purified tuberculin with the absence of all disturbing extraneous action.

For this purpose experiments were first made on healthy subjects and, indeed, on physicians who kindly presented themselves for the trials.

Dr. Kitarate received on June 24th, 1891, at 12 m. an injection of 2 mg. At the time of injection the temperature was 36.5°. It rose at 8 p. m. to 38.3°, remained until 11 p. m. at 38.2 and then fell quite rapidly. At 4 p. m. coughing set in which lasted for 3 hours. Then followed headache, languor and sweating. Otherwise the general condition was undisturbed. (Pulse rose from 72 to 92).

Dr. A. Wassermann received on June 25th an injection of 3 mg. The temperature rose in the course of 11 hours from 37.2° to 38.7°, then fell to normal. At the beginning of the reaction tenderness and a sensation of drawing were observed in the breast and abdominal muscles; also heat and dulness in the head, no chill. (Pulse rose from 80 to 114).

Dr. H. Maass, July 13, 4 mg. Temperature rose in the course of 12 hours, from 37.0° to 39.0°. The subjective disturbances consisted of slight chill and later, fever, languor and headache. (Pulse rose from 72 to 100).

Director Dr. P. Guttmann, July 28th, 5 mg. Temperature rose from 36.5° to 39.2° within 8 hours. Four hours after the injection increasing drawing in of the limbs, after a further 2 hours' chill he was forced to take to bed. Then followed fever and sweating. No headache but vomiting of gastric mucus (for sake of precaution very little food was taken). Also complete sleeplessness. (Pulse went as high as 135).

In all of these cases the patients had either wholly or nearly recovered after 24 hours.

The temperature rise corresponds exactly to the amount used in each dose:

2 mg.	gave	38.2°	maximal	temperature
3 "	"	38.7°	"	"
4 "	"	39.0°	"	"
5 "	"	39.2°	"	"

But the subjective symptoms also kept equal pace with the temperature, and all the known disturbances occurring after injections of crude tuberculin again showed themselves, so that a difference between the purified and unpurified preparation in this respect could not be observed. This was especially the case in one example which differed from the cases just described and, therefore, deserves special mention:

Mr. O. Wassermann of strong physique and without demonstrable evidence of tuberculosis, received on July 27th, 4 mg. of the purified preparation. The temperature rose from 36.9° within 10 hours to 39.5° then fell to 38.4, again rose to 40.2° 27 hours after injection. During the first rise of temperature the subjective disturbances remained within medium boundaries, so that he could take a walk. Shortly before the second rise of temperature a chill occurred, the pulse reached 140, was small and irregular, so that excitants (alcoholics) appeared necessary. Pulse and temperature only returned to normal after the lapse of 48 hours.

If in this case a suspicion of tuberculosis, for which a few symptoms point, or the restless condition of Mr. Wassermann can give the explanation for the irregular and violent reaction, must remain undetermined. This observation, however, undoubtedly teaches that purified tuberculin can, through a too strong reaction, bring about grave symptoms.

With correspondingly small doses and in a cautious manner, we made extensive researches with purified tuberculin upon tuberculous patients in the Moabit Hospital,

who were treated for months partly with pure tuberculin alone and partly in alternation with crude tuberculin. In short, these experiments lead to the conclusion that there was no essential difference in action between the purified and crude tuberculin. The first has the same diagnostic and therapeutic value as the latter, if it is used in such doses that the reaction phenomena, *i. e.*, the temperature, which is the safest guide, reach the same height. While it was observed that the purified tuberculin was, for guinea pigs, 50 times as strong as the crude, for man it was found, at the highest estimate, to be only 40 times as strong.

As regards the dosage the purified tuberculin possesses no advantage. For its effect cannot be gauged on the ground of chemical reactions any more than that of the crude, but must be determined by experiment on the animal organism, and the dose of both remedies is, in every case, to be measured to correspond with the conditions at the bedside, which would not be altered if the action of the purified tuberculin was absolutely uniform.

If the purified tuberculin is any more stable than the crude or not, further experience alone can tell. Up to the present time, crude tuberculin has shown itself to be very permanent in a solution rich in glycerin. At least I have not been able to notice a diminution in the efficacy of the oldest specimens of tuberculin at my disposal.

Interesting and important as the efforts to produce the pure active principle may be from a theoretical point of view they have made no practical advance; but this shall not deter me from pursuing these questions still further.

THE METHOD OF PREPARING TUBERCULIN.

In my last publication upon tuberculin I gave enough as to its origin and preparation to enable a competent person to follow my methods. The announcement that tuberculin is contained in the tubercle bacillus cultures, and that the presence of the same can be demonstrated at all times by experiments on tuberculous guinea pigs, and that the experiments to obtain the active principle from the cultures can always be controlled by inoculation on animals, should have sufficed to enable a skilled bacteriologist to obtain tuberculin or a similar substance. If, in spite of this, only a few bacteriologists have approached the task and, as I am able to judge from the heterogeneous mass of literature, have only partially solved it, still a certain amount of shame rests on the bacteriologists of the day who, instead of independently investigating for themselves, boisterously clamor for a receipe for preparing tuberculin. It is questionable to me if the method which I employ is the best or not. In the course of time I have continually improved it and hold that it can still be improved, and hope that an altogether different and better method may be found. If now, when the judgment of the tuberculin question has become quieter and more objective, I deem the time ripe for the publication of my methods of preparation, I should very much regret it, should others slavishly adhere to my rules and not try to produce something better.

I would further remark that the difficult point in the preparation of tuberculin lies in understanding how to cultivate tubercle bacilli in large quantities. Without extensive cultures, the preparation of tuberculin in any quantity is altogether out of the question. Skilled bacteriologists alone can cultivate tubercle bacilli in large quantity; the unskilled will also be able to produce large, but not pure cultures; with impure cultures he can only do mischief and he had, therefore, better keep his hands off.

Originally, I cultivated the tubercle bacillus on glycerin peptone-agar in test-tubes; after the cultures had reached full development, I washed them off, gathered them on a fine wire sieve, poured a 4 per cent. glycerin solution over them, evaporated to $\frac{1}{10}$ of the mass with this solution, filtered off and thus used the filtrate. The cultivation on agar in test-tubes is very tedious and the yield is comparatively small. As it was necessary to have large quantities, larger vessels had to be used for the cultures. Here there was difficulty in using the nutrient agar, and I went back to old experiments which I had made in cultivating the tubercle bacillus in a fluid nutrient medium. In the beginning the cultivation was not very satisfactory; they grew very slowly and poorly in the liquid. By chance I observed that certain flat pieces of the culture, which remained dry on the upper surface, floated on the surface of the liquid and developed in a most luxuriant manner. They formed in the course of a few weeks a pretty thick skin, above dry, and often folded, of a whitish color, which completely covered the surface of the liquid. After 6 to 8 weeks the growth is at an end; the skin then begins to imbibe the fluid and, finally, falls to the bottom in

ragged flakes. The yield of such a culture is much greater than that obtained upon a solid nutrient medium.

As a culture fluid, an infusion of veal, prepared in the ordinary way, can be used. It must be of a weak alkaline reaction and have the addition of one per cent. pepton and 4 to 5 per cent. of glycerin. Instead of the veal infusion, a one per cent. meat extract solution can also be used.

A bulb-glass with a flat bottom is the best culture vessel. They should be half filled, say with from 30 to 50 c.c. of the fluid and well sterilized, and then so inoculated that not too small pieces of the seed culture float upon the surface of the liquid. The cultures are best kept at 38° C.

In regard to the origin of the tubercle bacilli used in the cultures I have found no difference. It is immaterial as to the efficacy of the tuberculin whether the bacilli are taken from first cultures or from those several years old; likewise whether the cultures are derived directly from tuberculous persons or from those which have been several times passed through the animal body.

In this method of cultivation, part of the active principle goes into the nutrient fluid, which can be easily proven by injecting it into tuberculous guinea pigs. Therefore, after I had noticed this I no longer used a watery solution of glycerin, but extracted the nutrient medium with the tubercle cultures in order to also obtain in this way the active principle contained in it. That the cultures have been sufficiently extracted is proven by the fact that they are only capable of producing a very slight effect on tubercular guinea pigs and that the culture fluid, when evaporated without the cultures, produces a very much weakened tuberculin.

The cultures used for this extraction must be perfectly ripe, *i. e.*, 6 or 8 weeks old. They must, as a matter of course, be absolutely pure, of which we must convince ourselves by microscopic examination of each vessel. Only after long practice will we be in a position to judge of the absence of contamination through foreign micro-organisms without this examination, which as is well known, is far more difficult in a fluid than in a solid medium.

The cultures that have been found to be perfectly pure are to be evaporated to $\frac{1}{10}$ of their original volume, in a suitable vessel, on a water-bath. Since they are hereby exposed to a temperature of nearly 100° C. for hours, we may assume that the tubercle bacilli in the thickened fluid are killed without exception. In order to remove these bacilli as far as possible the fluid is filtered through a clay or gravel filter.

The tuberculin thus obtained contains about 40 to 50 per cent. of glycerin and is thereby protected from decomposition by other bacteria. We have only to be careful that it is not contaminated by moulds. Thus preserved, according to all appearances, it retains its efficacy for a long time, perhaps for years.

Before it is used, its strength, as a matter of course, must be tested. This is done by injecting diminishing doses in tuberculous guinea pigs. If for testing each dose we take at least two animals and the difference between the doses diminishes sufficiently, the strength of the tuberculin may be tested with ample accuracy. In selecting the animals for the test it is, however, necessary that they be, as far as possible, in the same stage of tuberculosis.

INTERESTING CASES OF ABDOMINAL TUMORS.*

BY JOSEPH M. PRICE, M. D.,
PHILADELPHIA.

Mrs. R. [Dr. Keller's patient], suffering from sarcoma of the left ovary. She has complained only for the last nine months, has rapidly lost flesh, and continuously enlarged from encysted peritoneal dropsy.

She gave a history of a tumor and spoke of it as dropping from the right side to the left. The appearance of her face was that of one suffering from ovarian disease. There was in her diseased condition indications of more serious complications.

June 14th we operated for the removal of the diseased condition, and found encysted dropsy and sarcoma of the left ovary as large as a child's head, and as the hæmorrhage was so great from a slight examination, it was thought best to remove it, and it was done in as perfect manner as possible. The ligature of the pedicle controlled the hæmorrhage perfectly; thorough washing of the peritoneal cavity; a drainage tube at the lowest point from which the tumor was taken; careful closure with simple dry dressings completed the operation. The tube was left in four days; the patient made a rapid recovery from the operation.

*Read before the Philadelphia County Medical Society, October 28th, 1891.

I expect this poor woman to have her disease return, and that very soon, and could I have been perfectly sure of what the trouble was, I would not have operated. But when we do undertake anything for their relief, let us at least leave them in as good condition as we found them, and not with dangerous hæmorrhage to destroy them in an hour or so, and all because we have not the courage to complete an operation we had the assurance to begin.

Present: Drs. Jos. Price, Morris, Murry, and Keller.

This patient was examined on the 26th day of October; she is perfectly well and doing her work, with no indication of a return.

Mrs. J. T. [Patient of Dr. Hutzell]; this young woman, twenty-one years old, has been suffering for eight years from a complication of diseases which culminated in an operation for her relief. At fifteen years of age she had a discharge from the navel of pus and hard calcareous matter; this discharge lasted some two years; she had not enjoyed a single day of perfect health for the last seven years, but had for the most part done her housework and assisted her husband in his laborious business for the last year, with a condition of things in her pelvis that is hard to imagine anyone walking about with, much less work. She only submitted to an operation because Dr. Hutzell told her nothing else would help her to get well. Examination of the pelvis indicated pus and a general adherent condition of all the pelvic contents, so that I did not expect an easy removal of the diseased condition, but I was not prepared for such an uphill undertaking as I found was necessary for the relief of this most distressing case.

After the usual opening of an inch and a half, I found the pelvis blocked with a peritoneal cyst with dark and bloody contents; this was emptied and the contents of the pelvis at once investigated. Both tubes were diseased; the left with a more than a pint of offensive pus, the right two or three ounces of pus, both adherent to all the surrounding viscera. The enucleation was most difficult from start to finish. In addition to the pelvic disease and the peritoneal cyst, there was a collection of large, hard concretions, some of them as large as a walnut, completely covered by folds of the bowels and the peritoneum.

In the removal of these concretions there was an additional risk to the patient, they had to be removed from their bed. The bowel folded around them so that it was difficult to tell where to begin without opening the bowel. The effort for their removal consumed considerable time, but all were removed that could be found. Perfect irrigation of the entire abdominal cavity after most of the adherent bowels were torn apart. I say most of them, for it was impossible to complete the separation; they were so well formed that I considered it unsafe to do so much tearing in this complicated condition of affairs. Thorough washing, with the drainage tube in the most depressed portion of the pelvic cavity, a complete toilet, and the patient put to bed. Time of operation, forty-five minutes.

She was by all odds the best patient I had the pleasure of treating. She made a perfect recovery after one week of drainage, with not a single complaint from beginning to end.

Examined on the 26th of October; perfectly well; no pain; able to do all of her work with perfect comfort.

Miss W. R., aged forty years, suffering from a rapidly growing hard tumor filling the pelvis. The cervix high to the right and above the brim of the pelvis and a hard body the size and shape of the uterus. The tumor movable all but the pelvic portion, which was apparently fixed. The patient was only aware of a lump in the side during the last two or three weeks prior to operation; she was sure it was not there a month. When I examined her the day before the operation, the tumor was as large as a womb at the seventh or eighth month of pregnancy, and nodular. She was incapacitated for work, and it was decided to remove it as its rapid growth indicated malignancy.

July 9th, with the assistance of Drs. Jos. Price and Morris, I removed the entire uterus and appendages, and left nothing but the cervix clamped by the Delta metal wire nœud, with dry iodoform dressings to finish the operation.

The tumor was a most interesting one, and in a great measure explains the history the woman gives of its rapid growth. In the pelvis there were three fibroids with all the pathological characteristics of tumors of that nature; the cervix to the right and high up, and the uterine canal not over three inches long, enclosed by the large tumor to the right of the uterus, and front and back of it one of the little fibroids.

The large tumor was entirely different in all of its pathological appearances, and when opened had a distinct capsule, and when the capsule was opened widely gaped, as if there

were great pressure from within pushing out the muscular tumor, or I have no doubt a malignant and rapidly growing tumor inside the capsule.

Tumor examined by Dr. Bigelow: spindle-cell sarcoma.

Patient examined October 28th: at work, free from pain and in good health.

Miss M. D., aged thirty-two years, suffering from left ovarian tumor with myxo-sarcomatous contents. This young woman was accused of being pregnant by several well-known doctors who had treated her for several months. Patient submitted to an operation to remove the suspicion of her unchastity. Operation was an easy one and she made an uninterrupted recovery. Weight of tumor, twelve pounds, with contents.

Mrs. M., aged forty-five years, was taken on the 13th day of Sept. with slight pain in the right side of the abdomen; on examination it was thought the area of dulness over the liver was considerably enlarged; had no increase of temperature or pulse. An effort was made to move the bowels, which was persisted in until the 17th. During this time ten calomel powders were given, four Seidlitz powders, two bottles of citrate of magnesia in divided doses, two ounces of Epsom salts, one drop of croton oil. There was no vomiting and no increase of pulse or temperature. The patient's condition was up to this time good, but a very anxious expression of the face was beginning to appear, and she wished something done for her relief.

Pulse beginning to show signs of weakening; no tympanites. At this time we thought something radical must be done to relieve the obstruction of the bowel. Gall-stone was not suspected. Ether was given. An opening directly over the region of dulness, two inches in length, was made, when a great distended gall-bladder was at once discovered, tapped, and the contents drawn off, which was a clear, gelatinous fluid; had none of the characteristic appearances of bile. The gall-bladder was examined, and two large and one small stones removed.

The direct cause of the obstruction of the bowel was the pressure made by the distended gall-bladder with the gall-stones laying on the transverse colon. This pressure was made possible by the distension of the gall-bladder as it enlarged and was pressed backward by the abdominal wall, making pressure on the colon, and causing the obstruction, which was as complete as any I have ever seen.

Drainage-tube placed in gall-bladder, which was securely stitched in upper angle of wound; two sponges had been placed in the peritoneal cavity to protect it from the discharges; these were removed and thorough irrigation of the abdomen was made. Silkworm-gut sutures; closure of the wound; dry dressings and bandage. The effort to move the bowels was continued until the third day after the operation, when a slight movement was obtained; flatus passed freely. On the fourth day there were free purgations after large and repeated doses of Epsom salts, both by the mouth and injection. Injections were also used freely before the operation, as well as all the other treatments. Calomel powders every twenty minutes; one dozen or more given. Patient made a most beautiful recovery and is now able to attend to her home as before.

Mr. G. C., aged forty-six years (Dr. Prendergast's patient), had been suffering for a long time, when making unusual exertion, with pain in the region of the head of the colon. Four days before operation, while at Atlantic City, was taken with very severe pain in the abdomen; on his arrival at home his physician gave him small doses of mild chloride and soda, followed by Rochelle salts. He was freely purged and all the urgent symptoms relieved, but he still complained of pain at the head of the colon. After a careful examination, Dr. Prendergast decided that his patient was suffering from appendicitis or abscess at head of colon. Patient had quick pulse, subnormal temperature, distended abdomen, anxious countenance, and was a very sick man. At this time I was called in consultation, it being the evening of the fourth day of his disease. An operation was advised and consented to by the patient.

August 29th, at 8 A. M., ether was given. An opening one and a half inches inside of the crest of the ilium directly over the area of dulness down to the abscess cavity, was made, and from four to six ounces of pus and fæces were discharged. The appendix was folded back, and to the outside of the colon, almost entirely separated from it by ulceration. The parts seemed to be so soft and gangrenous in appearance, that I thought it best to leave everything in position, use irrigation, two rubber drainage-tubes, and pack with gauze; but when I washed out the cavity I found that the slight barrier that had separated the abscess from the peritoneum had been broken, the intestines protruding through the wound. I at once decided to wash out the peritoneal cavity and use glass drainage into the pelvis, and dress

the external wound as above stated. Three stitches were applied, but two were cut away that evening. Patient was freely purged the night before the operation, and began purging on second day, and continued naturally, four or five movements per day, until the fourth day; after that salines were given to keep the bowels free.

Patient made a beautiful recovery. For this result I am greatly indebted to his physician for his untiring care and attention and good treatment before, during, and after operation.

Mrs. J. W. H. [patient of Dr. C. H. Dunham, of Trenton, N. J.], suffering from extra-uterine pregnancy. Operation, Oct. 14, 1891. Recovery.

August 1st, was taken with very severe pain on left side, accompanied with diarrhœa; she was four days over her expected period; while at stool felt severe pain in lower left side of abdomen, and immediately became sick at the stomach and faint. Her period made its appearance at this time and continued for three weeks. This is her statement of her condition. She was attended for nine weeks by a practitioner unknown to me, and had frequent recurrences of her first attack. When Dr. Dunham was called to her assistance, she was having daily chills with other symptoms of peritonitis, also a tumor filling the abdomen as high as the umbilicus. At this time Dr. Dunham telegraphed me he had a case of extra-uterine pregnancy, and asked me to come prepared to operate. I went to his assistance October 14th, and found the patient in bed, perfectly comfortable, without any indication of trouble, owing to free purgation which the doctor had given her preparatory to operation. The increase of pulse and the tumor remained as proof of the correctness of the diagnosis.

A small incision was made in a thickened and much changed peritoneum, immediately on the opening of which great quantities of very offensive blood was discharged from the abdomen. Instant search for the impregnated tube was made, brought up, and ligated. Thorough irrigation and drainage; the latter was continued for four days. Great, broad flakes of inflammatory lymph were removed from this cavity. At the time of operation there was a distinct inflammatory diaphragm extending from crest of ilium to crest of ilium, leaving a large cavity lined with this product, which would not permit the internal viscera to return to their place; this cavity was filled with boiled water. Not a single bad symptom an uninterrupted recovery.

Married two years; no children.

Mrs. A. G. B. [patient of Dr. C. H. Dunham, of Trenton, N. J.; his second case of extra-uterine pregnancy in five days,] suffering from extra-uterine pregnancy. Operation, Oct. 19, 1891. Death.

Patient is thirty-six years old; has three children; eight years between first and twins twenty months old. She passed one period August 8th, and September 6th had a slight discharge, pale in color. One week later she had severe hæmorrhage with pain and symptoms of miscarriage; persistent diarrhœa with sick stomach; felt weak and faint. A rupture at this time had unquestionably taken place; hæmorrhage continued with recurring attacks of pain. The doctor had made his diagnosis early in the case, but free purgation had so relieved her that he was persuaded to delay; but her condition continuing to grow worse—pulse 130, temperature normal, patient very pale, a decided boggy feeling in the pelvis, and hardened masses in the abdomen—decided him to have an operation, and he asked me to see her and operate at once. Through a small incision I opened the peritoneum. The abdomen was full of fluid and clotted blood to the diaphragm; no odor; no indications of peritonitis. I immediately removed the impregnated tube, which was on the right side. The fœtus was also found by Dr. Dean, of Spartanburg, S. C., who was assisting us. The blood-clot was adherent to every portion of the peritoneum, and to the anterior and posterior face of the omentum. It could not be removed by flushing or scraping. A large conical clot, as large as my two fists, extended down by the rectum. All the clots and free blood that could be washed out, using three large pitchers of water, were gotten rid of. After free irrigation the peritoneum has anything but a comfortable appearance, as it was perfectly black from adherent blood-clot. There was no odor to the blood, no apparent chemical change having taken place. As to the purging in these cases, I have no doubt it is from the pressure of the clot on the rectum. The absorption of most of the fluids and saline constituents of the blood may have some effect to increase the diarrhœa. The tenesmus and straining at stool unquestionably increases the loss of blood, greatly increasing the danger of the patient.

A seven inch drainage-tube was left at the lowest point of the enucleation, and the

top of the tube just reached the abdominal wall. Boiled Trenton water was used for irrigation, and about one quart was left in the peritoneal cavity. Twenty-four hours after operation the pulse was 120, and temperature 101½°. Heart-clot feared, otherwise patient doing well.

Death from heart failure three days after operation; patient was too comfortable to do well from the beginning.—For discussion, see Society Reports.

WHOOPING-COUGH AND ITS TREATMENT.

BY JOHN M. CURRIER, M. D.,
NEWPORT, VERMONT.

Whooping-cough I regard as a disease depending upon a specific micro-organism. That organism is introduced into the system through the air passages, by inhalation. On the mucous membranes of the air passages the organisms develop, producing succeeding generations and furnishing contagion in the expired air to other persons. The membranes of the air passages become irritated and inflamed by the development thereon. The persistent, periodical cough is the act to get rid of the foreign substance. The characteristic whoop is a nervous phenomenon resulting from the prolonged, unavoidable coughing, which develops only several days after the patients have been coughing.

The indications for treatment are: 1. To destroy the organisms in their homes, rendering them inert, and sterile; 2. To render the mucous membrane of the air passages as little susceptible to the irritation of the organism as possible. The old methods of treatment I have found useless or worse than useless. I have hit upon a form of treatment which has thus far proved satisfactory and seems sufficient to not only mitigate but cut short the disease. The following powder I use by insufflation four or five times a day in mild cases, and oftener in severe ones. It is better to use it in advance of a paroxysm than subsequently. If its use is delayed too long until the effect of the anodyne has passed off it will seemingly produce or hasten the paroxysm.

THE REMOVAL OF THE CRYSTALLINE LENS IN HIGH DEGREES OF MYOPIA.

BY ARTHUR D. MANSFIELD, M. D.,
ASSISTANT SURGEON AT THE PRESBYTERIAN EYE, EAR AND THROAT CHARITY HOSPITAL OF BALTIMORE.

It is not a new idea, it is not an original idea, but it is a novel idea as well as an old one.

Remove the lens in a healthy eye? Produce cataract and its risks that we may obtain benefit? Shall we convert a myope into a hyperope? That is exactly the question.

What shall be done for an eye that is progressing, as is seen in all cases of high degrees of myopia? Shall we allow it to progress and be unable to stay its course? By no means—I think the proper thing to do when the indications are clear, is to remove the lens and stay the progression of the refractive error and check the anatomical changes in the eye which is bound to affect it more or less permanently.

The originator of this ingenious device by means of which a dangerous myopic eye can be changed into a comparatively harmless hyperopic eye I do not know, but Dr. Fukala, of Pilsen-Karlsbad has within the past few years, experimented on some 19 cases, which he recites in the *American Journal of Ophthalmology*, Nov. 1890, a translation by Casey Wood, of Chicago, from Graef's *Archiv. für Ophthalmologie*, xxxvi. In these cases he clearly demonstrates that good results have been obtained in many cases, the improvement ranging in many from four fold to twelve fold, with a medium or average improvement of seven fold.

We are all well aware that myopia is necessarily a progressive trouble of the eye and that the more the eyes are used the faster and more rapid is the increase of the error. In examining myopic eyes we find the fundus in most cases very characteristic, usually a thinning of the choroid and this thinning may be so great as to cause the diagnostic rupture at the nerve entrance, viz: the myopic crescent. Again we may find patches of choroiditis and even choroidal atrophy in the fundus, along with the myopia; when this is the case operative measures are contra-indicated.

I shall confine my remarks in this brief article more to a resumé of the important

suggestion than to the advancement of any new or original ideas. That the subject is an important one cannot be doubted for an instant by any ophthalmologist and even the general practitioner can see the value of such a procedure when done under proper circumstances and advantageous conditions of the fundus of the eye, both of which I will endeavor to point out to you. Ophthalmologists are ever striving to perfect a science that already is as near perfection as can well be expected when compared with others of our general science of medicine. We have few disorders that we have doubt about as to cure, not that I mean to infer that all eye troubles are curable, but when curable it is as positively known, and when incurable a like and similar knowledge is possessed.

Ideas may be suggested and meet with little or no notice, may lie dormant for years and then noticed by some one, brought forward, and prove a boon and benefit to mankind; the science of medicine is full of such ideas and this one, the topic of my article, is an instance, suggested years ago, was little thought of and lately revived and tried by Dr. Fukala, of Pilsen-Karlsbad, may prove one day a blessing to a small portion of mankind. To take up the subject: First, when should the lens be removed? Second, how should it be removed? Third, what are the benefits that will follow?

Taking up the first question as to when the lens should be removed, I may state that the indications briefly given and summarized from the lengthy article of Dr. Fukala in the "*Journal*" are as follows: The degree of myopia must be above 13 dioptres, that they should be young adult persons not over 25 or 30 years old, and able to read No. 1 of Targer's test types as their punctum remotum, that further on examination of the fundus of such an eye the retina choroid and nerve should be healthy and free from all inflammation or results of inflammatory processes.

How should the lens be removed? Dr. Fulkala recommends in all cases an iridectomy upwards, lessening thus the danger from intra-ocular tension consequent upon the discission of the lens, the iridectomy also preventing any occurrence of iritis or choroiditis. The lens should be removed by discission and not by extraction—secondary cataract should always be guarded against. The only objection to the iridectomy is the disfigurement, but the presence of the coloboma as a disfigurement is infinitely outweighed as a precautionary measure. The advantages resulting from the aphakia are summed up briefly:

1. Distinct vision for the eye is obtained.
2. Retinal images are very much enlarged which in itself is a marked advance and benefit.
3. Visual acuity is improved.
4. When using the eyes normally for the distance the myope uses his accommodation, thus the relaxation of the accommodation is marked and complete in many cases, the accommodation being impaired, which latter condition cannot be called strictly an improvement, yet it is an advantage when compared with the previous condition present in the eye prior to the operation.
5. Often in high degrees of myopia the binocular vision is at fault, especially when the degree of myopia in the two eyes is far apart as to quantity and degree, binocular vision for near work is restored by this removal of the lens.
6. The work at the punctum proximum is held at proper distance from the eyes and not at the myopic distance which varies with the degree of refractive error.
7. Spasms of the accommodation and all disturbing elements disappear in this method of treatment; this is of a necessity so, as the accommodation is greatly impaired.
8. The myope is converted into an hyperope which is not progressive and ceases to be a form of annoyance as soon as the eyes are properly adjusted with glasses.

The subject is an important one, I take it, and hope it will call forth the expression of views from any who may have had experience with the subject as presented.

129 S. Broadway, Baltimore, Md.

Society Reports.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 28, 1891.

Dr. M. Price read a paper on Interesting Cases of Abdominal Tumor (see page 930.)

DISCUSSION.

Dr. B. F. Baer: I have been much instructed and interested in this report of the cases of Dr. Price, and I was especially interested in the case of sarcoma. I have had five cases of fibro-sarcoma, and in none of these cases has the disease returned. One

was operated on two years ago, another a year and a half ago, and the others at a more recent period. These were solid tumors. One weighed fifteen pounds, another nearly that, and a third five pounds. They were surrounded by peritoneum, but there were no papillary growths. I would infer from the report that in the case of Dr. Price the tumor was breaking down and papillomatous.

I have recently had a rather rich experience in regard to difficulties in the diagnosis of pregnancy. The most difficult operations that I have done in the last two years have been done in the past two months, in neglected cases diagnosed as pregnancy. One was a case of poly-cyst of the ovary in which the physician was so certain of his diagnosis that the pains of which the patient complained were regarded as labor-pains, and on two occasions the bed was made up for the accouchment. When the patient was *in extremis* it was decided that she was not pregnant. In this case the adhesions were frightful, and the operation was very difficult.

The second case was operated on a week ago, and the tumor weighed about sixty pounds. The patient was thought to be illegitimately pregnant, and was sent to this city two months ago, to be confined away from home. She went down hill very rapidly. Two or three of her physicians thought that she was pregnant, but in this instance, as well as the first, the mistake was due largely to carelessness. They took it for granted that she was pregnant, and did not examine carefully. She was the weakest patient on whom I ever operated. There were firm adhesions to the liver, and I think a piece of the liver was torn off. The adhesions were universal, and the tumor was removed with difficulty. So far the patient is doing well.

Dr. John C. Da Costa: I might speak of one recent case of interest in the matter of diagnosis. The patient was a woman forty-six years of age, who presented the symptoms of fibro-cystic tumor of the uterus. The only point against this view was the comparatively rapid growth of the tumor. There were two or three able men with me at the time of the operation. I found two tumors. The first one was enucleated, and seemed to be a true fibroid. The second looked like a fibro-cystic growth, but when it was cut open it was found to be a fibro-sarcoma. Hysterectomy was then done, and the uterus was found to be filled with sarcomatous tissue, although there had been no evidence of uterine sarcoma. Here we had three different conditions, two malignant and one non-malignant, but capable of change—sarcoma of the uterus, fibro sarcoma, and fibroid.

Dr. Joseph Hoffman: A point brought out by Dr. Da Costa's remarks is that a deferred operation is a dangerous one, because in all of these growths, especially those of a fibroid nature, degeneration is apt to go into something malignant. Sarcoma may take any form known to pathologists. Delay is, therefore, dangerous, and the idea of melting out tumors which are already practically on the road to malignancy by any means except radical removal is foolish, and not supported by the clinical facts. I know of one case of mistaken diagnosis of pregnancy for ovarian tumor, by which, after a very minute examination, the woman was put in the Episcopal Hospital, and allowed to remain three or four months in order to confirm the diagnosis, although the diagnosis had been made. Where the uterus can be felt outside of a fibro-cystic tumor, I do not see how a mistake can be made. In obscure cases it is better to see what we are about by an exploratory operation, than to make a diagnosis and hold on to it until time shows that we are wrong.

Dr. William E. Ashton: The danger of fibroids undergoing malignant change is an argument in favor of their early removal. In the majority of cases, however, it is impossible to urge early operation on account of the past education of physicians. We have been taught that fibroid tumors are of an innocent nature, and that when the woman reaches the menopause they will undergo certain changes which will result in the patient's recovery. I find, however, that the vast majority are not affected by the change of life. I think that in most cases in which oöphorectomy has been done in the hope of bringing about an early menopause, the results have been unsatisfactory. Another point is that a large number of these cases have diseased appendages. Many of these cases suffer pain, and this has been ascribed to pressure, but I think that this pain is due in many instances to localized attacks of peritonitis due to the diseased condition of the appendages. Taking into consideration the fact that there is danger that the growth will become malignant, and the fact that the appendages are usually diseased I think that it is the duty of the profession to educate the coming physician in regard to the necessity of the early removal of the fibroids.

Dr. Price, in his case of appendicitis, refers to the adhesions being frail, and not

trusting them. I think that if there is any doubt as to the pus being excluded from the peritoneal cavity, we should not hesitate to flush the abdominal cavity and drain. In a case on which I operated some time ago, and in which the head of the colon was ulcerated through, I had the same difficulty. I got into the abdominal cavity and found pus. With thorough irrigation and drainage there was complete recovery.

Dr. Ernest Laplace: I was interested in the apparent triple nature of the growth in Dr. Da Costa's case. A word or two will explain this. The growths started as fibroid tumors. The life of this fibroid tissue may be longer or shorter. As soon as it dies it disintegrates and softens. The apparently triple nature of the lesion was due to the growths being of different ages. The growth that had retained its integrity was the youngest, and the others were older and had undergone degeneration.

Dr. Frank Woodbury.—In connection with the remarks just made in favor of operative treatment in uterine fibroids I might refer to one patient whose history shows that circumstances alter cases, and that it is difficult to lay down any general rule that will cover every individual instance. This particular patient has been under my observation nearly twenty years. In 1874 I was called to see a colored woman, about twenty-four years of age, who had almost continuous menorrhagia. She suffered with pain, obstruction of the bowels, and difficult micturition. Examination showed a hard cervix with the uterus enlarged and firmly adherent, occupying nearly the whole upper part of the pelvis. I treated her on common-sense principles, inserting Barnes' rubber air-bags back of the uterus, inflating them twice a day until I had stretched the adhesions, and lifted the uterus out of the canal into the abdominal cavity. She became much more comfortable, and for a year continued the use of ergot and chloride of ammonium alternately. After freeing the uterus I introduced a rubber ring pessary inflated with air. She became greatly improved and passed from under my observation for some two years, when she returned with leucorrhœa. I found that the pessary had ruptured, and was almost imbedded in the vaginal tissue. I removed the remains of the pessary, and found a cicatricial ring forming a support for the uterus. The patient again disappeared, and was not seen until a year and a half ago, when she sent for me. She was then suffering with an acute attack of pain in the abdomen—probably something analogous to the pleuritic stitches which occur in old cases of pleurisy. An able physician had seen her and decided that she was pregnant and in labor. The uterus had steadily increased in size and was much denser than before, and bosses could be made out on the surface. On one occasion I remember that I had a member of this Society, an excellent surgeon and pathologist, examine the patient with me, and he pronounced it a case of sarcoma on account of the stony hardness of the cervix. I subsequently had a consultation with Dr. T. Betton Massey, a fellow-member, well known to us all as an expert in electro-therapeutics, in regard to the applicability of electrolysis to the growth. At this time I tried to introduce an exploring needle into the growth through the abdominal wall, but found the tissue almost like bone; subsequently I turned the case over to Dr. Massey, who treated her with excellent results by the Apostoli method. Under this treatment the tumor has become distinctly smaller. She now suffers no pain or inconvenience, and menstruates without difficulty. As I stated at the beginning, I regard this as an exceptional case; but, on the other hand, I am not as yet prepared to subscribe to the propriety of performing laparotomy in all cases of fibroma uteri.

An interesting point is that in 1874 she was willing to have the uterus removed, and indeed suggested the operation to me, but as I was able to afford her relief without it, I dismissed it on account of the risk; moreover, these operations were not as familiar to us then as now. Her general health has been very good, she has suffered very little, and during these many years she has been comfortable and able to earn her living by housework. The notes of the case may be found by consulting Dr. Massey's book.[1]

Dr. Charles P. Noble.—I wish to say a few words on the subject of the diagnosis of pregnancy. I think that there are cases in which the best of men may make a mistake in diagnosis as to the presence or absence of pregnancy. These are cases in which the pregnancy is complicated by a tumor, or cases in which the position of the uterus is altered, and in which the pelvis is more or less filled with inflammatory masses. I have myself seen one case in which I made a correct diagnosis at the fourth month of pregnancy, and after watching the case for two months gave up that diagnosis. It was afterward demonstrated that she was preg-

[1] Electricity in Diseases of Women, 2d ed., Phila., 1890, p. 147.

nant. The diagnosis in the first place was made partly from the physical signs and partly from the history, which was one of arrested menstruation for four months. There was a pelvic tumor continuous with the cervix, occupying the pelvis—apparently an adherent retroflexed pregnant uterus. After watching the case for two months, and finding that I could not hear the fœtal heart-sounds nor detect the intermittent contractions of the uterus, which should always be felt at this time, I gave up the diagnosis and she passed from under my care. I learned that an autopsy made later showed that the woman was pregnant, and had a tumor of the anterior wall of the uterus, which prevented one from hearing the fœtal heart-sounds and from feeling the intermittent contractions of the uterus. I can easily see how one might make a mistake where there was a uterine or other tumor in front of the uterus, but feel satisfied that if the cases are carefully investigated, mistakes of this kind will be very infrequent. It would be a great advantage to every practitioner if, when engaged to attend women in confinement, he would take every reasonable opportunity to become familiar with the feeling of the pregnant uterus. This is not only a great advantage to the pregnant woman and to the practitioner in the immediate case, but also educates the physician to distinguish between different conditions in the future. Such a course would enable the practitioner to recognize deformities of the pelvis and malpositions of the fœtus, and prepare for the proper treatment, and to become acquainted with the rhythmic contractions of the uterus. The only circumstances in which error might arise would be in cases of retained menstrual fluid, where the history would put you on your guard, and in some muscular tumors of the uterus which are said to present more or less typical intermittent contractions. Broadly speaking, when we have an abdominal tumor presenting rhythmic contractions, we can be satisfied that we have to deal with pregnancy. This sign is more reliable than the fœtal heart-sounds for the reason that if the fœtus is dead or there is a large amount of liquor amnii they are not to be heard.

Dr. James Collins.—After the rich experiences brought forward on the other portions of Dr. Price's paper, I feel that I may detain you for a moment with a reference to the case of impaction of gall-stones. These cases, I believe, are more frequent than one would suppose. I am glad that Dr. Price has given his experience. I recall two or three cases, and one especially, in which, after a long struggle and threatened obstruction of the bowel, a gall-stone the size of a pigeon's egg was passed, and the patient was relieved. In another case I begged the consultants to permit the abdomen to be opened, but they would not agree to it. At the autopsy we found that a large gall-stone had formed; that adhesive inflammation had taken place between the gall-bladder and intestine; ulceration had occurred, and then the stone had entered the bowel and lodged in the ileum, causing complete obstruction. This case occurred ten years ago. I have seen another autopsy in which a similar condition of things was found. I believe that this happens not infrequently.

Dr. Marie B. Werner.—The treatment of ectopic gestation has always interested me greatly. In discussing this subject with Professor Winckel, of Munich, I found his favorite way of treating it was with one to three injections of morphine (0.05) into the amniotic sac, feeling confident that absorption will take place. I asked him what he did in case of hæmorrhage. He replied that the blood could be disposed of by the peritoneum. Subsequently, in conversation with Dr. G. G. Bantock, of London, in regard to the disposal of the blood, I learned that he considered operation imperative. He believed that the blood would not be entirely absorbed, but that portions would become organized and produce adhesions, provided the patient escaped death.

One of the cases reported by Dr. Price to-night clearly shows that nature would have been unable to dispose of the blood, since omentum and intestines were so completely covered with clots that he found it difficult to separate them, and proves to me that, aside from arresting the flow of blood, the necesssity of cleansing the peritoneal cavity of foreign matter is distinctly called for.

These points have been of interest to me, and I thought that they might be of interest to the Society.

Dr. John B. Roberts.—I have been especially interested with reference to tumors of supposed malignant nature in the abdominal cavity. The fact that we often make diagnosis of malignant disease which are not substantiated by the subsequent histological examinations must be borne in mind. I am reminded of a case which occurred in my practice two years ago, where there was an abdominal growth which I believed to be a malignant tumor of the colon. On making an incision I came down upon a growth attached to the internal surface of the ab-

dominal wall, and, cutting through it, I found that it was a large growth of the omentum adherent to many coils of intestines. I felt sure that it was a sarcoma. I removed it as thoroughly as possible, probably getting it all away. It was referred to a competent pathologist, and found to be simply a lipoma of the omentum. I had assisted a friend a few weeks before to remove a tumor almost identical in appearance, and this has shown itself clinically to be malignant. The determination of the question whether or not these supposed cases of malignant disease are really malignant or simply a softening, or colloid degeneration of tumors of a hard nature, is, I think, important.

Dr. Wilson Buckby:—Twenty-one years ago a bit of information was given me by Dr. Atlee, who may be said to be the Father of Gynæcology, notwithstanding the pioneering of McDowell. He said that menorrhagia was due in ninety-nine cases out of a hundred to the presence of fibroid tumors, and that in the early stages they were amenable to medical treatment, and that the degenerative processes which take place are due to the neglect of the proper medical treatment in the early stages. I called him in consultation in a case of extreme menorrhagia, where the woman was almost exsanguine. He advised me to use sea-tangle tents, as was then the custom, and to make a thorough application to the interior of the uterus. He held that nine times out of ten the fibroid tumor was capable of being absorbed by his stimulating application, which consisted of compound iodine, iodide of potassium, and carbolic acid in glycerin. This was swept over the interior of the womb, and internally was given the old-fashioned ergot. My experience has been that in many cases this treatment will enable you, with benefit to the patient, to delay surgical interference.

Dr. Price:—In regard to my case of sarcoma, I would say that spindle-celled sarcoma is one of the most benign tumors of the uterus. I have had a number of cases, some of which were operated on a number of years ago, and they are absolutely free from disease. The tumor which I have reported was entirely of a different nature; it was attached to everything in the pelvis. The least touch would cause bleeding, and you could scrape out great handfuls of brain-like tissue. It was impossible to remove it all, on account of the adhesions. All that could be removed with care was taken away, and the patient is doing well. I do not believe that she will remain well. Fibro-sarcoma or spindle-cell sarcoma of the uterus is a very curable disease, and almost invariably is non-adherent. When removed it gives no further trouble.

In regard to the question of concealed pregnancy, I would say that in neither of the cases I have related did the physician examine the patient at all. Most of us in treating these cases treat them by simply looking at them without any examination; but if we attempt to do this kind of work, I think that we should go to the bottom of the condition. I do not believe that there is such a thing as concealed pregnancy—such a thing as a child of any size in the uterine cavity or outside of it. Is it not our duty to find it. If there is any question of doubt, we should wait until sufficient time has elapsed, for pregnancy, unless of the extra-uterine variety, gives no urgent indications for interference. The case referred to by Dr. Noble is one in which both the mother and child were sacrificed by attempting to remove what was thought to be an ovarian tumor. A little delay would have rendered the diagnosis clear.

I agree with Dr. Ashton in regard to appendicitis. I am confident that we are too timid in these cases. If there is the slightest shadow of a doubt as to the septum between the abscess cavity and the peritoneum, it is our duty to break through and irrigate the whole peritoneal cavity. I have seen my brother operate for appendicitis five times through a median incision, tearing away all the adhesions and doing a complete operation. In the case I have reported, I tried to avoid opening the general peritoneal cavity, but when I passed two fingers to irrigate, I found that the peritoneum was opened, and I therefore loosened up everything and washed out the peritoneal cavity, and the result was favorable. A physician in this State was taken ill and appendicitis was suspected, but a delay of twenty-four hours was advised in order to clear up the diagnosis. The diagnosis was cleared up by the man's death inside of that time. If you suspect appendicitis, explain clearly to the patient the condition you suppose to exist and the danger of the two methods of treatment—the delay method and that by exploratory operation. An exploratory operation under proper surgical methods, with absolute cleanliness, has no business to cause more trouble than a simple vaccination.

Now in regard to hysterectomy. If there is a suspicion of malignancy, it is our duty to remove the uterus. If the tumor is a

pure fibroma and the woman is near the period of the change of life, it is our duty to let it alone. At the change of life the tumor undergoes retrograde changes. The same occur where the appendages are removed. In nine cases out of ten, the appendages are diseased and they supply the stimulation to the growth of the tumor. The removal of the monthly congestion removes the cause of the growth, and at once you have a cessation of the growth of the tumor and the commencement of retrograde changes. The operation of the removal of the appendages is wholly useless in œdematous fibromas and fibroids undergoing cystic degeneration. In such cases it is folly either to wait or to remove the appendages; hysterectomy is the only treatment.

Dr. Collins has beautifully spoken my mind on the subject of gall-stones. In my case the transverse colon was immediately under the tumor and there was nothing to hinder the occurrence of adhesions, ulceration, and the discharge of the stone into the bowel; but in many such cases the patient will probably die from leakage into the peritoneal cavity. The ulceration may be outside of the position of the bowel, and it is our duty to open the abdomen and take out the stones.

A word as to the method of treatment mentioned by Dr. Buckby as having been recommended by Dr. Atlee. I have a supreme admiration for Dr. Atlee and the whole Atlee family. They have done more, with McDowell, for woman-kind in this land than any others, and have established on a firm foundation a condition of surgery that to-day, even in my own hands, has saved more than one hundred lives. The kind of fibroids that will be relieved by such treatment are not fibroids. They are either badly treated abortions or granular conditions of the endometrium: a condition that can be removed by the curette. Such a uterus is as smooth as a ball. It is not nodular.

I could wish no better example than the case cited by Dr. Woodbury as proof of the value of operative treatment. This poor woman was an invalid for twenty-two years, and was then treated with electricity by Dr. Massey—driving an electrode through the abdominal wall into the tumor. This is not Apostoli's treatment, and I congratulate Drs. Woodbury and Massey that they did not have a death instead of benefit from the treatment.

There are over 40,000 physicians in Japan.

Selected Formulæ.

PILLS FOR BLENORRHAGIC ERECTIONS.

The following pills are said to produce good results in the painful blenorrhagic erections:

℞ Camphor.....grammes 2.
Thebaic extract..... " 0.20.
M. Divide into 20 pills. Sig. Four pills to be taken in the evening, one every 15 minutes.

—*Journ. de Malad. Cutan. et Syphilit.*, October, 1891.

INJECTION FOR LEUCORRHŒA.

Heuske recommends the following injection for this disease:

℞ Chlorate of potassium.....grammes xxx.
Tincture of opium..... " xxx.
Tar water..... " cccclxx.
M. Sig. Two or three tablespoonfuls to be placed in a litre of lukewarm water, for vaginal injections, morning and evening.

—*Revista de Ciencias Médicas de Barcelona*, Oct. 25, 1891.

CHLOROTIC DYSMENORRHŒA.

The following mixture is recommended by Monin, for the above affection:

℞ Tincture of honey.
" of saffron.
" of iodine, aa.....grammes xv.
M. Sig. Twelve drops before each of the principal meals. At the same time, every 8 days a warm bath, to which 125 grammes of chlohydrate of ammonium is added should be taken.

—*Journ. de Méd. de Paris*, Nov. 1, 1891.

NAPHTHALIN IN THE TREATMENT OF SEAT-WORMS.

Naphthalin has been applied by Minerbi in the treatment of seat-worms. The author was able to completely cure 11 children, suffering from these parasites, in 8 days. The formula employed by him was as follows:

℞ Naphthalin.....grammes 1 to 1.50.
Olive oil..... " 40 to 60.00.
M. Sig. For a rectal injection.

For adults the following was used:

℞ Naphthalin.....grammes v to vj.
Olive oil..... " lx to lxxx.
M. Sig. For a rectal injection.

—*Journ. de Méd. de Paris*, Nov. 1, 1891.

POTION FOR BRONCHO-PNEUMONIA IN CHILDREN.

According to J. Simon, the following is an excellent potion to be employed in infantile broncho-pneumonia:

℞ Acetate of ammonium.....grammes 0.50.
Tincture of aconite root.....gtt. xv.
Syrup of codeine.....grammes v to viij.
M. Sig. A teaspoonful every hour at the beginning of the disease.

—*Journ. de Méd. de Paris*, Nov. 1, 1891.

THE
MEDICAL AND SURGICAL
REPORTER.

ISSUED EVERY SATURDAY.

THE BUTLER PUBLISHING CO, (Incorporated),
PROPRIETOR AND PUBLISHER.

EDWARD T. REICHERT, M. D., Editor,
(Professor of Physiology, University of Penna.,)
Office, S. W. Cor. 36th and WOODLAND AVE.,
Philadelphia, Pa.

CHAS. K. MOUNT, Advertising Manager.

DIRECT ALL COMMUNICATIONS TO
P. O. Box 843. Philadelphia, Pa.

TERMS: Five dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent 3 months on trial for $1.

REMITTANCES should be made payable to the BUTLER PUBLISHING CO., and when in sums of five dollars or less should be made by **postal note, money order** or **registered letter.**

THE POCKET RECORD AND VISITING LIST.

Two sizes. Prices to subscribers of THE REPORTER: For 30 patients a week (with or without dates), $1.00. For 60 patients a week (without dates), . . $1.25. Prices to non-subscribers, $1.25 and $1.50 respectively.

THE MODEL LEDGER.

Physicians who keep their own books will find this of great value. Enables the Physician to make out his bills with great ease, and gives at a glance the amount **earned, received** and **due** in any quarter. Sample pages sent on application. Price, $5.00.

☞SUGGESTIONS TO SUBSCRIBERS:

See that your address-label gives the date to which your subscription is paid.

In requesting a change of address, give the old address as well as the new one.

If THE REPORTER does not reach you promptly and regularly, notify the publisher *at once*, so that the cause may be discovered and corrected.

☞SUGGESTIONS TO CONTRIBUTORS AND CORRESPONDENTS.

Write in ink.

Write on one side of paper only.

Write on foolscap or legalcap paper.

Make as few paragraphs as possible. Punctuate carefully. Do not abbreviate or omit words like "the" and "a," or "an."

Make communications as short as possible.

NEVER ROLL A MANUSCRIPT! Try to get an envelope or wrapper which will fit it.

When it is desired to call our attention to something in a newspaper, mark the passage boldly with a colored pencil, and write on the wrapper "Marked copy."

The Editor will be pleased to get medical news, but it is important that brevity and actual interest shall characterize communications intended for publication.

LEADING ARTICLE.

THE NEW TREATMENT OF PNEUMONIA BY LARGE DOSES OF DIGITALIS.

We have certainly entered a new era in regard to the treatment of one of the most common and dangerous of affections: pneumonia. The routine practice of blood-letting and the administration of tartar emetic will now be laid aside, to be superseded by the employment of a drug that bids fair to become almost a specific in the disease under consideration.

Traube, Wunderlich and others who first employed digitalis in large doses, noticed good effects, and following the teaching of these investigators, Petresco and more recently Huchadert, Bardet and Tikl, have tried the drug with most gratifying results. Petresco, more extensively, perhaps, than other observers, has especially investigated the subject, and since he first began to employ the remedy he has entirely abandoned all other therapeutic measures. Before 1883, this author was a confirmed believer in the tartar emetic and blood-letting treatment; but all this was immediately abandoned after he began to employ large doses of digitalis. Petresco claims that the drug does good not only in infectious croupous pneumonia, but even in broncho- and pleuro-pneumonias. He asserts to have cut short the disease by this sole treatment, in from 24 to 48 hours, during which time he has observed an abrupt fall of temperature, from 106.5° F. (the highest seen) to 98°, 96 $\frac{4}{5}$°, and even 95° F., together with a marked reduction of the pulse, which from as high as 140, and even higher, was brought down to 60, 40, 30, and, in one remarkable instance, to as low as 24. In the last case the patient fell into a quiet sleep, this being followed by a local and general improvement. The author has compared the results obtained under the action of digitalis with those observed in the treatment by other drugs, such as alcohol, bromide of potassium, caffeine, stropanthus, and also with those offered by the expectant and emetic methods, and finds

that, taken all in all, digitalis is far superior in every respect. His statistics are certainly very interesting and fully sustain his assertions. Thus, in 825 cases treated by him since 1883 exclusively by large doses of the drug, he has only had a mortality of 2.06 per cent. Bennet, it will be remembered, obtained under the tonic treatment, a mortality of 3 per cent. in 129 cases; and a mortality of 6.08 per cent. in 720 cases under the expectant treatment. In the experience of Edinbourg in a record of 698 cases treated by venesection alone, the mortality was 34.05 per cent., which speaks for itself.

Petresco communicated the excellent results obtained by him under the new treatment to the Paris Academy of Medicine in 1888, to the Therapeutic Congress of 1889, and, lastly, to the recent International Medical Congress held at Berlin. Yet, up to a comparatively short time, Petresco had few followers. In November, 1890, Huchardet and Bardet presented to the Societé de Therapeutique the results obtained by Chardet in the clinical wards, and by Bardet in the Laboratory from a series of experiments on animals. Both authors agreed that the doses of digitalis should be considerably larger than those generally employed. Petresco has been in the habit of using from 60 to 90 grains a day, in infusion, for three and four days consecutively. With these quantities the author has never noticed untoward effects, such as vomiting, diarrhœa, disturbances of the pulse, and much less collapse.

The latest contribution to the subject is that of Tikl, of Vienna. His results have been most gratifying. This distinguished practitioner has made, up to the present time, 61 carefully studied observations, of which 47 were cases of fibrinous, and 14 of lobular pneumonia. All these cases were exclusively treated with large doses of digitalis. Only one death occurred out of this number, giving, therefore, a mortality of only 1.65 per cent., a gratifyingly low figure. In the whole series of these cases, some disagreeable, but not fatal, symptoms were observed: in two, there was a moderate collapse; in twelve, vomiting; in four, an intermittent pulse; and in a few, slight diarrhœa. These effects, however, disappear on the suspension of the drug, after which the good results come on rapidly. Tikl prescribed, during 24 hours, 3 grammes of the digitalis in 200 grammes of water in the form of infusion. According to the author, digitalis shortens the period of the disease, and causes it to assume a benign character. From the 2d to the 3d, or, at least, the 5th day, the temperature begins to decline, and *pari passu* with this phenomenon there is a gradual decrease in the cardiac rate, together with a marked amelioration of the general condition of the patient.

These observations of Tikl coincide with those of Petresco and it would seem as if in the use of digitalis, in the quantities indicated, we have a most valuable method for the successful treatment of pneumonia; a method, in fact, superior so far, to all others.

Correspondence.

PROMISCUOUS SPAYING OF WOMEN.

Editor of the Medical and Surgical Reporter:—In the issue of the Reporter for November 14th, 1891, there appears a letter from Dr. Todd with the above title. In it the Doctor reports that four cases of abdominal section for the removal of the ovaries have come under his notice, of which one died and three recovered; also that several patients did not understand the nature of the operation, and that one, a young married woman, was not relieved of irritability of the bladder a few weeks after the operation, and that he had regarded this case as one of nervous temperament, and irritable bladder due to marriage. He makes this report the basis of a severe criticism of modern gynæcologists, imputing to them the base motive of operating for operation's sake, and intimating that the ovaries are removed for all sorts of gynæcological diseases.

It is to be regretted that Dr. Todd has not been more definite, and that he has not furnished the evidence upon which he has based his animadversions. He says nothing at all concerning the nature of the diseases for which three out of four of the operations mentioned were performed. Hence we are left in the dark as to whether the indication was a pus tube, an ovarian cyst, or a tumor

of the womb. The fourth case he says was one of irritability of the bladder which he attributed to a nervous temperament and a recent marriage; but the evidence on which he based his opinion is not given. Did he make a careful pelvic examination? Did the recent marriage relation irritate the bladder through gonorrhœal infection, or by irritating a dermoid tumor previously quiescent? These matters we do not know, nor do we know what the surgeon found when he operated. Hence, with reference to the four cases in question, the intelligent reader is absolutely at sea as to whether the respective operations were indicated or not. All that we know or can reasonably infer is that the treatment which had been employed before these women consulted the surgeon had failed to afford relief, and that their sufferings were such as to induce them to seek relief through operation.

My object in writing this letter, Mr. Editor, is not so much to point out the deficiencies in the criticism of Dr. Todd, as to enter an emphatic protest against the baseless assumption of not a few members of the profession that gynæcologists are engaged in removing healthy ovaries. They say "it is the fashion now to remove the ovaries for all sorts of conditions." Let them fortify their statements with the proofs. I am not familiar with a single gynæcologist who advocates the removal of the ovaries, except for incurable disease of the ovaries themselves, or of the Fallopian tubes, or for the uterine fibromyomota. In exceptional cases, when the social status of the patient prevents her from obtaining the conditions necessary to a cure in cases of defective development of the sexual organs, and of ovaritis, this rule is departed from when life is made miserable by the morbid condition present. Nevertheless, the broad rule laid down is adhered to, and prominent operators one and all deny that they depart from it, and repudiate the allegation that they remove healthy ovaries. This being the case the burden of proof rests with those whose statements in general are unaccompanied by evidence. A very curious and interesting point is that those who say most about the removal of healthy ovaries do not base their statements upon personal observations of specimens removed. To make such charges against the gynæcologists of to-day and to impute the motives underlying their work is to say that that field in medicine which requires the firmest convictions, the greatest courage and judgment, the greatest manual dexterity and the most faithful attention to details, to ensure successful practice, has failed to attract to its service worthy successors and followers of McDowell, Atlee, Sims, Wells, Keith, and others, who have done so much for the science of medicine, and to perfect the art of surgery. If there be black sheep in the flock, gynæcologists will welcome their exposure; but let not the sins of these, if such there be, be imputed to all.

Ill-founded charges of the kind under discussion do great harm. Physicians who are unable to follow the work of surgeons receive a false impression, and they in turn convey this impression to their patients. And so many a poor woman whose life or whose health depends upon surgical aid, rejects it, because she has been led to believe that the surgeon "only wants to use the knife" and that the gynæcologist wishes "to remove healthy ovaries." This is no fancy picture, but one which I have not unfrequently seen.

The limits of a letter will not permit me to refer to the more than questionable use of the terms "spaying" and "unsexed" as applied to women whose uterine appendages have been removed for disease—perhaps more often of the tube than of the ovary—nor can I consider now, the serious statement that in one case the uterine appendages were removed without the knowledge of the patient; but my object is accomplished when I insist that it is a most serious thing to impute the motives of men as a class, and that it should be done only upon the most indisputable evidence; and, further, that great harm has been done, and is being done, not only to the profession but to unfortunate sick women, by what I may call the present fashion of making loose statements about operating gynæcologists.

Very respectfully yours,

CHARLES P. NOBLE, M. D.

IS TYPE-WRITING INJURIOUS TO THE EYES?

TO THE EDITOR OF THE MEDICAL AND SURGICAL REPORTER:—I have been not a little interested in the article in the issue of the REPORTER of November 21st, "Is Type-Writing Injurious to the Eyes." As I am engaged in short-hand and type-writing nearly all the day long, I think that I am prepared to answer, and my reply is in the affirmative; and not only are the eyes troubled, but the head as well. After type-writing all day my head has ached very much, and my eyes have been so weak that when I have struck the open air they became filled with water, and I could scarcely see

around me for a few minutes. This constant strain upon the eyes and head cannot do one any good; and those affected in this way should drop such work.

The question arises in my mind, does not writing at the desk affect one's eyes and head also?. I do not think that it does as much as type-writing, because in the latter one has to keep looking at the keys and at the work that he has done to see that it is correct, and hence a greater strain is inevitable.

A. T. Sherman, M. D.,
Brooklyn, L. I.

Book Reviews.

PRACTICAL INTESTINAL SURGERY. By Fred. B. Robinson, B. S., M. D., Professor of Anatomy and Clinical Surgery, Toledo Medical College, Ohio. Two volumes, 8 vo. pp. 172–206: Being two parts of The Physician's Leisure Library George S. Davis: Detroit, 1891.

The appearance of this work is timely. The last five years have marked a great advance in our knowledge of the surgical diseases of the intestines and in the technique of operations on these structures. This is made available to the profession in the present book, at the modest price of fifty cents.

The author has written from the standpoint of the experimenter upon animals, and he has borrowed almost exclusively from similar workers; hence, we find but little of the traditions of the elders. Volume one treats of the alimentary canal, the peritoneum, the mesentery, peritonitis, adhesions, diagnosis of intestinal obstruction, with abdominal section therefor; technique of intestinal surgery, omental grafting, intestinal anastomosis, intestinal invagination and volvulus. Volume two treats of gastro-enterostomy, patency of the ileo-cæcal valve, intestinal obstruction, resection of intestine, gastrotomy, Senn's hydrogen gas test, gunshot wounds of the intestine and abdomen, actual and experimental, with concluding propositions and an illustrated appendix showing various operations upon the alimentary canal. In short, the work is a full exposition of the subject. The style is plain but not elegant. Records of the various experiments are scattered throughout the book. The author himself has contributed four things to intestinal surgery: segmented rubber and rawhide plates for anastomosis, a new invagination operation, and a modified Jobert's operation. Finally, it is not too much to say that not only for what it contains but for what it suggests, the work should be read by every one dealing with the diseases of the alimentary canal.

PERISCOPE.

THERAPEUTICS.

ADMINISTRATION OF CREOSOTE.

Among the methods proposed for disguising the disagreeable taste of creosote when in mixture, the following appear to be the most preferable (*Rép. de Pharm.*, September 10th):

1. *In Milk.*—Dissolve the creosote in a definite quantity of rum, or in alcohol of 60 per cent. and add a measured quantity of this, containing a proper dose of creosote, to warm milk strongly sweetened with sugar.

2. *In the following Mixture.*

		About:	
Creosote	10 Gm.	160	grains.
Alcohol, 80 per cent	250 "	10	fl. oz.
Glycerin	100 "	3	"
Syrup of Tolu	500 "	10	"
Cherry Laurel Water	70 "	2½	"
Water	70 "	2½	"

Dose: 10 Gm. (or about 135 minims), containing 0.10 Gm. (or 1.6 grains) of creosote. The proportions may of course be somewhat varied to accommodate themselves to our usual measures.

METHYLENE BLUE IN MALARIA.

As it has been shown that both in dried and fresh blood preparations the malaria plasmodia can be perfectly colored by methylene blue, and as in both warm and cold-blooded animals it colors the red blood corpuscles, Drs. Guttmann and Ehrlich hit upon the idea of trying it therapeutically in malaria. Their expectations have been realized, and the investigators have shown that methylene blue exerts a decided action on malaria poison. The febrile attacks ceased the first day of its use, and in eight days at the latest the plasmodia disappeared from the blood. The form of drug employed was the chemically pure prepared by Meister, Eucius, and Bruening. It was given in doses of 0.1 grm. in capsules five times a day in the fever free interval. In the first case it was given every three hours, in two cases of quotidian the five doses were given at hourly intervals. The remedy must be continued in daily doses of 0.5 grm. for at

least eight days after the cessation of the fever. No disagreeable by-effects were observed, except slight bladder irritation. The daily excretion of urine was also observed to be increased. The urine was colored intensely blue. The intestinal evacuations contained the methylene blue in a reduced form, but they became blue on exposure. It was not ascertained whether the drug would prevent relapses.

UNTOWARD SYMPTOMS FROM THE ADMINISTRATION OF MERCURY.

Dr. Streffer, in his inaugural dissertation at the University of Würzburg, gives some statistics of untoward symptoms in the various methods in the administration of mercury, his material consisting of 453 cases from the Lock Hospital. He pays particular attention only to stomatitis, dysentery and brain symptoms, and arrives at the conclusion that the injection method produces the least percentage of untoward symptoms and that salicyl and thymol-mercury are the best combinations for the purpose, the former producing stomatitis even more rarely than the thymol-mercury; while the peptone compound is the best of all soluble mercurial preparations. In children mercurial ointment or baths and the internal administration of calomel were tried, and in one case sublimate was injected, all of these methods proving successful, but none more so than the ointment.—*Lancet.*

BRYONIA ALBA AS A REMEDY.

Dr. Huchard (*Rivista Clinica e Therapeutica* 1891) calls attention to a very old remedy, which has during our own time escaped attention, namely, bryonia. Bryonia is a member of the Cucurbitaceæ. The part of the plant used is the root, which may attain the size of a man's arm, or even the thigh. The root is fleshy and yellow in color, while its juice is acrid and bitter. In the spring it is full of a white, irritating, and drastic juice. Its active principle is called bryonine. This remedy is one of the most ancient of medicines. Dioscorides praises its purgative and diuretic properties. Boerhaave used the dried root in wine as a cathartic in the treatment of dropsy. Harmand du Montgarny (1783) called it "the true European ipecacuanha," and used it in dysenteric diseases. Bryonia is a hydrogogue purgative which causes profuse watery stools, similar to those of jalap or senna. Too strong doses cause poisoning and a choleriform state. Huchard recommends the remedy as a purgative, 3 grammes (45 grains) of the powder at a dose, this dose producing in a case of hypertrophic cirrhosis with constipation five liquid stools and slightly colicky pains; he also recommends it in whooping-cough, febrile diseases and inflammations of the respiratory tracts; in bronchitis, pleurisy, pneumonitis, etc. Bouchet used the tincture in febrile diseases. Dr. Louvet-Lamarre used bryonia in whooping-cough, where it diminishes tracheo-bronchitis, but does not shorten the duration of the disease. The dose is 1 gramme (15 grains) per day for a child of 7 years. During the spasmodic stage Lamarre prescribed the tincture of arosera, 1 gramme (15 drops) per day. Huchard uses a larger dose, 2 to 5 grammes (30 gtt. to 1¼ f℥) of the tincture. The two remedies may be associated, 1 to 2 grammes of bryonia tincture to 2 to 5 grammes of arosera. The powder may be given ½ to 4 grammes per day.—*Cincinnati Lancet-Clinic,* September 19th, 1891.

ATROPINE IN HEART DISEASES.

Dr. Cardarelli (*Norsk Magazin for Lægevindenskaben,* No. 4, 1891) has found that atropine is doses of one-half to two milligrammes (1-128th to 1-32d of a grain) injected subcutaneously removes the inhibitory influence of the pneumogastric. The pulse increases in frequency and the blood pressure diminishes. Hence atropine is indicated in irritation of the pneumogastric. Whenever a slow pulse, with dizziness, convulsions and syncope, are present, atropine is indicated.

OXYGEN AS A REMEDY IN CHLOROFORM NARCOSIS AND CHLORAL POISONING.

The therapeutic action of oxygen, taken by inhalation, has an imperfectly recognized position with the profession at large. The *Medical Press and Circular* for June 3d, speaking for the English medical faculty, states that the remedial employment of the gas has, in Great Britain, "been almost discontinued, chiefly for the reason that until quite recently the difficulty of procuring a supply of the pure gas and the delay, trouble, and expense attending its administration did much to prevent it occupying such a place in the therapeusis of the practitioner as its known physiological effects warrant." At the present time, however, the compressed gas in iron bottles can be obtained from the apothecaries in the English cities "with the same facility as any

other drug." The writer regards with surprise the unaccountable fact that one of the most active of therapeutic agents has been so little used that it may be said to have no place in practical therapeutics. As a quick and efficient respiratory and cardiac stimulant it is deserving of more frequent employment in cases of asphyxia, whether resulting from poisonous gases or general anæsthetics.

In the suffocation of angina pectoris, the writer says, the beneficial action of the gas has been abundantly proved, and among other cases occuring latterly was that of Gen. Philip Sheridan, in which the treatment followed was like that of Dr. Robert Reid, of Dublin, who, in 1817, used and advocated the gas as a practicable remedy for this affection. One of Dr. Reid's cases was that of a man, aged sixty-four, who had suffered greatly from angina, and who obtained an amount of relief from oxygen by inhalation that no other agency gave him. The effect of the gas is, however, generally temporary, but life may often be saved by a temporary tiding over of the suffocative attack. The writer quotes from a recent number of the *Nineteenth Century* a case of gas poisoning which was successfully treated by oxygen inhalation. A soldier was found apparently lifeless and pulseless in consequence of having been exposed for a considerable time to coal gas from a burst balloon. An officer of his command bethought himself of a bottle of compressed oxygen as a possible antidote. A tube having been attached to the bottle, its mouthpiece was conveyed to the man's mouth. The oxygen was liberated through the tube and appeared to force its way into the man's lungs and to become an immediate stimulant to the respiratory organs. In from ten to fifteen seconds from the first outrush of the oxygen gas the man, who had just before presented the aspect of a livid corpse, became agitated with paroxysms of a violence so marked that it was deemed expedient to order four of his comrades to hold him quiet. A half-hour later the man was calmly walking back to the barracks, all danger being at an end. The writer accepts both the authenticity and promptness of the recovery in this case as a lesson in the treatment of cases of poisoning with carbon gases, especially those of the methane series. He also commends it to the attention of all who are concerned in the administration of anæsthetics, and remarks: "How much better a whiff of pure oxygen than artificial respiration in chloral poisoning and chloroform narcosis!"

So far as the writer's knowledge extends, there are only two publications in which any advocacy has been made of this plan of treatment—namely, the work of Mr. George Foy on *Anæsthetics*, and M. Demarquay's *Pneumatology*. The writer adds: "Hospitals are provided with electric batteries to resuscitate the asphyxiated and to stimulate the respiratory function, but a more useful and active remedy, oxygen, finds no place in the emergency apparatus of the operating theatre. We hope, however, soon to be able to report that all our general hospitals are provided with a stock of oxygen gas and a suitable apparatus for its administration."

In a later number of the *Press and Circular* a retired army surgeon adds the suggestion, germane to the foregoing, that a supply of oxygen might with propriety be made a part of the medical supplies of military stations, for emergencies by drug poisoning narcosis, and other forms of asphyxiation. Oxygen may be serviceable in the after-treatment of surgical cases. Dr. A. W. Catlin touches upon this subject in the *Brooklyn Medical Journal* for August, in an article entitled, "Oxygen as a Distinct Remedy for Disease and a Life-saving Agent in Extreme Cases." He observes that after prolonged surgical operations, where the patient has been "thoroughly saturated with the anæsthetic," and where as a consequence recovery is tardy and convalescence is unsatisfactory, oxygen may be administered and will be found to enhance the reparative functions of assimilation and to quicken local repair. Oxygen is a great burden-lifter from the heart in most cases of dyspnœa, and indirectly quiets nervous storms so that sleep is seen not infrequently to follow in the train of an improved aeration of the blood by means of its inhalation.—*N. Y. Med. Jour.*

METHYLENE BLUE IN NEURALGIA.

Dr. Immerwahr (*Deutsche med. Wochenschr.*, October 8th, 1991) has recently studied the action of methylene blue in alleviating neuralgic pain, and is of opinion that under certain circumstances the drug is a valuable agent. Thus, in two cases of facial neuralgia and in three attacks of migraine complete relief was speedily obtained. Nervous headache, alcoholic depression, muscular rheumatism, and herpes zoster were also found to be benefited by the

drug. Hence, although Immerwahr has not yet been able to try it on a large number of patients, he is satisfied with this new antineuralgic agent, and recommends further trials. In sciatica, methylene blue appears of no value, nor is it suited to other than nervous pain, for example, that due to ulceration of the stomach or cancer. Dr. Immerwahr administers the drug as a dry powder enclosed in gelatine capsules (2 to 5 grains for a dose), three times a day. No ill effects have attended its administration, except that after prolonged use some strangury occasionally sets in, which soon yields to small doses of powdered nutmeg. The urine assumes a blue color, which may frighten the patient unless he is forewarned of its occurrence.—*Brit. Med. Jour.*

ON SALINE TRANSFUSIONS IN CHOLERA, HÆMORRHAGE, AND CHLOROFORM COLLAPSE.

Dr. Benjamin Ward Richardson, writes in the *Lancet*, that Mr. Arbuthnot Lane and Mr. Francis Heatherly, in their late able communications to this journal revive a long-forgotten but most important subject—namely, the effect of saline solutions injected into the venous circulation in states of collapse. The phenomena of temporary resuscitation following upon such injections are amongst the most remarkable on record. In a case of Asiatic cholera treated by the late Mr. Henry Ancell, Dr. Rose Cormack, and myself, a woman of middle age sank, in the collapse, into complete insensibility. In this state we injected through a vein in the arm two pints, after Stevens' original plan, with the astounding effect that our patient became quite conscious, sat up in bed, dictated a short will, and signed it in proper form. We left the house, thinking that recovery might follow, giving directions for the steady administration of a mixture of creosote and compound tincture of camphor, a mixture which had been in my hands successful in restraining the choleraic flux. But an hour later Mr. Ancell was back to me requesting me to return with him to the patient's house. The purging had returned, and the collapse was as serious as before. Once more we injected the saline solution, with the same phenomena of resuscitation. Dr. Richardson suggested this time that the injecting tube should be left tied in the vein, that the syringe at the other end of the elastic connecting tube should be filled with saline solution and placed in a hand-basin of water kept at blood heat, and that the injection should be gently repeated so soon as any symptom of collapse should reappear. This was acted upon, and for many hours the current of injection was kept up. It was observed under this line of treatment, which was identical with that to which Mr. Heatherly adverts, this very curious practical fact, that there was never any rallying at all from the injection so long as the current of saline solution was continued as a gentle feeding current. But when they pushed in the solution freely, so that the vessels were brought by the pressure into tension, then the signs of reanimation returned. They returned with decreasing activity no less than six times, but they were always succeeded by the choleraic discharge and with spasm of the lower limbs, so that ultimately death closed the scene about thirteen hours after the first injection.

Bearing on the subject of saline injections and transfusion of blood, Dr. Richardson made at one time a large number of observations. From the fact that the harpooned whale may sometimes live for long periods after profuse loss of blood, owing to the introduction of the saline sea-water into its circulation, Dr. Richardson thought it possible that an injection of a saline solution might be effective in sustaining life after loss of blood; and more than once he witnessed in the lower animals apparent reanimation from what seemed actual death. But this only occurs when there is still some remaining circulation, and when some blood is left in the veins with which the saline substances can admix. From this he drew the conclusion that the saline did its useful work, not by any sustaining power of its own, but by its action in mixing with and forcing blood still in the vessels onward in its course. He tried thereupon to produce an artificial saline fluid, like blood itself, that would convey the proper elements and would oxidize in the pulmonary circuit. In this direction he made one good advance. He discovered that if fresh venous blood were added to a saline solution sufficiently charged with proper saline substance to sustain the even fluidity of the blood, such solution, warmed up to natural blood heat, was the best of all injections for restoring the phenomena of life. In the course of his Croonian lecture to the Royal Society Dr. Richardson suggested that blood added to a saline solution might be dried down so as to be kept, in sealed bottles, ready for use in transfusion; but he believes now it would be most practical to add freshly drawn venous blood to the saline solution at the time it was wanted.

A saline solution, consisting of thirty grains of chloride of sodium and fifteen grains of phosphate of soda in a pint of distilled, water, takes up and holds in even solution at blood temperature ten fluid ounces of fresh venous blood, if the blood, as it flows from the vein, be caught in the solution whilst cold and be gently stirred into it with a clean glass rod. This, he conceives, would be the best of all fluids for venous transfusion in the collapse of cholera and hæmorrhage, in both of which emptiness of the circulatory cavities is the cause of the collapse. In extreme chloroform or methylene collapse, where no blood is lost, a portion of the saline solution alone, with the addition to it of five minims of strong solution of ammonia or a fluid drachm of the aromatic spirit of ammonia to twenty fluid ounces of it, would be a good venous injection in conjunction with artificial respiration. For injection purposes the automatic syringe, which Dr. Richardson exhibited at the Medical Society of London, last session, fulfils every intention. It prevents admission of air into the vein, and in working it the operator has simply to move the piston up and down in order to fill the barrel from the source of supply by the up stroke, and propel the charge onward, by the down stroke, into the circulation.

MEDICINE.

TYLOSIS PALMÆ ET PLANTÆ.

Dr. Radcliffe Crocker (*Brit. Journ. of Derm.* June, 1891, p. 1) relates a case of this disease in which the thickening of the palms and soles was preceded by general irritation of the skin. After six months itching all over the body, bullæ began to appear, and after a condition of dry skin, the patient (a woman, aged 56) began to sweat profusely, and within a year of the first appearance of irritation in the skin, the epidermis of the palms and soles began to thicken. Eighteen months after the first appearance of this disease the body was thickly covered with erythematous patches of a bright red color representing the sites of previous bullæ, whilst there were numerous bullæ from a pear to a pigeon's egg in size present on the trunk, and a few on the limbs. There was profuse hyperidrosis, and the author considers the question of hyperidrosis being an etiological factor in relation to palmar and plantar thickenings as worthy of further investigation.—*Brit. Med. Jour.*

PREVENTABLE BLINDNESS IN THE YOUNG.

Dr. C. D. Conkey, in discussing, in the *Northwestern Lancet*, this important and neglected subject reaches the following conclusions:

1. That the largest proportion of blindness in the young can be prevented.
2. That the majority of cases of blindness develop in the practice of the general practitioner, in the course of the invasion of the grave diseases of childhood, or as a sequence to these, or as a result of a contagious leucorrhœa in the mother.
3. That to successfully prevent them, prophylactic measures should be adopted in all cases where danger is suspected, or where the eye shows a tendency toward inflammatory action.
4. That the physician should be sufficiently acquainted with eye diseases to treat them skilfully when the eye becomes invaded.
5. After all severe attacks of the diseases of childhood the patient's sight should be carefully tested before he is dismissed as convalescent.

If these precautions were carefully observed, he is confident that the percentage of blindness would be greatly reduced among the young, and to the many thousand children that yearly become blind would be preserved this most precious of all the senses.

ANALYSES OF TWO HUNDRED AND SIXTY-CASES OF CHOREA.

Goodall (*Guy's Hosp. Reports*) has analyzed the above number of cases of chorea occurring in the Hospital during eleven consecutive years. Seventy-four of this number were males and one hundred and eighty-eight females. The youngest case was a female infant of one year; the oldest case a man of thirty-six years. There were one hundred and four cases that had recurrence of the disease. The smallest number of attacks occurred during the summer months. Hemichorea was present in sixty cases. In one hundred and fifteen cases the heart was normal, twenty-one of which number had had rheumatic fever. In one hundred and thirty-five cases there was some cardiac or vascular change. As no mention is made of the presence or absence of hypertrophy or dilatation, it is impossible to make out what per cent. of these the author regards as being chronically diseased.

There were eleven fatal cases, in which death was due to changes in the endocardium, emboli probably being formed in many cases. Seventy-one cases had had rheumatic fevers; in only sixteen cases did choreic manifestations precede the fever.

The family history showed chorea in twenty-eight cases, mother, brother or sister having been affected. There was no history recorded of a father having had the disease. As causes are mentioned rheumatic fever, fright (forty-two cases), irritation, pregnancy, injury.

AVOIDANCE OF STIMULANTS DURING HÆMORRHAGE.

It is customary, when the accident of hæmorrhage occurs, for the operator, or some bystander, to administer wine, brandy, or some other alcoholic stimulant to the patient, under the false idea of sustaining the vital power. It is my solemn duty to protest against this practice on the strictest and purest scientific grounds. The action of alcohol, under such circumstances, is injurious all round. It excites the patient, and renders him or her nervous and restless. It relaxes the arteries, and favors the escape of blood through the divided structures. Entering the circulation in a diluted state, it acts after the manner of a salt in destroying the coagulating quality of the blood; and above all other mischiefs, it increases the action of the heart, stimulating it to throw out more blood through the divided vessels. These are all serious mischiefs, but the last named is the worst. In hæmorrhage the very keystone of success lies so much in quietness of the circulation that actual failure of the heart, up to faintness, is an advantage, for it brings the blood at the bleeding point to a standstill, enables it to clot firmly, when it has that tendency, and forms the most effective possible check upon the flow from the vessels. In a case where I had to remove a hard palate, that had become carious, in order to reach and twist a bleeding vessel, although the quantity of blood lost during the hæmorrhage amounted to over three pounds in weight, and the syncope was so extreme the patient did not know anything had been done to him after he returned to consciousness, not a drop of stimulant was administered at any stage, and the care to avoid such administration was carefully sustained after recovery, in order that the rapid action of the heart might not overcome the resistance of the tenderly sealed up vessel. I am certain that this rule of avoiding stimulation was far more effective in saving my patient's life than any surgical skill of mine, for the vessel I twisted might have become plugged up, naturally, during the syncope, but nothing would have prevented the bleeding from breaking out afresh if the heart, instead of being allowed to swing round of itself, slowly and safely, had been whipped, for a brief period, into violent action. I refer to this case as typical, because if a stimulant were not wanted in it, a stimulant cannot be called for in examples less severe. The course followed was simply to lay the patient quite recumbent when signs of faintness supervened, and, so long as he could swallow, to feed him with warm milk and water freely. Such, in my opinion, is the proper treatment to be employed in every instance of syncope from loss of blood—*The Asclepiad*, vol. viii., No. 29, 1891.

SARCOMA OF THE FRONTAL BONE.

M. Ricard presented a patient on whom he had performed the removal of a sarcoma of the frontal bone, leaving exposed a considerable surface of the frontal bone. This loss of substance was supplied from the ilium of a dog completely sterilized. The union was immediate, and three and a half months after the operation the graft was perfect.—*Journal de Medicine, Paris.*

THE HYPERPYREXIA OF RHEUMATISM.

Dr. H. C. Male has prepared for the *Practitioner* a study of eighty-three cases of rheumatic hyperpyrexia reported during the twenty years ending in 1890. In fifty-five of these cases the temperature exceeded 106° F., running as high as 110·4°. In one series of cases, thirty-nine in number, all having as their maximum temperature 106° to 110°, thirty-four were treated by cold bathing, with fourteen recoveries. Of those having the more moderate pyrexia, with the maximum at 106° and 107°, eight out of eleven patients recovered under the cold-bathing treatment; all of those that were not bathed died. In the last ten years cases and recoveries have been reported from time to time in the journals, and no fewer than sixteen cases of temperatures ranging from 106° to 110° are on record. The number of recoveries was thirteen. The pack was used in eight of these, with two deaths; the bath was used in the other cases, with one death. It is not proposed from these figures to base a ratio of recoveries on a study of the re-

ported cases alone, for it is probable that many unsuccessful cases have not been reported, while the majority of the successes have without doubt been given to the journals. But these reported recoveries are a satisfactory witness that lives have been saved which under other conditions must certainly have been lost under the strain of extreme temperatures. The writer urges the importance of making a most careful record of the temperature in all cases of rheumatic fever, and of recognizing at once the earliest indications of approaching hyperpyrexia. So soon as the thermometer shows an undue rise, there should be no time wasted over the administration of drugs, but an attempt should be made at once to check this rise by the application of cold to the surface. The result of such treatment in a favorable case is most gratifying. The patient may seemingly be dying from excessive heat-production one hour, and in the next hour may be in comparative comfort, with prospects of a speedy recovery. One bathing has frequently seemed to turn the scale.—*N. Y. Med. Jour.*

SURGERY.

EXCISION OF PART OF RIGHT LOBE OF LIVER.

On October 9 Professor W. W. Keen, of Philadelphia, removed from a patient a considerable portion of the right lobe of the liver for the excision of a cystic tumor, the entire mass taken away being about two-thirds the size of a man's fist. The woman's temperature has remained normal, or nearly so, since the operation, rising only once to 100° F. There seems every reason to believe that the patient will recover.—*News.*

TRANSPLANTATION OF THE CORNEA.

Von Hippel reports in the *Berliner klin. Wochenschrift*, xxviii. Jahrg., No. 19, his seventh case subjected to this operation. The patient had a dark-brown opacity which covered the pupil, and which had been produced by repeated cauterizations of the cornea with nitrate of silver. He also had cataract. After extraction of the opaque lens, with iridectomy, he had vision equal one-fifth, but he insisted on the removal of the spot on the cornea. The corneal tissue, down to Descemet's membrane, was removed from a circle four millimetres in diameter, and replaced by the full thickness of the cornea from a young rabbit. The eye was afterward dressed with iodoform and both eyes bandaged. Although there was temporary clouding of the thin layer of original tissue behind it, the transplanted flap remained clear. In two weeks the epithelium was continuous from the cornea to the flap. After discission for a secondary cataract, the patient obtained vision equal one-third. It does not appear from the report that the transplantation caused any improvement in vision. But the operation deserves to be called successful in that it secured the continued life and health of the graft, and removed an unsightly scar.

TREPHINING IN A CASE OF GENERAL PARALYSIS.

M. Rey reported a case in which he thought the disease was benefited by the intervention of the surgeon. The dura mater presented no unusual appearance. Beneath the meninges the large vessels presented a gelatinous aspect and showed milk-like plates. The brain formed a hernia which filled up the opening in the skull. A rapid examination was made. The incisions in the dura mater were there reunited by sutures, as were also the rents in the pericranium.

The operation, which lasted an hour, was performed under strict antiseptic precautions. On awakening, the patient was quiet and contented. Eight days later, the cicatrization of wound was completed and the patient returned to ward. A month and a half later he returned to his family, the states of depression and exaltation having disappeared.

Mr. Rey remarks that cases of this kind may be benefited by the surgeon, even though there is no tumor or irritation of the brain, just as cases of symptomatic or essential epilepsy may de benefited. The incurability of general paresis and the recognized futility of internal treatment justify this operation. —*Le Progrès Médical*, August 15, 1891.

AN EASY METHOD OF PLUGGING FOR EPISTAXIS.

Dr. A. A. Philip describes a ready method of plugging the posterior nares, which in his hands is both effectual and easily accomplished. (*British Medical Journal, July* 18.) A piece of old, soft, thin cotton, oiled silk, or silk, about six inches square—a piece of an old handkerchief will answer—is taken, and by means of a probe, mental thermometer

case, or penholder, is pushed, "umbrella" fashion into the nostril, the direction of pressure, when the patient is sitting erect, being backward and slightly downward. It is pushed on until it is felt that the point of the "umbrella" is well into the cavity of the naso-pharynx.

The thermometer case is now passed on in an upward direction and then toward the sides, so as to push more of the "umbrella" into the pharynx, and is then withdrawn. The closed end of the sac protrudes well into the pharynx, and its open end protudes at the anterior nares. The inside of the sac may be brushed with some astringent, such as alum or turpentine.

A considerable quantity of cotton wool is pushed well back to the bottom of the sac in the pharynx. Then, the thermometer case being held well against the packed wool, the mouth of the sac is pulled upon, and thus its bottom is drawn forward, and forms a firm, hard plug wedged into the posterior nares. The sac may now be packed full of cotton wool, dry or soaked in some astringent solution. The mouth of the sac is tied just outside the nostril, trimmed with scissors, and the ends of the thread secured outside.

In removing the plug, open the mouth of the sac, and, with small dressing forceps, gently remove the cotton-wool bit by bit. If there is bleeding, simply syringe the sac with weak carbolic lotion or Condy's fluid, and repack with clean cotton-wool. If there is no bleeding when the wool is picked out, gently pull out the sac, or if it be adhering to the mucous membrane of the nostril, apply a little warm water, and it may then easily be removed.

By this method no damage is done to the floor of the nose or back of soft palate by strings, etc., no disagreeable hawking, coughing or vomiting takes place during introduction, and no disagreeable strings are left hanging inside the mouth.

POSTURE IN THE REDUCTION OF HERNIA.

I had, on Saturday evening last, a case which well illustrated the principles set forth in Dr. George H. Taylor's article, published in the *Journal* for April 25th.

About seven o'clock of the evening aforesaid I was called to see Mrs. R., who that evening had been digging in the garden. An hour or an hour and a half before my arrival she had developed a right, direct inguinal hernia. I found her with a hernia half as large as my fist, hard, tense, and painful; with great pain in the bowels and vomiting. After careful manipulation, finding that it would be impossible to reduce the hernia by taxis, I gave her repeated hypodermics of morphine sulphate to relieve the pain, subdue peristalsis, and prevent tympanites; elevated the hips on a board; applied ice to the tumor; and made repeated pressure, or "pulls," upon the bowels toward the diaphragm. A few minutes sufficed to produce a somewhat lessened tension in the tumor, and I felt that it would only be a question of time when reduction could be effected. Gradual diminution took place, and, finally, at 10.30, spontaneous reduction of the bowel took place, a portion of the sac still remaining down, but the latter was easily returned. I feel confident that this case could not have been relieved by taxis in the ordinary way, but a combination of taxis, posture, anodyne, and antiphlogistic easily effected a cure.

It is quite likely that many other cases, such as we have heretofore been accustomed to operate upon, might be relieved in the same way. There is, of course, nothing new in the postural treatment of hernia, *e. g.*, the hanging a man by his legs over the shoulders of another man—and then taxis. It is only in the application of the principle; the combination of gravity, atmospheric pressure, reversed rhythmical respiratory action; external abdominal pressure with the operator's hand, and persistent, patient waiting.—Dr. Thomas A. Elder, in the *N. Y. Med. Jour.*

GYNÆCOLOGY.

GONORRHŒA IN THE FEMALE.

Bumm (*Centralblatt für Gynäkologie*, 1891, No. 22) thus summarizes the results of his studies of this subject, which extend over a period of ten years:

1. Gonorrhœa in women is a process limited to the superficial layer of the mucosa; the cocci invade the epithelial layer, but are always arrested when they reach the submucosa. The epithelium is originally cast off by reason of the active suppuration, but is quickly renewed, assuming the pavement form; after this change has occurred the active invasion of gonococci is usually arrested, but they continue to grow in the secretion, in which they may persist for months and years.

2. The gonococci have no connection with septic processes; they do indeed cause

suppuration of the mucosa, but are destroyed when they reach the subjacent connective tissue. If sepsis develops it must be in consequence of mixed infection; septic germs are frequently present in gonorrhœal pus, and a favorable nidus for the reception of external germs is offered by the purulent genital secretion.

3. The urethra and cervical canal are the favorite seats of gonorrhœal infection; acute gonorrhœa of the cervix gives rise to symptoms only at the outset, but after it has become chronic it may exist for years without causing disturbances, unless it extends to the corpus uteri and thence to the tubes.

The cocci possess no power of spontaneous movement and extend only short distances by proliferation. Extension over larger surfaces must be through the agency of the secretion. Normally the cervical secretion cannot pass the os internum, which also serves as a barrier to the entrance of the specific infection. Menstruation favors the admission of cocci into the uterine cavity, also certain mechanical causes, such as coitus, the introduction of sounds and intrauterine medication; lastly, this is liable to occur during the puerperium. After they have reached the cavity they again remain stationary, and probably are only carried into the tubes from the causes already mentioned, the puerperium being the most favorable time, as the proximal openings of the tubes are then more patent. In fifty-three patients with gonorrhœa, who were kept under observation for at least five months after the initial symptoms developed, the cervix was infected in 75 per cent., the corpus uteri in 15 per cent., and the tubes in only 3.5 per cent.

Wertheim (*Centralblatt für Gynäkologie*, 1891, No. 24) reviews the subject of so-called gonococci-peritonitis, the existence of which is denied by Bumm, who affirms that when the cocci comes in contact with the peritoneum they are simply encapsulated like any other foreign bodies, the development of peritonitis secondary to gonorrhœa of the tubes being due to mixed infection. Subsequent microscopical studies have shown that the cocci may penetrate the squamous epithelium which covers serous surfaces. Their absence in the exudates of peritonitis is no proof that they may not have originated the inflammatory process prior to their disappearance. After a thorough investigation of the subject, he finds as the result of numerous experiments upon animals that the coccus may, under the same conditions, produce peritonitis the same as the other pyogenic microörganisms. Now, it may be urged that experiments on animals do not form a reliable basis on which to found a theory as to the development of this form of peritonitis in the human subject; but, as an actual fact, mucous surfaces in the former are less sensitive to the action of the cocci than those of man, hence in the latter peitonitis would be more likely to occur from contact with them. Not only may the gonococci penetrate squamous epithelium, but they may make their way into the subjacent connective tissue and there enter the lymph-spaces, extending in the same manner as other pyogenic organisms. This is an important fact, since heretofore all inflammations of the deeper tissues accompanying gonorrhœa have been referred to mixed infection; now, peri-urethral abscesses, suppuration of the glands, parametritis, and even oöphoritis, may be regarded as due directly to the influence of the gonococcus. It is a striking fact that no one has ever found any other pyogenic bacterium except the gonococcus in the contents of a pyosalpinx, even though the condition was complicated with extensive inflammatory changes in the tubes, ovaries and peritoneum.

The writer has found the coccus in the pus from sixteen cases of pyosalpinx, but never succeeded in discovering any other form of microörganism, even after the most careful search; there is no reason to infer from this that other bacteria are supplanted by the cocci, since Menge has shown that the former possess a much greater power of resistance than the latter. The writer has also disproved, by numerous culture experiments, Zweifel's assertion that old gonorrhœal pus forms a particularly favorable nidus for pyogenic and septic organisms; the reverse seems to be the case. It seems only fair to limit the term "mixed infection" to those cases in which, after a distinct preceding gonorrhœal infection, the presence of organisms other than gonococci can be demonstrated; of these the writer has seen but two undoubted examples. Abscesses of the ovary may be divided into two classes, according to their etiology—puerperal and gonorrhœal. The former are not uncommon; the *streptococcus pyogenes* is usually found in the pus. That ovarian abscess may be of gonorrhœal origin is proved by a case cited by the writer in which a girl of sixteen had a double pyosalpinx and abscess of both ovaries; in the contents of the right abscess-sac numerous gonococci were found, while the pus from the left one contained no bacteria whatever. —*Amer. Jour. Med. Science.*

RESECTION OF THE OVARY.

At a meeting of the Surgical Society of Paris, July 29, 1891, M. Pozzi read a paper on the above subject. He stated that it often happens that the ovaries are only partially diseased. It has been proposed, in these cases, that only the affected portions be removed; that is to say, resection of a portion of the ovary. Schroeder has already done the operation for dermoid cysts, others for sclero-cystic lesions, although more often total removal has been practiced for the latter condition.

Pozzi has recently made two resections of the ovary; the operation is a simple one, and attended with the best results. It may be asked: What is the ulterior result of this conservative operation as regards fecundation? It must not be forgotten that every portion of an ovary is capable of producing an ovule. Nevertheless, he would only advise resection of the ovary when the Fallopian tube is permeable.

In one patient he found sclero-cystic ovaries on both sides, prolapsed and bound down by adhesions. The tubes were twisted. He took considerable care in loosening them from their adhesions and in proving that they were permeable. This done, he removed one ovary, and from the other he removed the middle third. Like a quarter of an orange. A catgut suture restrained haemorrhage and assured coaptation of the surfaces. He than adjusted the fimbriated extremity of the tube over the surface of the ovary, and fixed it with four points of catgut suture.

The obliteration or evident alterations in the tube, by pyosalpinx or other disease, would prove an absolute obstacle to the passage of the ovule, and should constitute a contra-indication to this operation.—*Le Semaine Médical*, August 1, 1891, p. 310.

OBSTETRICS.

HYPEREMESIS GRAVIDARUM AS A MANIFESTATION OF HYSTERIA.

German journals have lately been occupied with a discussion between Ahlfield and Kaltenbach as to the priority of having pointed out the connection between the pernicious vomiting of pregnancy and hysteria. It has been recently shown, however, that Friedreich, as early as 1878, declared the vomiting of pregnancy to be a neurosis, and recommended large doses of potassium bromide as the best treatment. Cohnstein (*Centralblatt für Gynäkologie*, No. 36, 1891) reports success with this treatment, but very properly admits that even though in the beginning the disease may be a pure neurosis, it may quickly progress so far as to be beyond a treatment by nerve sedatives alone, and further that in cases of pernicious vomiting in pregnancy dependent upon some abnormality of the stomach or intestinal tract the nervous sedatives are not to be depended upon.—*Univ. Med. Mag.*

DOUBLE UTERUS; PREGNANCY; ABORTION AT THIRD MONTH.

Dr. Thaddeus A. Reamy (*Amer. Journ. Obstet.*, July, 1891) reported the following case before the Obstetrical Society of Cincinnati. The patient was aged 25; she had borne three children, the youngest being 13 months old. The period ceased on November 29th, 1990. Nausea set in and caused emaciation. On January 21st, Dr. Schoolfield was called in, as she was suffering intense pain in the right inguinal region, with shock but no vaginal "show." A mass was felt to the right side of the uterus, extending to the fundus. Dr. Schoolfield had no doubt that pregnancy existed and, but for the absence of hæmorrhage and decidual membrane, would have felt sure that it was ectopic. On February 10th the patient was anæsthetized. The sound could be passed to a depth of but 3½ inches, the uterine cavity being empty. Two days later Dr. Reamy explored the parts. At first he penetrated the same cavity that had already received the sound; it measured 3½ inches. Withdrawing the sound, he turned its concavity towards the right side, and without difficulty introduced it to a depth of more than 5 inches. While it was thus introduced, he found no difficulty in carrying the uterus to the middle line by aid of the sound and of the hand placed externally. The abdominal wall being very thin, the outline of the uterus was easily distinguished. It was not difficult to detect a foreign body in the right cavity. Manipulation by the sound, with the deliberate purpose of inducing an abortion, Dr. Reamy then withdrew the instrument, and advised that the patient should be kept at rest. On the next day Dr. Schoolfield found a fœtus, of nearly three months' growth, expelled into the vagina. The placenta was removed without difficulty and the uterine cavity washed out with a bichloride solution. Taking advantage of the dilated condition of the internal os, Dr. Schoolfield explored the uterus with

his finger and detected a firm antero-posterior septum extending from the fundus to a point corresponding to the ring of Bandl, thus clearing up some obscure points in the diagnosis. The patient recovered. Dr. Reamy, in conclusion, observed that, according to modern teaching the facts that pregnancy existed, that a mass lay to the right side of the uterus and that the patient had been seized with sudden pain and shock, would have justified an immediate abdominal section. The subsequent events showed that such a procedure would have been wholly unjustifiable.—*Brit. Med. Jour.*

CURIOUS CAUSE OF PUERPERAL FEVER.

Professsor Paramuchi has reported a case of puerperal fever in which a very unexpected cause was brought to light—that is to say, the putrid remains of a tapeworm in the uterus. No untoward symptoms seem to have occurred until the tenth day after delivery, when the patient became feverish and prostrate and lost her appetite. The lochial secretion was very foul. Large doses of quinine were ordered, but no effect was produced on the temperature, which the next day was 104.2°. The uterus was consequently washed out, two catheters being used for the purpose, as a regular uterine instrument was not at hand. The outlet catheter, after discharging some very fœtid fluid, was choked up by what was found to be a putrid tapeworm. This was of course removed and sublimate irrigations given, and the symptoms soon disappeared. Regarding the question of how the tapeworm came to be in the uterus, inquiries elicited the fact that a few days before her confinement the patient had been suffering from dysenteric symptoms, and, in view of her condition had not taken any medicine. It is probable that the worm managed to migrate after delivery from the rectum to the vagina, and that there it died and became putrid.—*Lancet.*

PÆDIATRICS.

TETANUS NEONATORUM OF ST. KILDA

St. Kilda is a small island of the Hebrides group on the West coast of Scotland. It lies far out at sea, and the population consists of but eighteen families. From time to time the prevalence of tetanus neonatorum on the island has been noticed. A description of the disease has recently been published by a nurse who has spent a year on the island. Not more than one out of every four our five children born survives, the vast majority succumbing to this terrible malady. The trismus generally appears at about the fifth or sixth day, and coincides in its commencement with the separation of the umbilical cord. At birth the children look plump and healthy, and, so far as can be seen, no abnormality is present at the umbilicus either before or after separation of the cord. The illness begins with a low, whining cry, and usually terminates in death within twenty-four hours. The child is seized with a series of opisthotonic convulsions, in which the fists are clinched, the jaws tightly closed, and the spine curved. The fits recur every quarter of an hour until death from exhaustion takes place.

The natives are not robust. They live in small, dirty, ill-ventilated houses, with every condition favorable to the development of the disease.—*Boston Med. and Surg. Jour.*

MODERN DRUGS IN THE TREATMENT OF PERTUSSIS.

An abstract in *La Pratique Médicale*, June 22d, 1891, makes a resumé of the modern drugs employed in treating whooping-cough. Von Genser was the first to advocate antipyrin, reporting 120 cases thus treated with a mean duration of twenty-four days. Rothe, who had observed some unfavorable results with antipyrin, advocated a combination of iodine and carbolic acid in the following formula:

℞

Carbolic acid.	
Rectified spirits, aa	gr. jss.
Tinct. of iodine	gtt. x.
Tinct. of belladonna	gtt. xxx.
Peppermint water	f℥ ij.
Syrup of poppies	gr. xv.

To a child 2 years old a coffeespoonful of this is given every hour.

Love, of St. Louis, has published fifty cases satisfactorily treated with antifebrin in doses of one-half to five grains, according to age, four times daily.

Heiman has found phenacetin, in doses of one and one-half grains, for a child 3 years old, to be efficient, even when antipyrin had failed.

In 1885, Moncorvo prescribed a local treatment with resorcin, a method which was followed by Bouchut, Callias and Moriac. Several other modern cures may be mentioned to complete the list: sulphurous acid, employed by Mauby; bromoform, by Stepp, Loewenthal and H. Neuman; chloroform water, by Stepp and Shilling; terpin hydrate, by Manassé; and, finally, ouabaine,

recommended in England by Gammel.—*Univ. Med. Mag.*

THE USE OF STROPHANTHUS IN CHILDREN.

Demme reports (*Jahrbuch f. Kinderheilk.*, xxxi., Nos. 1 and 2) that a 1:20 preparation of tincture of strophanthus produces a strengthening of the systolic contraction of the frog's heart somewhat less decided than is produced by digitalis. This effect can be sustained a long time by careful dosage, but as the dosage is increased the contractile force diminishes and gradually a cessation in systole results. The toxic effect of strophanthus on the heart-muscle may occur unexpectedly and more suddenly than with digitalis, hence the necessity of great caution in administering the drug to children. Strophanthus also causes a prolongation of the diastole and a diminution in the frequency of the pulse as long as the energy of the systole increases. The author used the drug in seven cases of uncomplicated mitral disease, in five of scarlatinal nephritis, in three of exudative pleuritis, and in two each of bronchial asthma, pulmonary tuberculosis, and whooping-cough in children between five and fifteen years of age. Dyspepsia was produced in the younger children, so that the treatment could not be continued. The initial dose for children from five to ten years of age was one drop, three times daily; for older children, one drop four times daily. After four to seven days the dose was increased to three drops four or five times daily. Nausea and cold-sweating indicated a suspension of the treatment and the administration of wine, cognac, or coffee. In heart-failure diuresis was increased after three or four days, the pulse becoming slower and stronger and the breathing easier. The dropsical phenomena became less marked. The diuretic effect ceased after three or four days in five of the cases of mitral disease, and compensation could be affected only by the combined action of strophanthus with digitalis. A prompt diuretic effect was produced by strophanthus in two of the cases of chronic scarlatinal nephritis, while in the acute cases no benefit was experienced. The effect in exudative pleuritis was satisfactory, and also in the two cases of bronchial asthma, in which strophanthus was given in connection with iodide of potassium. In pulmonary phthisis no positive result was observed, but in the two cases of whooping-cough, in which there was persistent dyspnœa and œdema of the lower extremities in consequence of dilatation of the heart, the results were satisfactory. The action of strophanthus consists in elevation of the blood-pressure and favorable influence upon the respiratory centre. It can complete the action of digitalis when both drugs are given, and neither cumulative effect nor diminished activity were observed in cases in which it was used during a long period.—*Amer. Jour. Med. Sci.*

HYGIENE.

INOCULATION OF A JAPANESE WITH SCARLET-FEVER GERMS.

A. S. Ashmead, M. D., reports in the *New York Medical Journal*, September 5th, some interesting experiments made with the object of obtaining a modified lymph to prevent scarlet-fever in the Caucasian. He reports two tests of this vaccination as follows:

On May 17th I inoculated with scarlet-fever germs a native of Nagona-Ken, Japan, aged twenty-four years, three years resident in this country. There was no family history of syphilis or leprosy. The germs were taken from the desquamations on the forearm and palm of a German child, aged two years and three months, a patient of Dr. Ernst F. Ruppe. I took them on the twenty-fifth day, pursuant to a suggestion of Professor Edington, of Edinburgh. They were inserted in the left forearm.

The result of this was the development of an areole of intense scarlet, severe inflammation of throat and fauces, headache—but very slight elevation of temperature.

In a second case Dr. Ashmead states: In this second attempt I have produced a condition which may or may not be a modification of the disease, but certainly is not the disease itself.

This case was exhibited, on the sixth day after inoculation, to Drs. Lester and Wolff, at the Willard Parker Scarlet-Fever Hospital. I gave Dr. Lester some of the lymph from the arm. On the seventh day after inoculation the case was exhibited at the Hoagland Laboratory, Brooklyn, to Drs. Bristow, Van Cott and Dickinson. Dr. A. T. Bristow received various products for bacteriological culture, namely, blood from the areola, lymph from beneath the crust, and specimens of the crust itself. I have since left with Dr. Edson, Chief of Contagious Diseases Bureau, New York Board of Health, and Dr. Lester, portions of the

crust. I intend to inoculate this case again with scarlet-fever germs, obtained as before, and note whether the same results will follow.

I may observe that during the whole time of the experiment the patient was in continual relation with my own children, without any contagion taking place.

I have a half-breed child (Japanese and American), aged four, a foundling, whom I intended to inoculate with pure scarlet-fever virus. Dr. Joseph William Stickler, whose investigations in this line are well known, wrote to me in regard to this case: "I do not consider it safe to do such a thing, unless you are certain that the virus has been attenuated in strength to a degree that will render it a safe agent to use; yon cannot tell prior to inoculation just how susceptible your subject may be. Hence the impression made upon the system may be very severe, or very moderate. It may be severe enough to cause death."

I therefore do not feel justified in making this attempt. But perhaps the presumably attenuated virus obtained from my Japanese subject may be used with safety.—*Med. Age.*

ON TAKING FLUID WITH MEALS.

A great deal of misapprehension is often found to exist in the popular mind in regard to matters of eating and drinking; the cause of this to some extent is to be traced to old time sayings, which have come down to us in the form of a concentrated infusion of somebody's opinion upon a subject of which he or she was wofully ignorant. One of these misapprehensions to which we may refer is as to the injuriousness of taking fluid with meals. One frequently hears it laid down as a maxim that "it is bad to drink with your meals, it dilutes the gastric juice." By way of explanation we may remark that "it implies that the fluid taken is harmful." Whence this sagacious postulate originally came we cannot tell; it has quite the ring about it of an inconsequent deduction formed by a person whose presumption of knowledge was only exceeded by a lamentable ignorance of the subject. Medical men often find much difficulty in dealing with these museum specimens of antiquated science, for even educated persons are disposed to cling to the absurdities of their youth. Upon this matter Mr. Hutchison's remarks in the last number of his *Archives*: "I observe with pleasure that the verdict of general experience and common sense has been confirmed by scientific experiment in the matter of taking fluid with meals. Dr. Tev. O. Stratievsky, of St. Petersburg, after elaborate trials, has found that fluids materially assist the assimilation of proteids, and announces the following conclusion, which is to be hoped no future experiments will controvert—on the whole, the widely-spread custom of taking fluids during or just before one's meals, proves to be rational and fully justified on strict scientific grounds. To take fluids with the meals is almost as important an adjunct to digestion as is the mastication of solid food preparatory to swallowing it." It is obvious, however, that there is a limit to the amount of fluid one can swallow with impunity—not to speak of comfort—just as much with meals as at other times. It would be dangerous to create a general impression that fluid is good with food irrespective of quantity. It is, moreover, a well-ascertained clinical fact that an access of cumprandial fluid does retard digestion in certain people, and gives rise to discomfort in most. A little attention to one's sensations in such matters will far better fix the desirable limit than all the "data" in the world.—*Med. Press.*

HANDWRITING AND HYGIENE.

It will be remembered that at the late International Congress of Hygiene and Demography, in Section 4, which was concerned with the Hygiene of Infancy and School-life, a resolution was passed in favor of the teaching of upright penmanship or vertical writing, on the ground that spinal curvature and short sight are caused by the faulty position of the youthful student, which is necessitated by the slope of the letters. We can all of us remember the trouble of learning to write, and the mental and physical toil which the making of our first pothooks and hangers involved. The number of muscles put in action when a person is writing is prodigious, and it is probable that in beginners every muscle of the body must yield its assent before the graphic symbols trickle from the pen. The fingers, wrist, elbow, and shoulder must all be held steady. The spine must be rigid and fixed below as well as above. The pelvis must be firm, and to this end the child often gets a support by its feet from the legs of the chair. The thorax is more or less rigid, and its movements are determined more by the work of the hand than the respiratory needs. Lastly, the knit brows and protruding tongue are unconscious muscular acts which serve to mark the effort, both of body and

mind, which the child undergoes when learning to write. It is notorious that in writing our individuality asserts itself in spite of the pedagogue. We are taught certain rules for sitting at the desk and holding the pen, which we ultimately learn to neglect, and finally write in a fashion of our own. The great drawback of writing as an exercise for children is the fact that it involves one-half of the body only, and the necessity of fixing the spinal column causes the child instinctively to loll upon its left side while the right arm is working. To what extent the asymmetry of posture is caused by the fashion of sloping the letters it would be difficult to say, but there can be no doubt that the writing master ought to carefully watch the attitude of the child and endeavor to make it sit square to the desk and maintain the spinal column vertical. Every child should have a footstool to give firm support to the feet, and the seat should not be slippery, so that the fixation of the pelvis may be easy. Vertical writing is very legible, and if it diminishes to any extent the tendency to sit "lop-sided," it ought to be encouraged. The true remedy for the evils produced by learning to write seems to us to be to teach the child to use both hands, and to practice alternately with either hand. Vertical writing lends itself more readily to ambidexterity than does sloping writing, and there can be no doubt that a clerk who could write with equal facility with either hand, and could rest one side of the body while the other was working, would be little liable to writer's cramp and similar troubles. Seeing how enormous is the muscular effort involved in giving the hand sufficient steadiness, and that the brain fag is scarcely less than the muscle fag, it goes without saying that writing lessons should at first be of very short duration. Ten minutes with each hand ought to amply suffice.—*Lancet.*

MEDICAL CHEMISTRY.

DETECTION OF TIN IN CANNED FOOD.

H. A. Weber, Ph. D., has investigated the canned foods of the market, and found all of those examined by him, except condensed milk, to contain *tin.*

The method employed in the determination of the tin was as follows:

The contents of each can were emptied into a large porcelain dish, and the condition of the inner coating of the can noted. After thoroughly mixing the contents, 50 grains were weighed off and incinerated in a porcelain dish of suitable size. The residue was treated with a large excess of concentrated hydrochloric acid, evaporated to dryness, moistened with hydrochloric acid, water was added, and the mass was filtered and washed, the insoluble matter being all washed upon the filter. After drying the filter with its contents, the whole was again incinerated in a porcelain dish and the residue treated as before. The solution thus obtained was properly diluted and saturated with hydrogen sulphide. After standing about twelve hours in a covered beaker, the precipitate was filtered off, incinerated, and the tin weighed as tannic oxide.—*Journ. Am. Chem. Soc.*

THE PURITY OF PHENOCOLL HYDROCHLORATE AND OTHER SALTS.

Phenocoll hydrochlorate having commenced to be in some demand as a combined antipyretic and anodyne, it may be useful to record one or two tests for its purity and that of other salts of phenocoll. It is stated (*Pharm. Zeit.*, September 19th, p. 586) that half a grain of phenocoll hydrochlorate should dissolve clear in about 12 c.c. of water, and that the solution should not turn ordinary litmus paper blue. Solution of ferric chloride should produce in the phenocoll hydrochlorate solution only the faint yellowish color of iron salts, but not a red coloration even upon warming.

Heated to 60° C. and treated with a few drops of solution of sodium carbonate, the aqueous solution should not give off the odor of ammonia; with a few drops of caustic soda solution the phenocoll base should be thrown down as a white crystalline mass. Burnt on platinum, phenocoll hydrochloride leaves no residue.

For the acetate the same tests apply, except that the aqueous solution is faintly alkaline and the behavior with ferric chloride is not the same. The free base melted under water and allowed to cool solidifies in crystals; it is also precipitated from a dilute aqueous solution by sodium chloride in long, silky needles. Melted with caustic soda, ammonia and phenetidin are formed, and when an aqueous solution is boiled with a few drops of hydrochloric acid for a few minutes it shows faintly the reactions of phenacetin treated similarly.—After *Pharm. Journ.*

PURIFICATION OF THE NILE WATER BY BOILING, IN THE MIDDLE AGES.

Ebn-Radouan-el-Masry, writes Dr. Elloui-Bey in a paper in the *Lyon Medical*, an Egytian physician who flourished in the fifth century after the Hegira, writing A. D., 1068, says:

"The waters of the Nile, to be fit to be used for alimentation, should be drawn where the current is swiftest, for they then contain the least quantity of decomposed matter in suspension, as in the locality known as Rhom-el-Ahmar (now known as Old Cairo), just above Gihzeh."

"The water thus drawn should be submitted to especial operations for its purification, according to the temperament of the consumers. For those who are oppressed with the summer heat, it will be found useful to clarify it by stirring into it chalk, Armenian bole, the bruised seed capsules of the lotus, and vinegar. Those who feel the cold of winter severely prefer to use bitter almonds, thyme, anise, etc. After letting it stand until everything in suspension is carried to the bottom by the clarification above mentioned, the water should be decanted, and is then ready for use."

"It may also be purified by simply filtering it through vessels of unglazed pottery. Another means of purification consists of heating the water over the fire and subsequently exposing it to the night air. If all impurities are not thrown down to the bottom of the vessel, decant the clear part and boil it again. If after this second cooking the water still has a disagreeble taste, it should be brought to a boil, exposed to the night air, and finally clarified by some of the means mentioned above.

"But the best means of freeing water from all principles hurtful to health is without doubt to boil it, to expose it afterward to the cool night air, decant from the sediment, boil again, to purify by one of the means first mentioned, and finally to filter through a filtering vase exposed to the night air. Water thus treated is fit to be used as an aliment. Such water should be preserved during the summer in vessels of burnt clay, or of cooked earth made in the month of Touba (January), in leather vessels of Hedjah, or in any other refrigerating vessel. In summer, water for the day's use should be exposed on the ground floor with the windows opening to the north."*

"But in winter it should be kept, by preference, in warm places, in glass vessels, or clay vessels made in summer time.

"To make water more refreshing we may mix with it a little rosewater, or, better still, put a little chalk into it, the seeds of the white poppy, or of *moghra* (mixture of iron oxide and clay), tied up in a bit of linen in such manner that the water can acquire freshness by contact with these substances without being rendered muddy by them.

During summer time all vessels destined to contain water should be frequently cleansed by first rubbing with broken pottery, and then by barley flour, purslane, and sandalwood. Finally, they should be submitted to fumigations of camphor and sandalwood. In winter such vessels should be rubbed with alkalies and rushes, and fumigated with gum mastic and *aloud* (a resinous wood having an odor resembling guaiac).

"Nile water becomes completely unfit for drinking purposes at the time of the overflow, and when the current becomes very slow at the decrease of the waters. In these two cases it should be boiled and clarified with extra care, and bitter almonds and other substances which destroy its viscosity should be used for its clarification.

"The Nile furnishes, on the contrary, water of excellent quality at all points, during the month of Touba, or in full winter. The Egyptians are not slow to find this out, and a great many of them draw sufficient to keep them in supply for the remainder of the year. They preserve it in large vessels of glass or porcelain. They claim that it is insusceptible of deterioration, and consequently take no precautions of purification of it, maintaining that it is always good. But thou must not follow their example. Take no faith in their say-so, and clarify the water whatever be its state, since thou must know that water thus kept is undoubtedly subject to alteration."

So far we quote Ebn-Radouan. Pasteur, Koch, and their disciples of to-day, after having studied the matter with all the aids of science and all the instruments of our civilization have gotten but little further. Their dictum is to *filter and expose to heat* all waters from open rivers to be used for human alimentation. Ebn-Radouan was 830 years ahead of them.

* The north wind in Egypt, blowing over the Mediterranean and from the cooler European shores, is the most refreshing.

PIPERAZINE AND PHENOCOLL

Are now sometimes given in combination, phenocoll as a symptomatic, to allay pain, piperazine as the curative by virtue of its solvent action on uric acid.

NEWS AND MISCELLANY.

THE LATE DR. S. R. KNIGHT.

At a meeting of the present and former members of the medical staff and ex-residents of the Episcopal Hospital held at the College of Physicians, November 21st, the following minute was adopted:

"The present and past members of the medical Staff of the Episcopal Hospital and its former resident physicians desire to express the deep regret which the death of Dr. S. R. Knight has caused them. All of the many who have been associated with him in his long service as Superintendent of the Hospital feel that they have lost a sincere and honest friend. They remember the kindly advice, the shrewd help and counsel that he had always ready for their difficulties, professional and personal, his constant interest in all the varied work of the institution, and the wisdom with which he made his own duties at once an example and an opportunity to the younger men in the sphere of their labors."

MANUFACTURED EGGS.

The contribution which the hen makes to breakfast possibilities would seem hard to imitate, yet it is freely stated in English journals that the industry of manufacturing eggs has attained large dimensions in that country, and further, that the manufactured article is for most purposes as good as the genuine.

THE AREA AND POPULATION OF THE GLOBE.

The recent publication of the *Bevölkerung der Erde*, of Drs. Wagner and Supan, by Perthes, of Gotha, gives us the most reliable information as to the area and population of the earth now obtainable. The estimate for the total population of the earth in this present year is 1,480 millions, or an increase of 46 millions over the estimate for 1882, when the last edition of these statistics was published. The exact enumeration of 835 millions (about 56 per cent. of the whole population of the globe) has now been accomplished by census or registration. The population of the chief divisions of the globe is, in round numbers: in Europe, 357 millions, giving 94 inhabitants to each square mile of area; Asia, 825 millions, or 47 to the square mile; Africa, 163 millions, or 14 to the mile; America, 121 millions, or eight to the mile; Australia, 3 millions, or 1 to the mile; and in the Oceanic Islands, 7 millions, or 10 to the mile. In Europe, Belgium exceeds all other countries in density of population, with 530 persons to a square mile; next follows Holland, with 365; and the United Kingdom, with 312; but whereas in England the density is 480, in Scotland it is only about one-fourth, and in Ireland about one-third that of England. In Norway and Finland, the most thinly populated countries of Europe, there are only about 16 persons to the square mile. Of China the estimate is 361 millions, giving a density of about 77 to the square mile. It is in respect of Africa that the greatest doubt necessarily exists. These statistics make it manifest that there are still vast areas of the habitable surface of the earth almost, if not quite, unpeopled; and which will for many a long year to come receive the surplus millions of Europe and other parts of the globe in which the density of population is most keenly felt.—*Brit. Med. Jour.*

A BUDDHIST TREATISE ON MEDICINE.

All those interested in the history of medicine, and particularly Indian medicine, will hail with scholarly delight, says the *British Medical Journal*, the announcement that an old Sanscrit treatise on the healing art has recently come to light under somewhat remarkable circumstances. The "find" is in itself hardly of such value as the work of Aristotle not long ago exhumed from the grave of oblivion in which it had lain so long entombed; but your true Dryasdust cares little for the literary or scientific quality of his treasure trove, if it but have the consecrating seal of hoary antiquity upon it. Last year, it will be remembered, Lieutenant Bower was fortunate enough, in the course of an exploring expedition in Kashgaria, to light upon a buried city in the neighborhood of Kuchar. Among the other antiquarian treasures found there was an ancient birch-bark manuscript, which was presented to the Asiatic Society of Bengal. The manuscript, which consists of thirty-three leaves closely written over on both sides, is in Sanscrit verse, and in the character known as the Nagari alphabet, of which three varieties occur in different parts of the work. The manuscript has been translated by Dr. Rudolph Hoernle, and appears to be a compendium of medicine, bearing the title of "Navanitaka," and divided into sixteen chapters. The author seems to have been a Buddhist, but, with a modesty not always found among medical writers, he has concealed his name so carefully that Dr.

Hoernle has not, up to the present, succeeded in discovering it. The work is divided into sixteen chapters, which are devoted to clysters, elixirs, eye-washes, hair-dyes, bitumen, castor-oil, women and children, etc. The prescriptions which are given in verse, recalling to the profane mind the gnomic scraps of clinical and therapeutic lore quoted by Albert Smith in his "Physiology of the Medical student," celebrate the wondrous effects of clarified butter, which our Buddhist brother seems to have considered the "sovran'st thing on earth" for all manner of bodily ailments. A draught containing this panacea, together with oil, treacle, vinegar, and ginger, will, we are assured, instantly conjure away the most acute lumbago. An ointment composed of thickened goat's milk and wheat flour, to which sesamum may with advantage be added, is a specific for gout and rheumatism. In addition to the pharmacological and therapeutic precepts which the work contains, the reader has, it need hardly be said, a goodly *armamentarium* of charms and spells of approved efficacy applied to him, so that if medicine fails, recourse may be had to the "faith cure." The date of the manuscript is fixed by Dr. Hoernle between 450 and 550 A. D. It is thus, so far as is known, the oldest Indian written book in existence.—*Med. Rec.*

SCHENCK'S PULMONIC SYRUP.

It is said that Schenck's Pulmonic Syrup consists of wormwood, catnip, tansy, hyssop, hoarhound, hops, chamomile, comfrey, senega and elecampane, of each four drams. Boil with sufficient water to make, after straining, one quart; add gum arabic one and one-half ounce, and licorice one and one-half ounce. Then add one good sized Indian turnip, and finally sugar three pounds, brandy one-half pint, juice of two lemons. This is evidently based on a poly-pharmaceutical perscription of the early nineteenth century.

SYPHILIS IN THE UNITED STATES.

It is stated on good authority that the number of persons affected with syphilis in the United States at the present time is about 2,000,000.

At the close of the World's Fair at Paris, it was stated that that city had within its limits, 50,000 women with syphilis. We have no means of knowing how many syphilitics there were in America before the World's Fair, or how many so afflicted resided in Paris before that eventful period, or neither are we able to estimate the number of persons from America who visited Paris on that occasion; hence we can only dismiss the subject after having stated facts and figures, as it is our duty to do.—*Med. Rev.*

THE CONSUMPTION OF TOBACCO IN FRANCE.

Last year French smokers consumed 4,600,000 francs worth of cigars, 10,000,000 of cigarettes, 29,000,000 of snuff, and 91,000,000 worth of pipe tobacco. The greatest snuff-takers are old peasant women and priests. Snuff is often allowed to Sisters of Charity, as it renders the nose insensible to the bad smells of slums and hospitals, and acts as a disinfectant of the air taken in by the nostrils. The greatest number of pipe-smokers are along the coast from Nantes to Calais. Fisherwomen as well as sailors use the pipe. The consumption of ladies' cigarettes rose from 101,900 francs to 800,000 francs last year, and the orders received at the tobacco manufactory promise a still further increase under this head. There is one anti-tobacco society in France.—*The Sun.*

WILD AND CULTIVATED HERBS.

At the recent meeting of the German Scientific Congress Dr. Schweissinger, of Dresden, read a paper dealing with the examination of a few narcotic herbs, showing the effect upon their alkaloidal value. The results obtained, so far as henbane is concerned, practically corroborate Mr. Gerrard's work. They are as follows:

	Per cent. alkaloid.
Herb. aconiti, wild	0.58
" " cultivated	0.60
" belladonnæ, wild	0.40
" " cultivated	0.17
" hyoscyami, wild	0.085
" " cultivated	0.070
" stramonii, wild	0.32
" " cultivated	0.26

Dr. Schweissinger extracted the herbs with water acidulated with sulphuric acid, evaporated, removed pectin by filtration, then added ammonia, and extracted the alkaloid with ether-chloroform, checking the result by titration. In the course of the discussion it was stated that wild stramonium is preferred in Germany, and Mr. Dieterich mentioned that cultivated belladonna and henbane yield not only very good extracts, but extracts which are rich in alkaloid.—*Chem. and Drugg.*

PISTOL BALL LODGED IN AND REMOVED FROM THE NECK OF THE FEMUR—UNDESCENDED TESTICLE REMOVED—APPENDICITIS; OPERATION.*

BY THOMAS G. MORTON, M. D.,
ATTENDING SURGEON, PENNSYLVANIA HOSPITAL.

Gentlemen :—On the first of September this patient, aged 29, then at Newport News, Virginia, received a shot from a revolver; the ball entered the left thigh about three inches to the inner side of the great trochanter on the anterior face of the thigh; two attempts were made at the time to remove the ball, and on the fourth day the man came to the Hospital.

When admitted, his temperature was 101°; the tissues of thigh were swollen and much inflamed, and unhealthy pus was discharging from the wound. A probe carried in deeply at right angles to the femur, came in contact with bone.

I made a six inch incision, and following the bullet track, at considerable depth came upon a pus collection; on reaching the neck of the femur, found the ball had entered and evidently lodged in the bone; there was no other solution of continuity.

With a chisel and a gouge the track in the neck of the femur was opened up and the ball was found about an inch and a half above where it had entered; it was with difficulty displaced and then extracted. The wound was thoroughly curetted and cleansed.

You will notice that there is yet a small amount of discharge from the wound, but it is quite healthy.

In looking over the literature of the subject, I am unable to find any record of a ball penetrating and lodging in the neck of the femur and being removed; Hennen states in his Principles of Military Surgery, that he has seen "balls lodged in every part of the femur, head, neck and shaft, but in all such cases after the most careful examination it was impossible to establish the diagnosis during life."

The records of the Crimean war and of the war of the Rebellion do not, it appears, present a similar case to the one before you.

The ball is a conical one and weighs 136 grains; it is considerably flattened and distorted.

UNDESCENDED TESTICLE REMOVED.

This boy has been suffering a long time from a small tumor in the groin; on examination I find that upon the same scrotal side the testicle has not descended, and undoubtedly the tumor at the external abdominal ring is this organ; usually we find the testicle more or less atrophied when it is not in its normal position, and this case is no exception. From its unnatural position it has become very painful and is constantly subjected to pressure which gives pain. It is well to remember that malignant disease very commonly attacks such undescended organs so that extirpation is generally advisable.

In performing this operation the skin is freely divided, and in doing this the organ is exposed. You see it is somewhat atrophied, and so firmly attached to the external ring that I cannot displace it, and it is better to get rid of it altogether,

The operation consists in dividing the skin as in the ordinary hernia operation, and then carefully ligating the cord, before removing the organ, then closing the wound by gut sutures.

RELAPSING APPENDICITIS; EXCISION OF THE APPENDIX IN THE INTERVAL BETWEEN ATTACKS; RECOVERY.

I now direct your attention to a useless and dangerous organ found in the abdominal

*Delivered at the Pennsylvania Hospital, October 10, 1891.

cavity, known as the vermiform appendix, which is rudimentary in man, but in some animals is of large size and performs an important function in digestion. The appendix is liable to irritation, inflammation and perforation; indeed it is subject to the same maladies as the intestine itself, of which it is a part. The occurrence of inflammation and perforation is commonly due to the presence in the appendix of some foreign body, which may be soft or hard, made up of fæcal matter or it may be some hard substance which has been forced into it from the cæcum; simple catarrh of the mucous membrane of the appendix may cause swelling of the organ, a retention of the secretions, ulceration and perforation; the result of a perforation of the appendix is peritonitis and abscess. Until very recently little or nothing was done surgically for such cases; most died; in others the abscess being shut off from the abdominal cavity, found its way either to the surface and there discharged, or to some internal organ, the bladder or intestine.

You will appreciate how recently attention has been given to the surgery of the appendix when I tell you that the first operation for its premeditated and successful removal was done by me as recently as March 1887.

The appendix varies in length from an inch and a half to several inches. Here is a specimen from our museum, nine inches long; authentic cases are recorded of absence of the appendix; the late Professor Joseph Leidy, under date of February 27th, 1891, in a note to me, says: "I have observed the appendix varying from about three to nearly six inches in length, but have never seen such a case in which it was absent. In the infant it appears to be less abruptly an extension of the cæcum, that is to say, from the subsequent greater proportionate enlargement of the latter, the appendix becomes a more abrupt extension."

To show you how frequently the appendix contains foreign material, I would say that in a number of post-mortems made in this Hospital, the appendix generally contained concretions; in several there was only a single mass, while in the others there were several. The appendix in its muscular contractions may expel its contents, but now and then being unable to do so, irritation ensues, and as time goes on, inflammation and its results follow.

In appendicitis, relapses are not uncommon, and at variable periods, and in such cases, since the case is generally retained substances, and as perforation is liable to occur at any time, the removal of the organ should be considered in the interval between attacks, for obvious reasons, and the appendix can always be found directly under a point, two inches on a horizontal line from the anterior superior spinous process; this I pointed out some time ago, and you will find this direction an important one to remember.

The case I now present to you is one of this character; the patient, a man of 26 years of age, had an attack of pain in the right iliac region in February last; he soon recovered from this, was in this hospital with a more severe attack in June, and in August a third attack. He was recently admitted with a small, hard tumor directly over the appendix which was unquestionably an enlarged organ with a retained foreign body. After a lateral section the appendix was found enormously enlarged, tightly bound to the cæcum from which it was with difficulty separated sufficiently to allow a ligature to be placed near its cæcal attachment. On opening the appendix this stone was found; it measured an inch in length and one inch and a half in circumference. The walls of the appendix were greatly thickened.

PERITONITIS FROM PERFORATION OF THE APPENDIX; PERICÆCAL ABSCESS; EXCISION OF APPENDIX; RECOVERY.

I now show you another case in which I recently operated. This boy aged 10 years, a Hungarian, from whom, or his friends, but little history could be obtained, was admitted with symptoms of pericæcal inflammation. He had, shortly before admission eaten an enormous quantity of fruit, had sick stomach and pain; when brought here he had local peritonitis, involving the appendix region. Symptoms of pus formation soon presented; irregular temperature; general abdominal swelling and pain, most intense over the right iliac region; constipation, chills and rigors. An abdominal section brought in view a large abscess and an appendix gangrenous at its extremity, in which there was a hard, fæcal concretion. The abdominal as well as the pus cavity were cleansed, and a glass drain was inserted into the pelvic cavity, and one into the abscess cavity; at short intervals the drain tubes were cleansed, using peroxide of hydrogen freely. So soon as the secretions become odorless, they should be removed. At once after the introduction of a drain tube into the abdominal cavity, lymph is thrown out around it which shuts it out

from the general cavity, forming a lymph tube, so that when the drain tube is removed any further secretion readily and safely reaches the surface.

COMMUNICATIONS.

THE MEDICAL TREATMENT OF CYSTITIS.*

BY JAMES TYSON, M. D.,

PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY OF PENNSYLVANIA.

The medical treatment of cystitis does not furnish a very satisfactory chapter in therapeutics. It includes such treatment as the physician is called upon to use supposing the exciting cause, such as a stone or obstruction in the urethra, to have been removed, whenever possible. I say when possible, because the enlarged prostate which is responsible for so many cases of cystitis is, in the vast majority of cases, not removable even in these days of brilliant surgical results. It must also include the treatment of a certain number of cases in which no removable cause is ascertainable, as well as cases where, as with a long previous gonorrhœa, the cause has long since been removed, but has left a deep-rooted tendency scarcely eradicable.

It should be stated, too, at the outset, that the vast majority of cases of so-called cystitis are inflammations of the neck of the bladder and of that part of the urethra passing through the prostate.

Acute cystitis is far less commonly met by the physician than the chronic form, while its treatment is far simpler, and, I may add, more satisfactory, at least so far as the removal of the acute symptoms is concerned. Rest in bed is a primary and essential condition. Leeches to the perineum should be applied more frequently than they are. A poultice to this same region and over the abdominal region is always useful, while a brisk saline cathartic should never be omitted.

As the feverish state which always accompanies cystitis is more or less constantly associated with a scanty urine, concentrated and irritating to the inflamed mucous membrane, it is desirable at once to increase the secretion, and thus dilute it. Copious libations of pure water, to which the citrate or acetate of potassium is added, in fifteen to twenty grain doses for an adult, should be allowed. The ordinary spirits of nitric ether in two drachm doses every two hours is an admirable adjuvant, and may be combined with the officinal liquor potassii citratis, which contains about twenty grains of citrate of potassium to the half ounce. Formerly the mucilage of flaxseed or flaxseed tea was much used as a diluent menstruum for the diuretic alkalies indicated, but I am doubtful whether it is any more efficient than a like quantity of water.

Where there is much pain and straining, as is often the case, especially where cantharides is the cause of the inflammation, opium is indispensable, always in the shape of a suppository, half a grain to a grain of the extract being thus administered, or a proportionate amount of morphine. Iced water injections into the rectum, or pieces of ice similarly applied, are very efficient in allaying the pain and irritation where additional measures are needed.

The successful treatment of *chronic cystitis* is a much more difficult task, for three evident reasons: 1st, the constant presence in the bladder of the urine with its irritating qualities, especially to an inflamed mucous membrane; 2nd, the difficulty in getting remedies to reach the inflamed surface; and, 3rd, the pent-up inflammatory products, which in their decomposition often make the urine still more irritating by exciting in it ammoniacal changes. There is no doubt that, if the urine could be kept from entering the bladder during the existence of an inflammation, the latter would rapidly heal; that cure would be facilitated by obtaining ready escape for the pus and mucus formed in the inflammatory process; while happier results might also be reasonably expected if we could secure readier access for remedies to the inflamed areas. None of these indications can be met entirely, hence the difficulty in attaining a cure. They remain, however, the conditions to be fulfilled, and while none can be thoroughly secured, they may be approximated in various degrees. To do this should be the object of treatment.

First, the irritating qualities of the urine may be diminished by the use of diluents as already recommended in the treatment of acute cystitis. Almost any of the negative mineral waters, so highly recommended by their owners, are useful for this purpose. Just as good is pure spring water, or even Schuylkill water, and better is distilled water. From one to two quarts should be

*Read before the Philadelphia County Medical Society, November 11th, 1891.

taken daily. If the kidneys are equal to their office, a large quantity of light-hued urine, of low specific gravity and relatively weak in solids, will be secreted.

When it is proposed to go further and add to the efficiency of diluents, mistakes are often made. While one can scarcely go astray in adding alkalies to the fluid ingested in acute cystitis, it is very different with the chronic form. In this the urine is often alkaline, or ready to become so on the slightest addition of alkali to the blood. Such alkalinity of urine in turn favors decomposition, the effect of which is to convert the pus, if present, into a tenacious, glairy fluid which the bladder cannot evacuate. Notwithstanding this tendency, I have known liquor potassæ and other alkalies to be administered under precisely these conditions —adding fuel to the flame. The indication under these circumstances is to render the urine acid, if possible, although this is very difficult to accomplish. Benzoic acid has the reputation of doing this, and it probably is true of it when administered in very large doses. It may be given in the shape of a five-grain compressed pill, of which at least six must be given in a day to produce any effect. The same property has been assigned to citric acid, but this is a mistake, as all of the vegetable acids, when ingested, are eliminated as alkalin carbonates.

The second indication is to medicate the inflamed surface. Two ways, of course, suggest themselves: (*a*) by the internal administration of drugs; (*b*) by the injection of medicated liquids into the bladder.

To carry out the first method, an enormous number of infusions, decoctions, and fluid extracts of vegetable substances have been suggested, the vast majority of which are absolutely useless, except as they serve by their quantity to act as diluents. Among the best known of these are buchu, pareira brava, uva ursi, and triticum repens. I have never known any beneficial results from any of them, and have long ago ceased to prescribe them.

The only class of remedies I have found of service in cystitis through their internal administration are the balsams. Of these, the balsam copaiba is practically unavailable, because not one stomach in a hundred will submit to its ingestion in sufficient doses or for long enough time to permit it to be of any use. On the other hand, I have found sandal-wood oil very useful, and it is about the only remedy of which I can say this for its direct effect upon the mucous membrane of the bladder. It is also comparatively well borne by the stomach, and is best administered in capsules containing ten minims. I believe it has heretofore been the usual custom to give these and like remedies after meals, but I have recently adopted the method of giving them on an empty stomach before meals. I believe they are as well, and even better, borne than when given after food, and they pass into the blood much more quickly. It is desirable to impregnate the blood and impart to the urine a balsam odor. This is scarcely possible with less than eight capsules a day—two before each meal and two at bedtime. I think I may say that I have found the so-called Santal-Medy capsules, which are, I believe, nothing but a very pure sandal-wood oil, better borne than the other specimens of the oil. I have given as many as twelve of these a day for considerable periods of time without deranging the stomach.

Both boric acid and benzoic acid are useful adjuvants to the treatment of chronic cystitis through their antiseptic effect on the urine, each in 5 grain doses rapidly increased to 10. I have used resorcin in 5 to 10 grain doses, and naphthalin in 2 grain doses for the same purpose.

The application of remedies to the bladder by injections can be conveniently considered in connection with the third indication—the getting rid of the products of inflammation, the pus and mucus, and the compounds resulting from their decomposition. The latter are, of course, not always present, but all who have had much experience with cystitis are familiar with the tenacious, glairy mucoid matter, which will not drop or rise up in a pipette, glistening with large crystals of triple phosphate, and exhaling a stinking ammoniacal odor which quickly contaminates an entire apartment. There is only one way to get rid of this, and that is to wash out the bladder, and too often this is too long deferred. Tepid water should be first used, and the injection made through the soft catheter now so invariably adopted. Sir Henry Thompson is very emphatic in his directions that no more than two ounces should be thrown in at a time, and that this should be allowed to run out, a like quantity again injected and allowed to run out, and this repeated until the water comes out as clear as it enters. In a very large experience in washing out bladders, I have never met an instance in which the amount named by Sir Henry may not be doubled with advantage, so that I begin with four ounces. When this quantity is used, a much shorter time is necessary to cleanse the bladder

thoroughly; and after the capacity of the bladder has been determined I often throw in more, because it is sometimes useful to distend the viscus a little, for in this manner the depressions and inequalities between the muscular trabeculæ, always present in advanced bladder inflammations, are thoroughly reached. These simple injections, practiced once a day, or in severe cases twice a day, often result most happily. I have seen the pus reduced from large bulk to a mere trace, and micturition reduced from five or six times to once a night. Commonly, after a few injections with plain water, I add some medication. My favorite is the salicylate of sodium in the proportion of a drachm to the pint. Its disinfecting qualities are undoubted, and I have some reason to believe that the soothing effect claimed for it is not without foundation. I have used a good deal of Sir Henry Thompson's soothing solution—of biborate of sodium an ounce, glycerin two ounces, water two ounces, and of this mixture half an ounce to four ounces of tepid water—with about the same result. Boric acid, in the proportion of a drachm to the pint, is also very satisfactory.

Alum is an astringent which has been too much overlooked of late in suppurating processes in mucous membranes, and may be substituted for the salicylate with advantage where the pus does not diminish as rapidly as is desired. It should be more cautiously used than the salicylate of sodium. Sufficient of the powdered alum should be first added to a pint to give it a distinctly astringent taste, when the bladder should be washed out as described, while a small quantity may be allowed to remain after the last injection.

Where there is a foul odor present I use the bichloride of mercury in solution, but exceedingly dilute. It is almost incredible how small a proportion of this salt is irritating to the bladder, and having learned by experience, I never begin with a solution stronger than 1 : 26,000, but gradually increase the strength if it is well borne. Carbolic acid may be substituted for the bichloride of mercury, but it has not been so satisfactory in my hands.

Other drugs are recommended to be similarly used, but I have had little or no experience with them. One from which much may, with reason, be expected is the peroxide of hydrogen, one part to five of water. In the single instance in which I have used this, the patient, who had been previously using the bichloride solution, returned of his own accord to the latter, because he thought it more satisfactory. Among other remedies recommended to be used the same way, are acetate of lead, one grain to four ounces; dilute nitric acid, one or two minims to the ounce; and nitrate of silver, one grain to four ounces; but I have had no experience with them.

Anodynes are indispensable in many cases of cystitis to relieve the patient of extreme pain and the frequent desire to pass water, which are the result of the same cause. Opium and its alkaloids are the most efficient, and they are best introduced by the rectum. There appears to be no absorbing power in the bladder for opium at least, and there is no use in attempting to use anodynes by that channel.

Cocaine, from which so much might reasonably be expected, has failed of its purpose in my hands. I have injected as much as two ounces of a 2 per cent. solution into the bladder without effect, except to produce some of the symptoms of cocaine poisoning. Most disappointing, too, has been the use of cocaine to remove the exquisite tenderness of the urethra which sometimes attends this condition, and is a serious drawback to the use of the catheter.

Where there is greatly enlarged prostate, catheterization is indispensable, and is attended often with the most happy results. It is often too long deferred because of the natural repugnance to the use of the instrument. Of course, the patient or his friends should be taught to use the catheter and to wash out the bladder. In these days of refined antisepticism it is scarcely necessary to say that the extremest precautions should be taken to cleanse the catheter after its use, in order to avoid sepsis. There is nothing better for this purpose than the bichloride solutions 1 : 1000, in which the catheter should be allowed to lie for a short time after being cleansed with boiling hot water.

How much can be accomplished by such treatment as the above-described? That an absolute and total cure is ever obtained in chronic cystitis is exceedingly doubtful. Hence the statement at the beginning of my paper, that the medical treatment of cystitis does not furnish a very satisfactory chapter in therapeutics. On the other hand, that a life of suffering may be converted into one of comparative comfort is certainly true, and I have many times seen it. Nay, more, I have more than once seen a life prolonged half a dozen years in such comfort by careful attention to the bladder, of the kind described.

It occasionally happens, of course, that all treatment of this kind fails, and yet the patient lives to be tortured by the discomfort of the situation. Three times I have had perineal section done by the surgeons for the relief of such cases, in each case with some relief, although with less than was hoped for.—For discussion, see Society Reports.

THE URETHRA, BLADDER, AND URETERS DURING PREGNANCY, LABOR, AND THE PUERPERIUM.*

BY W. H. PARISH, M. D.,

PROFESSOR OF OBSTETRICS, DARTMOUTH MEDICAL COLLEGE—PROFESSOR OF ANATOMY, WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA, ETC.

The condition of increased vascularity and irritability of the urethra, bladder, and ureters during pregnancy is due in part to the pressure of the uterus, and in part to the alterations in the general pelvic circulatory and nervous conditions awakened by the stimulus incident to gestation.

The bladder in early pregnancy is less capable of distention in the antero-posterior direction, and its enlargement is chiefly lateral. Later in pregnancy the enlarging uterus draws the bladder upward above the pelvic brim. The changes in the position of the bladder during pregnancy doubtless determine to some extent, more frequent, and at times annoying micturition, yet the elevation of the bladder above the brim is a conservative provision, for in this way the bladder is largely protected from harmful pressure during normal labor.

However, the utero-vesical ligaments are so unyielding that the bladder participates in such abnormal displacements of the uterus as occur during the pregnant state; as, for instance, it follows the uterus in procidentia, and is drawn downward and backward in retroversion of the gravid womb. The urethra becomes elongated with the elevation of the uterus, and in early pregnancy if uterine prolapse occurs, and also in advanced pregnancy if the uterus drops into the true pelvis, the upper portion of the urethra curves backward and downward, constituting dislocation of the upper third of the urethra, with the symptoms pertaining thereto.

*Read before the Philadelphia County Medical Society, November 11th, 1891.

With the changes in the position of the bladder, the lower portions of the ureters necessarily change in position, but these tubes suffer chiefly from pressure of the pregnant uterus, and, as a consequence, they, above the point of pressure, often become dilated to the size of the finger or of the thumb. The blocking up of the urine in the ureters influences the renal condition unfavorably, and doubtless, at times, contributes in the production of urinæmia and eclampsia. The pressure exerted upon the ureters, suggests the advisability of repeated recumbency, or, better still, of the knee-chest position, during advanced pregnancy. When peri-uterine adhesions, with uterine displacement, exist, there is still greater risk of injurious compression of the ureters, and of eclampsia.

Mild cystic catarrh, some say inflammation, is of somewhat frequent occurrence during pregnancy, and may be the cause of albuminuria when the amount of albumin in the urine is small.

Hæmaturia occasionally occurs, because of the impeded pelvic circulation. A varicose condition of the bladder and urethral veins, usually with a like condition of the anterior vaginal wall and of the vulva may arise, and be the cause of hæmaturia, with frequent urination and pelvic distress. This morbid vascular condition calls for rest during pregnancy. After labor it usually disappears, but when subinvolution occurs, it may become persistent.

When cystitis, even of mild type, exists during pregnancy, its careful treatment is strongly indicated, for labor and the lying-in are very prone to aggravate the inflammation. Especially is this true if the cystitis is of gonorrhœal origin. It has been observed also, that when cystitis exists during pregnancy, subinvolution of the uterus is very apt to occur, and the inflammation is very liable to become chronic.

In retroversion and incarceration of the gravid uterus, the lesions produced in the urinary apparatus constitute the most serious morbid changes incident to this grave complication of early pregnancy. Ischuria is the earliest, and one of the most important symptoms. The early compression of the urethra by the uterine cervix produces œdematous swelling of the urethral wall, with at first partial obstruction to the exit of urine. The pressure instituted by the enlarging uterus increases until urinary retention occurs, accompanied, it may be, with dribbling of urine from the over-distended bladder. The retained urine rapidly under-

goes ammoniacal decomposition, and cystitis becomes an early complication. The inflammatory action produces diphtheritic flakes over the mucous membrane of the bladder, with erosion and ulceration. Absorption of the decomposed urine occurs with constitutional symptoms.

The mucosa may be cast off from the entire bladder, but especially from the portions of the organ above the neck, showing that the separation of the mucous membrane is due to the degree of congestion and of inflammation, rather than to direct pressure—for the pressure is greatest at the neck. I have seen large portions of the mucosa cast off and blocking the urethra. It is stated that the separation of the mucous membrane is not likely to occur before the sixth day of the incarceration.

In some instances portions of the musculosa have been thus separated, and gangrene of the entire thickness of the bladder-wall has occurred. Owing to the retention, the ureters become greatly and the renal pelvis moderately dilated. The inflammation extends along the ureters and invades the kidneys. The suppression of retention also occurs with constitutional manifestation.

In the over-distention the bladder wall, though thinned at points, becomes remarkably thickened throughout most of its extent, and in a few days, even when entirely empty, will present to the palpating hand a firm mass, wonderfully like the non-pregnant uterus, and may mislead the examiner into supposing that the uterus is empty, and that a retro-uterine tumor exists.

In some instances the distended bladder has reached even to the ensiform cartilage. Rupture of the bladder has occurred, especially in the attempt at replacement. As an essential preliminary to replacement, the bladder must be emptied either with the catheter or by aspiration. When the over-distended bladder is being emptied, a bandage should be drawn firmly around the abdomen to lessen shock, to prevent the entrance of germs with atmospheric air, and to prevent hæmorrhage from the cystic vessels.

Paralysis of the bladder accompanies the over-distention, and catheterization will be necessitated at intervals of six hours after replacement, otherwise distention will again occur, with danger of a reproduction of the uterine displacement. Irrigation of the bladder will be indicated for several days, for the cystitis and ascending ureteritis endanger life after the uterine displacement has been corrected.

In the original production of retroversion of the gravid uterus, an over distended bladder probably has very little influence, except in instances in which retroversion preceded pregnancy, and in other instances in which superior adhesions prevented the distending bladder enlarging upward.

When we study the relations of the bladder to labor, we find that in an entirely normal delivery, the bladder does not usually impede labor, and labor does not interfere with the integrity, or injuriously with the functions of the bladder. For, in addition to the elevated position of the bladder at the end of pregnancy, the frequent micturition of labor is conservative, for thus the bladder is kept so nearly empty that its presence is in no manner harmful.

Should, however, œdematous swelling of the urethra, or the immediate effects of pressure, or perverted nerve-action lead to distension of the bladder, parturient expulsive efforts are rendered feeble and less efficient, and the presentation or position may be modified unfavorably.

In neglected cases, an over-distended bladder becomes a grave complication, partly in the same manner that it does in incarceration of the pregnant uterus. A distended bladder may contribute also to the formation of a fistula, or to rupture during expulsive or extractive efforts. In rupture, the tear usually occurs in the posterior wall and into the peritoneal cavity, though it may occur anteriorly, and, in the latter case, if low down may give rise to infiltration of the anterior abdominal wall. Collapse accompanies rupture of the bladder, and if urine escapes into the peritoneal cavity, a fatal result is very probable. Under such circumstances cœliotomy would be urgently demanded, with trimming and suturing of the lips of the rent, and careful toilet of the peritoneum.

Rupture of an over-distended bladder has occurred during expulsive efforts in an abortion at the third month of gestation, even when there was no incarceration of the uterus.

Cases of cystocolpocele, or prolapse of the bladder, usually with distension, have occurred during labor, impending delivery and leading to the enormous diagnosis of the bag of waters, or of a fluid pelvic tumor. Under such erroneous diagnosis the bladder has been incised or punctured *per vaginam*. A knowledge of the possibility of such a complication should lead to an easy diagnosis with the catheter carried into the bladder.

The downward dislocation of the upper portion of the urethra which sometimes occurs as the uterus enters the pelvis near the end of pregnancy may be further aggravated as the head descends, or when, with the forceps, a large head is pulled through the pelvic canal before moulding has occurred. This condition of the urethra is often associated with partial prolapse of the bladder, but both conditions usually disappear after labor if proper involution occurs, but may be persistent in subinvolution, and especially when ununited laceration of the perineum exists.

Undue distension of the bladder rarely occurs during labor, except in the second stage, and is then usually dependent upon pressure of the presenting part upon the urethra and the neck of the bladder. When an anæsthetic is administered during either the first or the second stage of labor, retention may arise, and be due to the obtunding influence of the anæsthetic. It should also be remembered that the secretion of urine is increased during labor, and the bladder may become filled rapidly. Sometimes, when spontaneous urination seems impossible in the recumbent posture, an attempt to urinate while sitting and between the pains will relieve the retention and obviate the necessity of catheterization, unless the head is fixed in the pelvis. When catheterization is necessitated during labor the simple precaution of pushing up through the vagina, in the abscence of pain, the presenting part is too often overlooked, with the result of always endangering the integrity of the urethral and bladder mucous membranes, and sometimes of failing to introduce the catheter.

In neglected cases it is occasionally necessary to resort to supra-pubic aspiration of the bladder during labor, but before this is done one should call to his aid the relaxing influence of anæsthesia, and the favoring latero-abdominal and genu-pectoral positions.

Prolonged pressure, especially of the fœtal head, or occasionally of any part of the fœtus, endangers the integrity of the cystic, urethral, and uterine walls.

Ninety per cent. of urinary fistulæ are dependent upon injuries sustained during labor, and in most instances are produced by the prolonged pressure of some part of the fœtus. An evidence of the truth of the latter statement is the generally recognized fact that since the more prompt resort to the obstetric forceps has become the rule of practice, urinary fistulæ occur with greatly reduced frequency. The old practice of administering ergot during labor contributed, doubtless, in the production of fistulæ, through its influence in bringing about continuous uterine contractions.

It is long sustained pressure that determines the sloughing from which the fistula generally arises. Although the general use of the forceps has promoted in many instances the formation of fistulæ, yet I am confident that the injudicious use of the instrument has been at time productive of such lesions.

The resort to the forceps when the head is movable above the brim, especially with a flat pelvis considerably narrowed, places in great danger the walls of the urethra, bladder, and ureters. Also the too frequent mal-direction of the force exerted in traction with the forceps, as when this force is directed against the anterior pelvic wall, produces contusions and sloughing of the soft parts, including, at times, the walls of some part of the urinary apparatus. The contusion may be sufficient to produce a fistula, or it may less seriously yet injuriously affect the urinary structures.

Were the axis-traction forceps in universal use, as in my opinion they should be, the mal-directed and too great force so often resorted to in traction would be avoided, and consequently the pressure exerted would be less prolonged and less forcible. At times a fistula may result from excessive pressure exerted even for a short time, especially if the bladder is partially or greatly distended.

Prolonged or undue pressure during labor may also give rise to erosion or ulceration and inflammation of either urethra, bladder, or ureter.

These structures are liable to serious injury during the performance of craniotomy, from being punctured with either spiculæ of bone or with the perforator.

The performance of version and of extraction by the feet has resulted in rupture of a distended bladder, and in other instances in sloughing productive of fistulæ, or of vaginal cicatrices which interfere with the functions of the bladder.

Vesico-intestinal fistulæ have sometimes followed labor in cases of old adhesions between the bladder and some part of the intestinal tract.

In the performance of the classical Cæsarean or of the Porro operation the bladder and ureters should always escape injury, unless there exists a patulous condition of the urachus.

In a large proportion of the cases of the cœlio-elytrotomy the bladder was opened into, and the danger of this accident occurring was one of the several good reasons why that operation quickly fell into disfavor. Occasionally a calculus exists in the bladder during labor, and its presence as that time always brings considerable danger to the patient. It is advised by some to endeavor to push the calculus upward above the brim, but it seems to me that this procedure would often be impossible of performance, and would be always of uncertain benefit. Extraction through the urethra after dilatation, preceded, it may be, by lithotrity, would promise the best result. Or, if this were impracticable from the low and fixed position of the head, vaginal, or, possibly, supra-pubic lithotomy, would be indicated. If the stone could not be carried above the brim the supra-pubic operation would not be possible. I can scarcely understand how the circumstances can be such as to justify the performance of craniotomy, the child being alive and viable.

During the puerperal period perforation of the ureter, bladder, or urethra may arise from ulceration or from sloughing due to injuries sustained during labor. In fact, most fistulæ do not appear until several days have elapsed. In some instances by judicious treatment, especially with vaginal, antiseptic douches, such perforations may be avoided. This is effected by lessening the intensity of the ulcerative and inflammatory processes. The liability to cystocele may be lessened by proper observance of recumbency and by immediate perineorraphy, if indicated. The measures influential in securing due uterine involution may be said to be generally favorable to the establishment of a normal condition of the urinary apparatus.

The inability to empty the bladder, so frequently existing during the few days following labor, may be due to one or several causes. At times swelling of the urethral wall may be the principal cause, though I do not think that this it frequently the sole cause. Often the loss of support sustained by the bladder due to the emptying of the uterus occasions the retention, while in other instances recumbency is chiefly at fault, for not a few women are unable to urinate at any time while recumbent.

It is best that the bladder should be evacuated every eight hours after labor.

If the labor has been a normal one, it is safer for the patient to be placed on the commode without being on her feet than to use the catheter. Nearly always the sitting posture will enable her to urinate. The use of the catheter after labor brings peculiar risks. Septic urethritis, cystitis, ureteritis, and nephritis, one or all, have certainly been thus produced, and not infrequently. The catheter often causes abrasion, and although absorption through the urinary mucous membrane in its normal condition must be exceedingly slow, yet when this membrane is congested, but especially when abraded, absorption readily occurs. Practically the physician is never certain that the catheter is aseptic unless he cleanses it himself, and even then he must have correct knowledge as to how the instrument can be cleansed. Many nurses are either careless or ignorant, and the catheter is not easily kept aseptic. Moreover, the catheter may be perfectly clean, and yet it may pick up from the external genitals after labor, septic material, or material that will quickly become septic, and carry it into the bladder. The custom, still recommended in some text-books, of passing the catheter under the bed-covering, is exceedingly erroneous. If the catheter must be used, the genitals and urethral meatus should be exposed and rendered entirely clean, and the clean catheter should be introduced with the parts in view—for only in this way can one guard against the introduction into the bladder of foul material. Hence, unless the contra-indications are plain, the patient should be placed on the commode, or in the sitting posture on a vessel in bed, or in the knee-elbow position if she cannot urinate in a urinal or a bed-pan. After primary perineorraphy the patient should be permitted to urinate spontaneously while lying on the bed-pan, and immediate douching of the external parts will prevent decomposing urine from interfering with primary union.

A catheter should be perfectly smooth, and with small orifices near the distal extremity. Some writers prefer the gum catheter. The best is of glass, and each patient should have a new one. The glass catheter can be more easily and more certainly rendered aseptic than the gum. Cystitis after labor determines subinvolution—may lead to urethritis, and possibly to pyelitis, which may rapidly terminate fatally, or become chronic, with eventual loss of life. An active inflammation of the bladder, especially after labor, may be productive of pericystitis or pelvic peritonitis and of pelvic cellulitis. Chronic cystitis in the female often dates back to the lying-in. Stricture in the course of the urethra, or at the meatus, also finds its origin in a post-partum urethritis,

or in external ulceration.—For discussion, see Society Reports.

THE RATIONALE AND TECHNIQUE OF SUPRA-PUBIC CYSTOTOMY.*

BY JOSEPH HOFFMAN, M. D.,

PHILADELPHIA.

The history of this now classical operation for all the affections of the bladder where surgical interference is justifiable is a travesty upon the acumen of the surgeon. I speak widely, and it may seem to some, unwisely, but it appears to me such expression is only moderate when all facts in reference to the subject are considered. The lateral operation for stone, as is well known, became popular because of its success upon children. Hence the reasoning by which it was indiscriminately applied to all cases in the adult seems only ridiculous when the same methods of arguing the so-called high operation out of sight are scanned. The high operation was dangerous because of wounding the peritoneum, and this was gravely held to, after it was well known that the operation had been performed at an early day with success and that the anatomy of the parts is such that the peritoneum is easily escaped. Up to within a decade the same logic is followed, and the supra-pubic operation is gravely dismissed with the feeble criticism that the statistics of the operation are not good, though such condemnation is followed generally with the explanation that this is perhaps due to the fact that the operation has been reserved for cases in which other operations could not be done, and accordingly the patients were in an unfavorable condition. It is not the intention of this paper to go into the history of the operation, only as to show that the reasoning against it both present and past, is in the highest degree unworthy of acceptance and in fact does not amount to reasoning at all. It is intended rather to call attention to the fact that in the opinion of the advanced surgical exponents of to-day it is the operation, beside which all others, in the treatment of vesical disease, must play an unimportant part. Here in Philadelphia we have had much urgent opposition to the acceptance of this fact, but also, it is pleasant to know, that here also there has been much and well-argued stand taken for the operation. In this connection Dr. Dulles must have unstinted credit.

It is too much the fashion in surgery, as in physic, to follow out an ancient idea as if it were inspired. The mummies of science are no more worthy of adoration than error in any other form. So-called scientific data which are not and never were scientific, are at the bottom of much mischief and many disasters in practical surgery as well as in physic. The arguments by which the supra-pubic cystotomy can be urged for general acceptance in all cases in which it is proposed to enter the bladder, are all based upon anatomical fact and practical results in good hands. Those who are having the most experience with it are giving it the highest praise. Looking at the now generally accepted axioms of this latter-day surgery it is difficult to understand how this can be otherwise. In the perineal point of attack by which the bladder is to be entered there are many structures of vital importance and whose anatomical distribution are far from uniform. On the other hand, in the supra-pubic operation, there are no important structures to be met; there are no blood-vessels that cannot be easily controlled in the sight of the operator; there are no anomalies to be expected, and if they do occur, need have no terror for the operator. The operation then being always under the complete control of the operator, is clearly the one to be preferred from a merely theoretical standpoint. But theory does not always hold good in practice, so let us see whether here we are also misled. The danger most to be dreaded from the perineal operations are hæmorrhage and contusion of the parts by the passage of a large stone, especially injury to the seminal vesicles. In the procedure under consideration we have seen there is no danger from hæmorrhage, and the contusion cannot interfere with vital structures because they are not met; the bladder is not wounded where its integrity is interfered with, and even if a stone larger than is suspected is to be dealt with, there is no difficultty in removing it far more successfully and certainly and simply than by any other method. I do not except the now generally accepted method of crushing. The reasoning by which this conclusion is reached I think so clear that I will not follow it out. How many of the older operators in this Society, in this room, have in mind harrowing attempts to get control of calculi imbedded in the bladder, of hands introduced into the rectum, in order to bring the stone into the grasp of the forceps, of lacerated

*Read before the Philadelphia County Medical Society, November 11th, 1891.

bladder, perineum, urethra, and all of which it is hope of the operator to escape! It will be evident to the veriest tyro in anatomy that all this not only can be escaped, but is escaped, in the supra-pubic operation.

The next *bete noir* of the perineal operation is urinary infiltration. It cannot be questioned that in this latter operation the larger the stone the greater the danger of contusion and, therefore, the greater the danger of urinary infiltration. Now, in supra-pubic cystotomy, the danger of infiltration is practically nil, for the reason that there is no deep dissection of parts, that the urine passes gently upward and outward, and cannot lie collecting and dissecting by gravity into the adjacent structures. The danger of infiltration in the supra-pubic incision can only be said to obtain when an attempt is made to close the incision, and hence it has become an axiom in the operation that the incision is better left open. There is found to be but little danger of fistulæ—in fact, the great difficulty is to keep the bladder open as long as necessary. Accordingly we see that the three paramount dangers of the perineal operation are absent in the abdominal operation, and that theory and anatomical facts combine to demonstrate the legitimacy of the newly adopted operation. Now let us further consider some of the points in which it is asserted that the lateral operation for stone is superior. In children, for instance, where there is less danger of extensive laceration, it is claimed such is the case. Let us see. A year ago I said to Dr. Deaver: "I am going to do a supra-pubic cystotomy for stone." The question was: "What is your case?" The answer was: "A boy, three years old." Again the answer: "You have a favorable case," and the opinion was justified by the result. It must be remembered that in children the bladder is rather an abdominal than a pelvic organ, and that lying higher it is more readily reached. In the case just referred to the recovery was absolutely uneventful. After the first day the child lay comfortably in bed, playing, with neither fever nor pain. In great contrast with this case comes the report in a volume of the *Transactions of the Southern Surgical Society* in which a vaginal cystotomy was done upon a child six years old. Imagine the consequences at their best—the laceration, the pain necessarily supervening; but take into consideration subsequent operation for vesico-vaginal fistula, and the too late concession of the operator, that had the size of the stone been suspected, the supra-pubic operation would have been selected. Herein lies the folly of choosing any operation instead of another which will answer all conditions, because in tradition no alternative has been preserved. I take it to be a surgical postulate that in every instance that operation should be selected which promises the greatest relief with the least danger or discomfort to the patient. It is not a question of what operation we are used to performing. It is which operation best covers the ground. The argument has, up to this point, been directed to cystotomy from the standpoint of operation for caculus. It is not limited to this, however. In the male we have prostatic disease, than which there is no greater bane to old age. Hitherto the only relief was by constant catheterization. Now it is a recognized procedure to drain the bladder permanently from above. No one needs further argument than the cases reported by McGuire, of Richmond, and of the Davises, of Alabama, to be convinced that this operation to old men is the greatest possible boon. Not only is the bladder drained, but the prostatic enlargement is itself removed with the greatest success, and in many cases the disease permanently cured. Belfield, of Chicago, a year ago gave an exhaustive tablature of this operation, and its success places it among the most important additions of the day. It now becomes evident that since drainage is a most important element in the treatment of chronic cystitis in women, a most desired step is attained, by which the woman with comfort and cleanliness is able to go about while she is being cured, with no discomfort, and cleanly. McGuire gives as his opinion that there is no difficulty of so managing the supra-pubic opening so that the urine can be retained for six hours. This being the fact, there is no longer reason for drainage *per vaginam*. By this it will be seen that in all cases in which it is intended to open the bladder the supra-pubic operation gives most assurance of all-round success, whether in adults or children, whether the disease be simple inflammation or chronic prostatic enlargement. This is my experience, both in operations upon the child and adult. It is evident also that in lieu of an encysted calculus the operation is absolutely sure of success.

The details of the operation are exceedingly simple. Much has been written that tends to produce an impression that the steps are more or less complicated. No special instruments are needed. A bistoury and a few artery clips are all that is required

—additional instruments only being called for according as to the conditions met after exploration. The injection and washing out of the bladder are, I believe, all that the surgical aspect of the operation requires.

The bladder can be easily reached both in the child and adult without packing the rectum. The relative size of the bladder in the adult and child is to be regarded, care being taken not to over-distend the viscus. The incision is made close down to the pubis, and two pairs of artery forceps used as retractors, as the incision is deepened, obviates all necessity for special instrument or additional procedure. The supra-pelvic fat is pushed asunder with the finger, and the bladder comes into view or is easily felt at the bottom of the wound. The viscus is easily raised into the wound by the forceps applied again after the manner of using them to raise the peritoneum, and the incision is readily made. The forceps can still be retained in position or, if deemed expedient, a thread can be introduced by which control over the edges of the wound is maintained. The subsequent procedure is now dependent on the operation to be done. If drainage only is intended, a rubber tube is stitched into the wound or a hard drainage-tube retained by simple means.

If a calculus is to be removed, the procedure is as simple as taking a cherry from its seed. The operations for tumor and prostatic disease are, of course, more extensive and dangerous, and these it is not the purpose of the paper to consider, but only to call attention to the fact that their removal by this operation becomes more a matter of surgery and less of experiment than by any other means whatsoever.

Finally, for the operation all can be claimed that simplicity, accuracy, and safety can commend. The so-called statistics of the operation before it was fairly tried, or used for other than forlorn cases, cannot be used either to condemn or recommend it. Its results, as obtained at the present time by exact surgeons, working thoroughly and entirely from an anatomical standpoint, give it a record unequalled by any other method of dealing with the surgical disease of the bladder.—(For discussion, see Society Reports.)

LUMBAGO.

Dr. Lyman Watkins says (*Med. Gleaner*) that ten drops of the tincture of gelsemium every four hours will almost invariably relieve that painful condition, or backache commonly called lumbago.

NOTES ON FOUR CASES IN GYNÆCOLOGY.

BY JOHN D. MAURY, M. D.,
PHILADELPHIA.

The author is indebted to Doctor Price, for the material upon which to operate, and all requisites for the operations.

REMOVAL OF THE RIGHT OVARY AND TUBE.

Case I.—Patient unable to work because of pain in right ovarian region, increased by motion, defæcation, &c. The operation was performed without difficulty. The right ovary, being raised to view, and found enlarged and cystic, was, with its tube, ligatured off with the figure 8 ligature and removed.

The left tube and ovary, being healthy, were returned. Incision closed with silkworm gut. Recovery.

REMOVAL OF BOTH OVARIES.

Case II.—Colored. History of vaginitis at previous date elicited. Suffered constant and severe pain in both ovarian regions. By vaginal examination a mass could be felt on each side of the uterus, tender on palpation, the right being more easily made out.

At the operation both tubes were found distended with a clear fluid, the right containing about two ounces and the left a little less.

There were a few adhesions, easily broken up. Both ovaries were enlarged.

Discharged, cured, in three weeks from date of operation.

REMOVAL OF BOTH OVARIES.

Case III.—Had suffered pain on left side for several months. Pelvic examination showed a mass posterior and to the left. On opening the abdomen, on the left was found an ovarian cyst the size of a hen's egg and on the right a smaller one. Both were removed. Patient discharged in three weeks.

OPERATION FOR VENTRAL HERNIA.

Case IV.—Patient suffering from ventral hernia as a sequel to ovariotomy done six years previously to stop hæmorrhage from fibroids. The rupture appeared about a year after operation, and continued slowly to enlarge until corresponding in size to an orange. At the lower right border of the hernia was a sinus, which would open periodically and discharge pus, close spontaneously, to reopen at a later date.

An incision two inches long was made to the left of the hernia through the anterior

layer of the sheath of the left rectus muscle, the muscle pulled aside, and the incision deepened until the peritoneal cavity was opened.

After exploration the incision was enlarged, up and down, until its length corresponded with the parallel diameter of the hernia.

The contents of the sac, omentum tightly adherent, were reduced, and the portion of the omentum which had been adherent ligated and cut away to diminish the amount of raw surface in the peritoneal cavity. Attention was then turned to the sinus. The right corner of the uterus was found anchored to the abdominal wall by a mass of cicatricial tissue two inches in diameter through which the sinus ran. The sac of the hernia with fascia and skin covering it, was cut away; and with it that portion of the sinus which ran through the abdominal wall. The dissection was carried on into the cicatricial mass, part of it being removed with the rest of the sinus. The silk ligature placed around the pedicle six years before, was found at the bottom of the sinus surrounded by pus having apparently undergone no change. Next the right lip of the wound was split, exposing freely the inner border of the right rectus muscle, from the upper to the lower end of the wound. Silk worm gut stitches were introduced and the wound closed as after ordinary abdominal section. She was up and around in three weeks.

The frequency of ventral hernia as a sequel to abdominal operations is, for obvious reasons, hard to estimate. Dr. John Homaus has, with much care and labor, published a table of the after-history of his cases, a study of which is exceedingly interesting. In looking this table over we find several things of interest. Out of 242 recoveries of ovariotomy, thirty-four, or a fraction over fourteen per cent. were followed by rupture. In no case in which rupture occurred, was drainage used. In the 34 cases followed by rupture, fourteen had long incisions (5 inches or over), and in the remaining 20, the incision was less than 5 inches. Thirteen of the 242 cases are known to have borne children subsequent to the operation, 4 of them having had more than one child, and in only one was there rupture, she having gone to term twice.

The deductions from this table do not seem to agree very well with the causes for rupture usually given.

There are numerous methods of operation for the care of this condition. Wylie unites the fascia with a separate suture. Tait splits the edges of the wound deeply all around making two flaps. He then brings the inner flaps in apposition, raw surface to raw surface, and the outer flaps the same way, the result being an internal and an external projection. Chadwick passed sutures, by means of a Peaslus needle, an inch back from the margin of the wound. Marion Sims, after cutting away the sac, united the peritoneum by Lembert's stitch, and the rest of the wall by a separate stitch. Richardson cut away the peritoneal sac, and closed the wound by deep sutures, passed through the peritoneum. The advantages of the method used in the above case, which is the method practiced by Price, is the union of broad muscular surfaces. The two muscles are made as one and there is no crack or weak place, into which the "wedging or separating transverse force," spoken of by Wylie, can insinuate itself.

Society Reports.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 11, 1891.

Dr. James Tyson read a paper on The Medical Treatment of Cystitis. (See p. 963.)

DISCUSSION.

Dr. H. A. Slocum:—I am sorry that Dr. Tyson did not say something about diet—about such articles as tomatoes and asparagus, particularly the latter.

In the local treatment of cystitis I have obtained good results from the use of boracic acid, two drachms to a pint of water used warm. This is introduced with a catheter with a little funnel. I have recently seen described a method of washing out the bladder by means of a catheter introduced into the urethra. To this is attached a tube, and the fluid is allowed to enter by hydrostatic pressure.

I have also used boracic acid internally. This in ten grain doses every two hours has been of more service than anything else that I have tried.

Dr. T. S. K. Morton:—In the treatment of chronic cystitis I have found most satisfaction from the use of salol in conjunction with milk diet. I have the greatest confidence in the administration of salol in doses of from three to five grains repeated several times daily. The theory is, that in the kid-

neys salol liberates carbolic acid. While many cases have been benefited by the use of the drug, in other instances it has, like everything else, failed.

I feel convinced, also, that I have had good results from the internal administration of cocaine, owing to its diuretic action. I think that it has some local effect upon the bladder.

A third drug from which I have had good results is sandal-wood oil, and the preparation mentioned by Dr. Tyson (Midy) is the best; but it is objectionable on account of the fact that it is largely advertised, and the name of the manufacturer is stamped on the capsules, thus giving to a certain class of patients a clue to their treatment which is an advantage neither to them nor us.

Dr. George E. Shoemaker:—I wish to add a word in regard to the internal administration of boracic acid. I have in the past four years used it in a number of cases with a great deal of satisfaction, giving it in doses of from five to eight grains every two hours in plain water or cinnamon water. I have used it with benefit in one case of perineal fistula of long standing in the male. Of course, all medical treatment is subsidiary, but this is the drug which has given me most satisfaction.

Dr. Charles P. Noble:—I have heard no mention of benzoate of ammonia or benzoic acid. I have found these drugs of great advantage in foul alkaline urine. Under some circumstances I have had good results from boracic acid. Rest, a restricted diet, and leaving off meats, have had a good influence. Locally I have used a saturated solution of boracic acid, and rarely have had to reduce the strength of this. I wash out the bladder every second or third day. I have seen good results from triticum repens, particularly in cases where *ardor urinæ* was very marked. Better results can be had by combining it with tinctures of aconite and belladonna, and with bromide of sodium. In summer-time a pleasant remedy is watermelon used freely. This, as is well known, is a powerful diuretic. It gives a bland, unirritating urine, and in a measure avoids the necessity for irrigation.

My experience in the treatment of cystitis has been largely with women. A growing experience makes me the more convinced that cystitis has some local cause, as a rule, which must be sought for and removed. In women a torn perineum, resulting in cystocele, and tubo-ovarian inflammation are the most common causes of cystitis. When these conditions receive appropriate treatment the cystitis disappears.

Dr. Joseph Hoffman:—There is a combination of three drugs which I have used with benefit—these are benzoate of ammonium, salicylate of sodium, and bromide of potassium. The last is a local sedative. I think that benzoate of ammonia is perhaps the most efficient of all remedies in chronic, and even in acute, cystitis. The salicylate of sodium is also of value. The mechanical treatment should not be forgotten. It is absolutely impossible to cure acute cystitis with the patient going about. Rest is an important factor in the treatment. It is only by rest in bed that we can secure absence of abdominal tension, which is important.

Dr. Donnally:—In one or two instances in which I have used iodoform in the proportion of two grains to the ounce in four drachms of mucilage, it acted very efficiently and prevented ammoniacal decomposition.

Dr. Longaker:—I have found benzoate of ammonium most effective, but prefer to give it with belladonna rather than with bromide of potassium. Ten grains of the salt, four times a day, is sufficient.

Dr. Mary E. Allen:—In one case where I tried a number of remedies without effect, benefit followed the use of fluid extract of buchu, which was used in conjunction with Buffalo lithia water and a diet consisting principally of milk and vegetables.

Dr. Tyson:—I have had no experience with asparagus as a therapeutic measure in cystitis. Boric acid and benzoic acid I quite forgot to mention in the paper, which was prepared hurriedly. I have used them both freely. Benzoic acid has the disadvantage of affecting the stomach unpleasantly. I have not used benzoate of ammonium, but shall take the first opportunity to give it a trial. I cannot say that I have seen any curative results from boric acid or benzoic acid. They affect the urine favorably. I have also used salol, but have found it very uncertain. In one case where the disagreeable odor of the urine was complained of, I gave salol in large doses without any effect.

Dr. W. H. Parish then read a paper on The Urethra, Bladder, and Ureters During Pregnancy, Labor, and the Puerperium. (See page 966.)

DISCUSSION.

Dr. M. Price:—I agree with Dr. Parish that the traction-rod forceps should be the only ones used. I disagree with the statement that bladder injuries in labor are more

infrequent than formerly. I believe that they are more frequent. The reason that we see fewer of these cases is that in every town there is now a man who is able to close these fistulæ. In the last few years I have seen many injuries of the bladder that have not been recognized.

I agree with Dr. Parish that an intelligent attendant should prevent most, if not all, of these accidents by his knowledge and care of the parts involved, and his investigation of the condition of the bladder during labor.

Dr. Charles P. Noble:—I wish to say a few words in regard to the use of violence in forceps delivery when the head is high in the pelvis. I am satisfied that it is not uncommon for men to deliver with all the power they have. This undue use of force is certainly injurious to the bladder as well as to the other pelvic organs. If the forceps are put on before the cervix is well dilated, it is very apt to happen that the anterior lip of the cervix and the bladder are drawn down in front of the head and are in great danger of contusion. So far as primary injury of the bladder is concerned, I am satisfied that not a few cases are due to great force used in delivery. I quite agree that the amount of force required can be lessened by the use of traction forceps. I think that too much cannot be said about the inadvisability of trying to deliver a large head through a small pelvis by the use of great force. This subject has been agitated recently by the introduction of a new forceps by Dr. McGillicuddy, called the "anti-craniotomy forceps," to be applied to heads too large to come through a given pelvis. The idea of drawing children through pelves relatively too small cannot be condemned too strongly. The natural result is serious or fatal injury to the mother and a dead or "spoiled" baby.

I was brought up with the idea that after delivery a woman should not be permitted to move, but under the teachings of Dr. Goodell and others I have allowed women more latitude, and have seen no reason to regret it. Very often if a woman turns over on her elbows and knees she can lean back and pass water in a chamber placed between her feet, without getting out of bed. Of course this should not be permitted in feeble women, or where there is danger of hæmorrhage. In this way the use of the catheter can be avoided, and likewise a possible catheter-cystitis. The position likewise favors drainage of the lochia, and hence is an efficient and natural antiseptic precaution. Women who are allowed some liberty in the bed are much more comfortable than under the old method of treatment.

Dr. Joseph Hoffman:—I am glad to hear a man of Dr. Parish's experience urge the use of the traction forceps to save the bladder. I use it always, and have never seen any injury to the bladder. It has been said that with the traction forceps less force is used. In reality more force is used, but it is applied in the line through which the head escapes, and no force is wasted on the soft tissues as is the case with the ordinary instrument.

Dr. Daniel Longaker:—I consider the use of the catheter after labor as very undesirable, and my experience is that its use can almost always be avoided by allowing the patient a little liberty. I have had a series of fifty cases in which I did not once use the catheter. Then there occurred a case of permature labor in which the dilating stage was protracted and the second stage prolonged. The patient was unable to pass water without the use of the catheter.

The statement that injuries of the bladder are as frequent or more frequent than formerly is, I think, incorrect. I think that it is a fact that the Women's Hospital in New York owed its birth to the number of cases of vesico-vaginal fistula, and the treatment of these cases formed a large part of the work of the institution. Now the cases of that trouble treated there are very few indeed.

Dr. Parish:—Dr. Price has unintentionally quoted me somewhat incorrectly. I did not say that injuries of the bladder were less frequent, but that vesico-vaginal fistulæ were less frequent. I do not believe that the injuries in the aggregate are less common. Prolapse is probably more common than before the general use of the forceps.

In preparing this paper I was compelled to refer to some points but briefly. In regard to sitting up or turning over on the kness after confinement, one must be careful that he does not permit a patient to sit up who should not. We must consider the individual case; otherwise great harm would result.

Dr. Joseph Hoffman then read a paper on The Rationale and Technique of Supra-pubic Cystotomy. (See page 970).

DISCUSSION.

Dr. John B. Deaver:—Simplicity should not, under all circumstances, be the best recommendation of an operation. I grant that many do supra-pubic cystotomy because it is

simple. The left lateral operation is also simple. I have never had a death from the operation; I have never seen the dangers to which Dr. Hoffman refers. Uncontrollable hæmorrhage and extravasation should not occur. The greatest danger was not mentioned by him—that is, wounding of the spermatic duct.

There is no one operation for stone in the bladder, but each case must be judged on its merits. The ideal operation for stone in the bladder is litholapaxy, after which the patient can usually be up in five days. It, however, requires experience and manual dexterity. To do it successfully requires that one should have done it several times. Anyone can do the supra-pubic operation. It is, however, not simplicity alone, but the merits of an operation that should determine its value.

Dr. M. Price:—Dr. Deaver has given us the strongest reasons why the supra-pubic operation should be selected. The fact that anyone can do it must be an argument in favor of the operation.

An argument against the perineal operation is the fact that in fifty per cent. of the cases of that operation the spermatic duct is injured. The supra-pubic operation has no such risk, and there are no large vessels which may be injured, as is the case in the perineal operation. The supra pubic operation, also, is preferable to crushing. Sir Henry Thompson has had a number of deaths, although he has crushed many cases.

Dr. John B. Roberts:—I feel that I am almost entirely in accord with the reader of the paper. Ever since the publication of the paper of Dr. Dulles, some fifteen years ago, I have felt that the supra-pubic operation was a most desirable one. He soon convinced me of the correctness of his position upon anatomical grounds. In a discussion of this subject before the American Surgical Association, in Washington, in 1884, gentlemen of skill and experience took the position of Dr. Deaver, that it was a good operation, but that the operation *par excellence* was the perineal incision. Dr. Tremaine, who read the paper favoring supra-pubic operation, was entirely in the minority. At that time I said: "I venture to say, that within ten years the supra-pubic operation will be the operation adopted for all cases of stone that are not treated by Bigelow's operation." This was before the brilliant results of supra-pubic cystotomy for tumors of the bladder and enlarged prostate. The supra-pubic route is certainly the most desiriable for those who are but seldom called upon to remove cystic calculi. Those who have undertaken to teach students perineal lithotomy, well know that such inexperienced persons almost as often get between the bladder and rectum as into the bladder. The upper route is accompanied by few complications and gives an opportunity to explore the bladder. From my experience I would say that it is the easier operation and the better one for the tyro.

Dr. A. H. Hulshizer:—I have seen only two cases in which crushing succeeded, but I have seen four in which it failed; in two cases the lateral operation was resorted to, and in two the supra-pubic incision. I think that the supra-pubic is far better than even crushing.

Dr. G. Betton Massey:—Hypertrophy of the prostate is often regarded as a hopeless condition, both from a medical and a surgical standpoint. I have, however, recently had two case of cure of the prostate enlargement. The first case was that of a gentlemen seventy-three years of age, who was sent to me some years ago with an old-standing enlarged prostate. He was treated by me after the plan of mild negative electrolysis in the urethra. The applications were made twice a week, the current-strength being from five to ten milliampéres. I subsequently increased the dosage to twenty-five milliampéres, which produced considerable irritation. The duration of each application was from three to five minutes. This was repeated three or four times, when I lost sight of the case. Two years afterward I met the physician who sent him to me, and learned that the patient claimed that he was entirely well.

The second case was that of a gentleman seventy-four years of age, who for two years had dribbling of urine, and finally had complete retention, necessitating the use of the catheter. The prostate was so large as to interfere with defecation. There was complete retention but no true cystitis. In this case I applied to the prostate gland a current of from twenty-five to forty milliampéres, with the negative pole electrode, consisting of a silver prostatic catheter insulated to within an inch of its extremity. There was hardly any sensation of pain and no irritation following the application. The current was simply turned on and then off. I did not use electrolysis, but a galvanic constringing current. I obtained a galvanic effect on the semi-muscular organ. I also used the faradic current and the galvanic current in the rectum, employing from sixty to seventy milliampéres. As a result of a

month's daily treatment, the man empties his bladder completely, and the prostate is shrunken two-thirds. If we have an agent which can contract these organs, its use is preferable to operation which ablates only one part.

Dr. Hoffman:—The key to the situation is, that Dr. Deaver uses tradition and not logic. Dr. Ashhurst, in the last edition of his *Surgerg*, does not recognize the importance of the operation. Dr. Agnew, in a paper in the *University Magazine*, uses the expression that he does not see the sense of going into a house by the roof when you can get in by the cellar. It, however, does make a difference if there is dynamite in the cellar.

There is one other claim for the supra-pubic operation, and that is its use to afford drainage after operations on the male urethra. In all such operations there is great danger of extravasation, especially when a new urethra is to be made. By supra-pubic incision, this danger can be avoided and the wound can be attended to properly and healed without the additional dangers of urinary infiltration and irritation.

Selected Formulæ.

PRESERVATION OF FEHLING'S SOLUTION.

Of all the tests yet discovered for glucose, perhaps none is more valuable than Fehling's solution. The only objection to its use is its proneness to decomposition and the necessity of preparing it fresh when needed for use. Dr. L. Patel suggests, in the *Lyon Medical*, the following means of obviating this trouble:

Everybody knows that Fehling's has the following composition:

℞

Crys. copper sulph	grammes	34·65.
Tart. sodium; potass	"	173·00.
Soda lye	cm.	300.
Distilled water, q. s. ad	cm.	1000.

The 173 gm. of sodium and potassium tartrate require for solution 300 cm. of distilled water, which added to the 300 cm. of liquor sodæ make 600 cm. of alkaline solution. The sulphate of copper dissolved in the remaining water, there is nothing remaining but to unite the two to have 1 liter of Fehling's solution. This we postpone until it is desired to use the solution, and then we take only so much of them as is needed in the proportion of 6 cm. of the alkaline solution to 4 cm. of the copper solution. We thus have a fresh solution every time. I have used this plan for over a year past, and find nothing in results attained by me to make me believe that either liquid has deteriorated.

HYPODERMATIC INJECTIONS IN PHTHISIS.

Dr. Louis E. Ruiz reports a case of consumption cured by hypodermatic injections (in one year, 827) of carbolic acid. He used one or two syringefuls of the following solution:

℞

Water	parts	l.
Carbolic acid	"	iv.
Glycerin	"	vj.

Bacilli were found in the sputa. The patient enjoyed good hygienic surroundings. Two tablespoonfuls of Churchill's hypophosphites were given daily, with hypodermatic injections of phenic acid. The expectoration finally became very scanty, and the bacilli disappeared; 1037 injections altogether were made in nineteen months. No abscess or local lesion was produced. The case was one of hereditary consumption.—*Gazeta med. de Mexico*, April 15, 1891.

MIST. SYRUPI PRUNI VIRGINIANÆ.

℞

Morphinæ sulphatis	gr. ¾.
Vini antimon	3ij.
Syr. ipecac	3iij.
Syr. pruni virgin.	
Syr. Tolu, aa	3xiij.

M. Sig, Teaspoonful as occasion requires.

—*Weekly Med. Rev.*

CREASOTE GIVEN BY THE RECTUM.

Dr. Revillet (*Gazzetta degli Ospitali*, 1891) administers creasote by means of rectal injections. He uses the following:

℞

Creasot. purissim	gm. ij--iv.
Ol. amygdalar. dulc	gm. xxv.
Aq. destillat	gm. cc.
Vitell. ovi	gm. j.

The injections are generally given in the evening before the patient retires, after a preceding injection to clean out the intestine. Absorption takes place at once, the patient notices the characteristic taste and the urine assumes the blackish or black-green color. At the same time the temperature falls, as after antipyrin. The injections are well supported and absorbed. It is taken up by the branches of the portal vein and eliminated by the salivary glands, pulmonary mucous membrane, and, above all, by the kidneys. One should be certain of the soundness of the liver, heart and kidneys before prescribing creasote in large doses. In tubercular diarrhœa the injections seem to arrest the discharges.

A DISORDERED CONDITION OF THE PRIMÆ VIÆ.

Dr. J. M. Hays, of Oxford, N. C., writes to the *Medical Record:* "A furred tongue—large and flabby, with a bluish cast—anorexia, constipation, perhaps alternating with diarrhœa, slight headache, general lassitude, sleeplessness, loss of interest in business and pleasure. Do you see such cases? Give them.

℞ Podophyllin.....gr. x.
Tinct. nux. vom.....ʒ j.
M. Sig. Shake and take from five to eight drops in a little water before each meal.

You will be pleased with the results. Use this also where nitromuriatic acid seems indicated, but fails to produce the desired result. After an experience of several years with this prescription I can recommend it with confidence."

NAPHTHALIN IN DYSENTERY.

Naphthalin is recommended by Minerbi and by Calphe for dysentery:

℞ Naphthalin.....gr. xv.
Olei theobromæ.....q. s. M.

For one suppository, or

℞ Naphthalin.....ʒ j.
Olei olivæ.....ʒ iv. M.

For a rectal injection, several times a day. The latter is useful also for oxyuris vermicularis in an adult. For children with pin worms the following injection is used:

℞ Naphthalin.....gr. xv.
Olei olivæ.....ʒ x. M.

—*Boston Med. Surg. Jour.*

THREAD OR SEAT-WORMS.

W. Thornton Parker recommends most highly the following: Copious rectal injections of chloride of sodium in solution, or of boro-glyceride, one to twenty, followed by small rectal suppositories of boro-glyceride; a dose of fluid extract of spigelia and senna in the morning, with a moderate dose of castor oil a few hours later, with reasonable attention to errors in diet, and particularly as to water supply, is all the additional treatment required.—*Medical News,* July 18, 1891.

PERMANGANATE OF ZINC IN URETHRITIS.

Berkley Hill has employed with success permanganate of zinc in the treatment of acute urethritis. The drug does not produce irritation of the mucous membrane of the urethra, even when used for a long time, provided the solutions are not concentrated. The following formula is recommended by the author:

℞ Permanganate of zinc.....grammes 0.05.
Distilled water..... " 200.00.
M. Sig. For injections.

NOTE.—Never administer, at the same time, preparations containing alcohol, vegetable extracts, etc., as the permanganate forms with these, highly explosive substances.—*Journ. de Malad. Cutan. et Syphilit.,* October, 1891.

PREPARATIONS OF EUROPHEN.

Eichhoff gives the following in the *Zeitsch. d. Allg. Oest. Ap. Ver.:*

1.

℞ Europhen.....grammes v.
Olive oil..... " x.
Lanolin..... " lxxxv.
M. Sig. "Unguent."

2.

℞ Europhen.....grammes j to v.
Olive oil..... " x.
Gum arabic in powder..... " x.
Distilled water..... " cc.
M. For intra-urethral injections in blennorrhagia.

DIABETES INSIPIDUS.

Prof. DaCosta prescribed the following to stop the large flow of urine:

℞ Antipyrin.....gr. v.
Quininæ sulph.....gr. ij. M.

To be given twice a day, and if this does not act satisfactorily, increased to three times a day.—*Coll. Clin. Rec.*

SEMINAL EMISSIONS.

The following (*Norsk Magazin for Lægevidenskaben,* No. 5, 1891) is praised:

℞ Potassi bromat.
Tinct. ferri muriat. } aa.....grammes xxx.
Aq. destillatæ..... " lxxxx.

One to two teaspoonfuls after each meal and at bed-time.

TREATMENT OF DIPHTHERIA BY CYANIDE OF MERCURY.

Ruelle has obtained good results from the use of this salt internally, recommended by Werner and Lœffler, and as follows:

℞ Cyanide of mercury.....gr. j.
Alcohol.....ʒ ij.
Water.....ʒ vij, M.
Sig. A teaspoonful every hour.

NEURALGIA.

Dr. W. M. Hightower recommends the following:

℞ Ammonii bromidi.
Sodii salicylatis, aa.....ʒ j.
Tinct. hyocyami..... ʒ ij.
Aquæ ad.....ʒ iv.
Sig. One teaspoonful every half-hour until relief is obtained, or four doses have been taken.

LEADING ARTICLE.

THE TREATMENT OF HERNIA BY MEDIAN ABDOMINAL SECTION.

In the September number of the *Brit. Med. Journ.*, 1883, Dr. Lawson Tait first made public a proposal to treat certain forms of hernia by median abdominal section. He was led to this idea by the fact that in many cases where he was called upon to operate for ovarian cyst, he succeeded in reducing, by traction from within the abdomen, old irreducible hernias. Finally, he devised a method of suturing together the columns of the ring, for the radical cure of hernia, which he practiced with success in many cases of chronic hernia occurring in females.

Recently (Annual Meeting Brit. Med. Assoc. Bournemouth, July, 1891) Dr. Tait has again brought forward this method of dealing with hernia, and now proposes it for all varieties of hernial protrusions, with or without strangulation, and for the radical cure of hernia. His claims for the superiority of his method over the ordinary operations performed, are chiefly as follows: (1) the strangulation is relieved without enlargement of the tendonous aperture through which the hernia has escaped; (2) the operation is a simplification of existing methods; (3) reduction is more easily accomplished by traction upon intestine or omentum from within the abdomen than by taxis performed externally; (4) the diagnosis is rendered certain as soon the fingers have access to the intestinal ring; (5) the radical cure by suturing together the columns of the ring from within is a less grave operation than incision of the sac often is. Dr. Lawson Tait's method, by which, he says he has succeeded in curing many cases of chronic hernia in women, consists of a medium suprapubic incision, the relief of strangulation or of chronic protrusion by gentle traction from within upon the protruded intestine or omentum, and after this has been accomplished the application of his method for radical cure, which he describes as follows: "Two

common glover's sewing needles armed with one piece of salmon silk-worm gut are fastened in some convenient needle-holder at a very slight angle to one another, so that their points completely coincide, and can be made to enter through one hole in the skin. The left forefinger covers or occupies the inner aperture of the sac, the needles are made to enter from without, and are then separated. The outer needle is then made to dip deeply into the external column of the ring, and the inner needle similarly into the inner column. The needles are then pulled out through the central incision, and as many sutures as may be thought desirable are inserted in this way. When the insertion of the stitches is completed, they can be tied from within and cut short. The abdominal wound is then closed properly and the operation is over."

Such is then the operation which this distinguished surgeon has strongly advocated and pressed upon the notice of his English colleagues at the last meeting of the British Medical Association; while his suggestion was most conservatively received by the majority of the able surgeons present, still, this surgical inovation is not deemed advisable in some cases, was evidenced by the remarks made by several distinguished operators. One of the chief objections to this mode of operating for the relief, for example, of a chronic irreducible inguinal hernia, is, that very often old adhesions will prevent reduction by traction from within, and thus a second incision opening up the sac will be a necessity. This happened in one of Dr. Lawson Tait's own cases, but he does not regard a secondary incision over the sac as a serious complication to the operation. Another objection which will instantly occur to anyone having any practical knowledge of strangulated hernia, is, that where the strangulated part has become gangrenous, traction from within would certainly rupture the gut; but Dr. Tait considers the median suprapubic incision a better place for an artificial anus than in the groin.

We cannot think that Lawson Tait's abdominal incision should be used in ordinary cases of strangulated hernia, but that his original suggestion is a very valuable one no one can deny. In umbilical, or in obdurator hernias the introduction of two fingers, and the manipulation with traction possible in that way, would seem of decided value, while for diagnostic purposes such an incision would be an addition to our best of surgical procedures in such cases.

The high position occupied by Dr. Lawson Tait as a surgeon, and the discussion which his very radical suggestion for the treatment of hernia has evoked, will undoubtedly lead to an extensive trial of his operation in cases that are suitable for it. Dr. H. Widenham Maunsell, lecturer on Surgery in Otago University, Dunedin, N. Z., highly recommends abdominal section in strangulated femoral, odurator, umbilical, and diaphragmatic hernias. He only differs from Tait's method by using needles with handles armed with silver wire, which he twists up tight outside, instead of the silk-worm gut sutures which Dr. Tait ties inside the abdomen.

It is to be hoped that this mode of dealing with hernias will receive careful consideration from our own surgeons, and that, if the procedure is found of real value, its true limitations will soon be ascertained.

PERISCOPE.

THERAPEUTICS.

SULPHATE OF MAGNESIUM IN EPITHELIOMA.

The treatment of warts by the internal administration of small doses of sulphate of magnesium is said to have been attended with a considerable amount of success, even large growths disappearing under the remedy when persisted in for a sufficient length of time. It is now claimed that epitheliomatous warts may be dispersed by the same means, a paper on this subject having been read before the New Hampshire Medical Society by Graves. Three drachms of the salt are added to a pint of water, and a teaspoonful of the mixture taken four times a day. The author gave an account of eight cases in which the treatment had been adopted with success; but he admitted that the possibility of erro-

neous diagnosis had to be considered. It was, however, a fact that growths of an elevated character with round or oval bases and ulcerated summits discharging an ichorous fluid were transformed by the treatment into perfectly healthy spots, which exhibited no signs of diseased structure, and his conclusion was that the result was obtained by the remedy employed.—*Med. Press.*

FELL'S OPERATION (TRACHEOTOMY) IN MORPHINE POISONING.

The recent successful termination in this Hospital of a case of morphine poisoning, in which the patient had taken 20 grains of the drug, leads us to speak of the plan of treating extreme cases of narcotic poisoning introduced to the profession by Dr. Fell, of Buffalo. The operation consists in a tracheotomy and the use of a pair of bellows, which provides for driving air into the lungs and by means of a valve lets the carbon loaded air escape from the lungs. It insures a constant supply of fresh air to the pulmonary capillaries, at the same time that it promotes the escape of air laden with organic products of respiration, which may have been exerting an influence tendering to the death of the patient.

The case referred to was an extreme one. She was 21 years old; not addicted to morphine. Took 20 grains and vomited none of them. Her respiration was, at the time, but four per minute. She was anæsthetized by the drug. Artificial respiration by the Sylvester method had been thoroughly tried. The trachea was opened by incision and a tube inserted; then a hand bellows was attached and for three hours the respiration was kept up. At the end of that time the reflexes began to return and it was apparent the case was saved.—*Detroit Emergency Hosp. Rep.*

OPIUM IN CHRONIC CONSTIPATION.

Dr. Nevins (*Il Raccoglitore Medico*, No. 14, 1891), in chronic constipation, to overcome the chronic irritation and subacute inflammation of the colon present, employs Dover's powder (12 grs.,) with turpentine fomentations to the abdomen, with the best results. He exercises great care in the patient's diet, and avoids purgatives.

MERCURIAL INUNCTION IN GLANDERS.

Gold (*Berlin. klin. Wochenschr.*, October 5th, 1891) publishes the case of a man, aged 32, suffering from a severe attack of glanders, inflammatory deposits being present in the right thigh and leg and the left arm. There was no history of equine infection, but the nature of the attack was proved by the presence of the characteristic bacillus under the microscope, and, further, by the fact that pus taken from the inflamed areas communicated glanders to animals inoculated with it. The treatment adopted by Gold was (as in a similar case published two years ago) to incise the phlegmonous areas and dress the wounds with corrosive sublimate (1 to 1,000) and iodoform gauze. The other important feature in the treatment was the use of mercurial inunctions, sixty-two applications being spread over eighteen days. The results were highly satisfactory. The temperature, which at first reached 104° F., gradually subsided, the wounds cicatrized, and the general condition of the patient improved so rapidly that he was before long discharged quite well.—*Brit. Med. Jour.*

THE TREATMENT OF PURULENT OPHTHALMIA.

At a recent meeting of the Harveian Society, Mr. Jules gave an interesting lantern demonstration on the chief varieties of ophthalmia. In speaking of purulent ophthalmia, he strongly recommended the hourly use of a weak solution of perchloride of mercury (1 in 5,000) to cleanse the conjunctival sac, combined with the daily application of strong nitrate of silver solution to the everted lids. Division of the outer canthus was recommended, if necessary, to gain access to the conjunctival surface, and to relieve tension on the globe. Dr. Boxall stated that acid solution of quinine (gr. v. to ʒj) and boracic acid solution had been employed with success at the General Lying-In Hospital ten years ago. The President (Mr. Cripps Lawrence) spoke highly of liquor sodæ chloratæ.—*Brit. Med. Jour.*

OZONE FROM A PHYSIOLOGICAL AND THERAPEUTIC POINT OF VIEW.

Heretofore, in order to obtain the biological properties of ozone, animals have been shut up in closed receptacles traversed by a current of ozonized oxygen, prepared chemically, or by the action of electricity on oxygen. This *modus operandi* is unfavorable, and has given rise to the opinion the respiration of ozone is dangerous.

Prepared chemically, ozone is impure and mixed with toxic compounds—phosphorous

acid, for example. If it be prepared with pure oxygen, considerable quantities are obtained which, mixed with oxygen non-transformed, constitute a compound dangerous to respire, especially in an enclosed space. The results are absolutely different if we obtain the conditions approaching those of the habitual production of ozone, that is by causing animals to respire a mixture of atmospheric air and ozone; in the latter cases accidents are never observed.

Messrs. Labbé and Oudin have prepared ozone by passing a current of air through two concentric tubes 3 to 4 millimetres apart, the intervening space being traversed by electric sparks. To obtain a sufficient quantity of ozone, they take the interior tube, sealed, and containing the rarefied air, which acts as a perfect conductor and is perfectly applied to the surface of the dielectric, which is the glass. The other armature of this form of condensor is constituted by a metallic sheet applied to the internal face of the external tube, and it is between this metallic sheet and the surface of the internal tube that are formed the sparks engendering the ozone. The slightest elevation of temperature which is produced in the cylindrical space separating the two tubes, is sufficient to produce a current of air, ascending and bearing along the oxygen formed. Under the circumstances, the air does not contain more than 11 to 12 hundredths of a milligramme of ozone per litre, which the authors called the therapeutic dose. In subjecting animals and themselves to inhalations of air ozonized in these proportions, the quantity of ozone respired in about a quarter hour is 2 milligrammes—a dose hitherto reputed dangerous, and yet inhalations continued for several hours under the foregoing circumstances have produced no disquieting symptoms. Convinced of the absolute innocuousness of these inhalations, Messrs. Labbè and Oudin have experimented with cachectic patients and even with children of tender years.

It is known that the quantity of oxyhæmoglobin contained in the blood is 13 to 14 per cent. If a subject whose blood contains only 10 to 11 per cent. of oxyhæmoglobin (which is the ruling proportion with city people), be subjected to inhalations of ozonized air, an augmentation of 1 per cent. will be found at the end of a quarter of an hour. This increase persists only for 12 to 24 hours, if the patient takes no more inhalations, but, if they be renewed every day, the quantity of oxyhæmoglobin continues to augment little by little until it reaches the physiological figure.

We know also that ozone is a powerful germicide, capable of arresting most advanced fermentation, even in small doses. On the other hand, the tubercular bacillus is gifted with the greatest resisting power to antiseptics. Will ozone act on this bacillus as on so many others? This is what Messrs. Labbé and Oudin have sought to determine.

For this purpose they have instituted the following experiments with the coöperation of M. Veillon: they took a culture of tubercular bacilli, on peptonized gelatin, which they divided into four tubes. Two of these tubes were traversed during two hours by a current of ozonized air, furnished by the apparatus above described, and the cultures were inoculated into guinea pigs which are yet living, fifty days after inoculation. The other tubes, non-ozonized and preserved as witnesses, were inoculated into guinea pigs which succumbed after 25 days. Without attributing to this experiment more importance than it merits, the authors consider it interesting and encouraging.—Helfman, in *Med. Age.*

NITRO-GLYCERIN FOR NEURALGIA AND PHYSICAL DEPRESSION.

Dr. John N. Upshur said that he had been sent for recently to see a woman, aged 35, whom he found suffering from acute diarrhœa rapidly going on to dysentery, with a neuralgic headache, insomnia, irritable stomach, and great depression. The bowels were controlled by enemata. On account of the depression and irritability of stomach, the administration of such analgesic remedies as phenacetine, antipyrin, etc., was not considered advisable; so he determined to employ and observe the effects of nitro-glycerine. One one-hundredths of a grain was given 11.58. In three minutes its effect, as manifested by increased tension of pulse, could be positively identified. In two minutes more, she expressed herself as greatly relieved, and experienced a desire to sleep. By ten minutes past twelve (twelve minutes since the administration of the remedy), the patient was comfortable, and the doctor left, leaving an additional dose with the husband with instructions to administer if there should be a return of the depression or headache. When seen in the evening, there had been no recurrence of these distressing symptoms, and consequently

no occasion for a repetition of the dose.—*Virg. Med. Monthly.*

DESTRUCTIVE ACTION OF CARBOLIC ACID.

A. Frankenburger (*Inaug.-Diss., Erlangen,* 1891,) warns against the injury to skin, and even bone, which may result from the long-continued application of weak (3, 2½, and even 2 per cent.) carbolized applications, especially upon peripheral portions of the body, such as the fingers. This effect is due in a small measure to the action of carbolic acid upon the vaso-motor system, but in the main to its destructive effect upon the red and white blood corpuscles. This induces, partly in a mechanical and partly in a chemical way, stasis, first in the capillaries, and, if the action of the drug be continued, then in the larger veins and arteries, with the result that the nutrition of the part is interfered with, and the removal of harmful substances hindered. The maceration of the epidermis caused by the acid favors evaporation, so that the gangrene is a dry one, a mummification as it were. The author believes that even weak carbolic solutions as external applications are to be either completely discarded, or to be used only with the very strictest precautions, and that the sale of carbolic water by druggists should be wholly stopped.

A READY AND EFFECTIVE REMEDY FOR INSECT STINGS.

As soon as possible after being stung saturate the corner of a handkerchief with fresh urine and apply freely. As soon as the liquid has penetrated to the poison the pain subsides, the inflammation soon disappears, and in a very short time scarcely a trace of the wound remains. The completeness of the cure depends somewhat on the length of time allowed to pass before applying the remedy; for if the poison is completely absorbed, and its destructive effects accomplished before the antidote is used, such complete and instant relief cannot be expected.

About fifteen years-ago I had occasion to give this remedy a severe test. With others, one a small boy, I was exploring a forest on the mountain. We had separated, when I was startled by terrific screams. Rushing toward the sound, I met one of the party dragging the boy away from a hornet's nest. He was covered from head to foot with yellow hornets, and was writhing and screaming in agony from their stings. Finding it impossible to beat off the insects in time to prevent further serious injury, I seized him by the collar and dragged him at high speed through the thick bushes for many rods. When we finally emerged into an open space the hornets had been left behind. The child was instantly undressed and handkerchiefs saturated with fresh urine applied repeatedly to his numerous wounds. In a very short time the little fellow exclaimed, "I'm all right!" and commenced to dress himself. He suffered no further inconvenience from the stings, and before we reached home nearly every trace of them had disappeared.

I think the active agent in antidoting the insect venom is the urea. I always intended to carry experiments further and test its effects on the venom of reptiles, but circumstances have prevented.

An acquaintance of mine in those days, an intelligent man, used to relate his experience in two cases of snake bites; one of a rattlesnake, the other a red adder. He claimed they were both cured by chopping the snakes into short pieces, splitting them open and applying them in succession to the wound. We are told that the contents of the intestines of snakes consist almost entirely of crude urea, and I have thought it possible that enough of this got into the wounds in these two cases mentioned to at least partially antidote the poison.—Wm. H. Terry, in *Medical Progress.*

TREATMENT OF BURNS AND SCALDS

Having observed the good results obtained from the application of rubber cloth to wounds upon which skin has been grafted, as well as to the surface from which the graft has been taken, Dr. O. P. Barber, of Saginaw, Michigan, has suggested a similar procedure in the treatment of burns and scalds. The burned surface is freely irrigated with carbolized water, all necrotic tissue removed and blebs punctured. Then the entire wound is snugly wrapped in rubber tissue that has been kept in a carbolized solution. Over this is placed absorbent cotton and a bandage. The advantages claimed for the dressing are that it relieves pain, that it does not adhere to the wound, that it excludes air, and that it protects the granulations, whilst preventing their exuberant growth.—*News.*

THE GERMICIDAL ACTION OF EGG ALBUMIN.

A. Wurtz (*Compt. Rend. Soc. Biolog.,* 42, 20; *Ber. Deut. Chem. Ges.,* 24, 465,) found

that by the digestion with the uncooked white of egg at 38° a small number of bacillus anthrax, cholera-spirillum, Ebert's bacillus, bacillus pyrogenes aureus, and of bacillus subtilis were killed. This property of the albumin prevents the invasion of eggs by bacteria. Coagulated egg albumin has no germicidal properties.

CONSIDERATION OF CERTAIN NEW REMEDIES EMPLOYED IN THE TREATMENT OF CUTANEOUS AFFECTIONS, AS SUBSTITUTES FOR IODOFORM.

E. Chatelain (*Journ. d. Maladies Cutan. et Syph.*,) discusses the objectionable characteristics of iodoform and then reviews the literature of aristol, bromol, cresalol, eugenol, iodol, lysol, camphorated naphthol, retinol, salol and camphorated salol, sozoiodol, and eulyptol.

Among these aristol is perhaps the most important. Chatelain himself found it useful in varicose ulcers; in syphilitic chancre the effect was not more rapid than iodoform, but in a case of eroded papules of the glans penis he obtained a cure with it in a few days. He experienced a complete failure with it in a case of ulcerating epithelioma of the face, which had first been treated surgically by himself. He was obliged, in order to obtain healing, to have recourse to iodoform.

The various observers who have recorded their opinions find that aristol is valuable in syphilitic ulcerations of all kinds. Some speak favorably of its use in chancroids, others, however, the opposite. The majority have obtained good results with it in suppurating buboes, psoriasis, lupus, and eczema, still there are some who obtained the opposite. The same conclusions are also recorded in connection with epithelioma. The author concludes that aristol is worthy of being retained among dermotherapeutical agents and may prove to be, in the end, a precious successor and substitute for iodoform.

Among the others eugenol may be mentioned, an oleaginous liquid obtained from cloves insoluble in water, but soluble in alcohol and in ether. Unna found that it destroyed lupus nodules without pain; Leubuscher used a 70 per cent. ungt. on a case of very pruritic, weeping eczema with immediate removal of symptoms.

The author has also obtained excellent results from the use of iodol in 10 cases of ulcerating gummata. In 20 cases of chancroids the action of the drug was favorable, but it was less than iodoform.

According to the reports, camphorated naphthol has acted well in ulcerations of various nature, in buccal tuberculosis, and also in mycosis fungoides. Nélaton claims that in 27 cases in which he injected into tubercular glands from 7 to 8 drops, a cure was obtained in 21. On the other hand, another observer reports no results from the drug in a case of cutaneous tuberculosis with maxillary and inguinal adenitis.

INHALATIONS OF HYDROGEN DIOXIDE IN DISEASES OF THE RESPIRATORY ORGANS.

Dr. Gabrilovicz has employed inhalations of peroxide of hydrogen in cases of phthisis. The patients presented all the symptoms of the disease (infiltration at the apices, bronchial breathing, râles, loss of flesh, night-sweats, occasional hæmoptysis, etc.). A solution of peroxide of hydrogen in water, in the proportion of one to ten parts per hundred, was employed, the weak solution at the beginning. The inhalations were continued for several months. Six patients treated in this manner were greatly improved, the pulmonary symptoms being greatly ameliorated. The cough was relieved, the expectoration diminished, and in some cases the consolidation was reduced. Although the author's observations are limited, the results are certainly encouraging. Dr. Gabrilovicz thinks that inhalations of peroxide of hydrogen will prove very serviceable in the various forms of laryngitis, tracheitis, bronchitis and also in the early stages of laryngeal and pulmonary phthisis. He also advises this treatment in laryngitis stridulus, whooping-cough, asthma. In tubercular laryngitis it is best to commence with a five per cent. solution of the peroxide; in other diseases it is advisable to employ at first a one per cent. solution, gradually increasing the strength until the proper dose is reached.—*Gaz. Med. de Liége.*

MEDICINE.

ULERYTHEMA SYCOSIFORME.

Sack (*Monats. f. prakt. Derm.*, No. 4, August, 1891) describes an example of a skin disease affecting the face, which has been described by Unna under the above name. The case occurred in Unna's clinic, in a man aged 24. The affection began on

the left temple, causing complete baldness and atrophy of the skin. It advanced slowly in the direction of the beard, and produced symptoms of severe irritation of the skin, was attended with loss of hair and progressive diffuse atrophy of the affected part of the cutis. The characteristic symptoms were the extremely chronic and slowly progressive nature of the affection, its serpiginous course, and its intractability. In the later stages of the disease a considerable amount of pus is formed. Relying on a histological examination, Sack considers that the affection may properly be described as "dermitis (not dermatitis) perifollicularis parenchymatosa atrophicans." It is, in fact, a chronic inflammation of the cutis, especially occurring in the connective tissue around the follicles, accompanied by growth of the cellular elements of the cutis, and finally atrophy of the skin.—*Brit. Med. Jour.*

HOUR-GLASS CONTRACTION OF THE STOMACH, WITH LARGE ULCER.

Dr. R. Saundby (*Birmingham Med. Rev.*, October, 1891, p. 228), relates the following case: A woman, aged 31, was admitted to hospital complaining of severe pain and tenderness in the stomach. On the day of her admission, she twice vomited watery fluid matter, depositing a sediment like coffee grounds. Seven years before, she had suffered from "ulcerated stomach" with coffee-grounds vomit. Again, four years ago she was ill with the same complaint, but she did not remember any hæmatemesis. Her present illness dated from six months previous to her admission; it began with pain in the left hypochondrium radiating round to the back, and vomiting, sometimes immediately, at other times two hours after food, but no hæmatemesis till four months from the beginning of the attack, when she vomited a quantity of blood, and passed a lot by the bowel. She complained of great flatulence and acidity, and of frequent pain over the stomach, which was at once greatly increased by taking food, and was only relieved by vomiting, which occurred usually half an hour to an hour after a meal. The abdomen was retracted and soft, except just to the left of the epigastric region, where there was some resistance and pain on pressure. She was first treated with milk and lime water, but as the sickness continued she was fed by nutrient enemata alone, for a short time, after which the milk, etc., was resumed, but eighteen days after admission the vomiting and pain were very troublesome. The vomit was described as being like thick yeast, very foul-smelling, alkaline, and gave no evidence of containing free hydrochloric acid. The vomiting continued, and rather more than two months after admission she was suddenly seized with symptoms of perforation, intense pain in the abdomen, vomiting, and collapse, and died the same evening. At the necropsy general septic peritonitis was found. The stomach was hour-glass shaped, and bound down to the left lobe of the liver by old inflammatory adhesions. It was divided into two cavities by a narrowing situated about five inches from the pylorus; the opening between the two admitted one finger. There was no appearance of a cicatrix or thickening here, and the microscope showed no changes in the mucous or submucous coats around it. In the cardiac portion there was a large ulcer, about four inches long, situated along the greater curvature. This had exposed the pancreas, to which it was everywhere adherent, except at one point which had given way. The exposed pancreas, was ragged and partly digested. The hour-glass contraction presented all the features of a congenital malformation, that is to say, there were no indications of any inflammatory process to cause the constriction.—*Brit. Med. Jour.*

NERVOUS AFFECTIONS IN INFLUENZA.

In a paper communicated to the Chicago Medical Society, June, 1891, Church refers to many of the nervous complications and sequelæ of recent influenza epidemics. He finds in the records of the Chicago Health Office that in the years 1888 and 1889 there was very trifling variation from month to month in the death-rate from nervous diseases. Under the subheadings cerebro-spinal fever, apoplexy, convulsions, and meningitis, the mortality was also equally distributed. In 1890 there was a great increase in the number of deaths from nervous diseases—mainly under the heads "meningitis" and "convulsions"—for several months following the subsidence of the *grippe*. During the first four months of 1891 the deaths assigned to these causes much exceeded twice the average of preceding years. When divested as far as possible from all falsifying circumstances, the lunacy reports of the Cook County Court show a marked increase in the number of persons becoming insane during the prevalence and decline of the influenza.—*Brit. Med. Jour.*

THREE CASES OF ELECTRICAL TRAUMATIC NEUROSIS.

Dr. James W. Putnam gives in the *Buffalo Medical and Surgical Journal* some very interesting notes: In July, 1890, during a severe thunder and lightning storm, three telephone operators received an electric shock, from an unusually vivid flash that passed through the lightning cut-off with which the key-board is supplied. At the time of the shock each operator was wearing a metallic arrangement closely fitted to the head, which holds the receiving phone in position against the ear. They were each holding a metal plug in the hand, preparing to make a connection on the key-board.

No. 1 was a large, healthy, well-developed young woman of Irish decent, aged 20. She was rendered unconscious for a few moments. On regaining consciousness, she complained of severe headache, and of deafness of the left ear, which was in contact with the phone, and which received the shock. Examining this patient, Dr. Putnam found complete cutaneous anæsthesia of the left side, the pharynx and conjunctivæ. There was no paralysis. From the symptoms he diagnosticated the deafness to be functional, and treated it as such by suggestion, with the result that the hearing was perfectly restored. The headache remained, and only yielded to bromide of potassium.

No. 2. A young woman of German parentage, with previous good health. She was in bed when Dr. Putnam first visited her. She said it made her dizzy to stand up, and made her headache worse. Examination showed cutaneous anæsthesia of left side of face and scalp, left side of thorax anteriorally, left arm, conjunctivæ anæsthetic. The anæsthesia disappeared after two treatments with the faradic brush, briskly applied. In addition she took a spinal douche, 40 degrees, 15 seconds, daily. The headache was treated with 20 grs. pot. brom. and 15 drops ergot. The headache disappeared, but always came back if she attempted work at the telephone office. Believing this to be a headache suggested to her by the sight of the apparatus from which she received the shock, Dr. Putnam hypnotized her, and suggested that she should have no more headache, either at home or at the telephone office. She has remained well, has returned to work, and has had no return of headache.

No. 3. A slight girl, aged 21, of American parentage; was rendered unconscious for a few moments by the shock, was taken home, and was delirious for one hour, after which she became quiet; complained simply of throbbing headache. Examination discovered anæsthesia, as in the others, of the left side. Sensation was restored by one application of the faradic brush; headache disappeared after a few doses of pot. brom.

The similarity of the cases at once strikes us. There was headache and anæsthesia in them all, and each showed susceptibility to suggestion. Dr. Putnam believes these cases to be a combination of hysterical symptoms of anæsthesia, with the headache we naturally expect to result from severe electric shock.

THE DIAGNOSIS OF DISEASES OF THE CORPORA QUADRIGEMINA.

Eisenlohr (*Centralblatt für klin. Med.*, No. 30, 1891,) reports in detail a case of gunshot injury of the corpora quadrigemina. The lesion affected the tubercles of the corpora quadrigemina on the right side, destroying a great portion of both, together with the right habenula, a part of the right anterior brachium of the corpora quadrigemina, and extended close to the neighborhood of the aqueduct of Sylvius and the nucleus of the third nerve. The first and most important symptoms were abnormalities in the movements of pupils, diminution of the reaction of both pupils to light, and dilatation of the pupil on the same side as the lesion. At first there were none of the other symptoms regarded as characteristic of lesion of the corpora quadrigemina. These occurred later through secondary changes in the immediate neighborhood of the foreign body which had penetrated this region.

From his observation Eisenlohr draws the following conclusion respecting affections of the corpora quadrigemina.

The abnormalties in the movements of the pupils possess a higher importance in the diagnosis of affections of the corpora quadrigemina than one has ascribed to them. The ataxia is to be regarded as a symptom of lesion of the corpora quadrigemina. Probably for its occurrence the affection of a very limited portion of the posterior tubercles of the corpora quadrigemina is necessary.

A certain diminution of vision, independent of optic neuritis and optic atrophy, and without lesion of the optic tract, can be produced entirely by affection of the anterior tubercles, and of the anterior brachia of the corpora quadrigemina.

DEATH FROM PYEMIA AS A RESULT OF THE STING OF A FLY.

Paltauf (*Wiener klin. Wochenschr.*, No. 35, 1891) has recorded the case of a woman, thirty years old, who was stung on the right eyelid by a fly. On the following day there were considerable swelling, redness and pain in the right temporal region, with fever, and to these were added cerebral symptoms. On the second day manifestations of collapse appeared, with heart-failure; death ensued on the morning of the third day, little more than forty-eight hours after the fly-sting.

At the autopsy, in addition to the conditions observed during life, there were found multiple phlebitic thrombi and abscesses in the texture of the right temporal muscle, thrombi in a radicle of the cavernous sinus and in the sinus itself, an excess of fluid in the pleural cavities, and multiple, softening, hæmorrhagic and purulent thrombi in the lungs. There were also parenchymatous swelling of the kidneys and liver and acute enlargement and softening of the spleen. The pus of the phlebitic abscesses in the temporal muscle, of the pulmonary infarcts and incipient abscesses, and the fluid of the spleen contained many cocci, which on culture proved to be principally staphylococci aurei together with staphylococci albi.

DESTRUCTION OF SUGAR IN THE BLOOD.

Lépine and Barral (*Comptes Rendus*, cxii, Nos. 5 and 8, 1891) collected some arterial blood from a dog in a vessel cooled to 0° C., then defibrinated it, and at once estimated the amount of sugar it contained. Other samples of the same blood were kept at different temperatures; *b* at 39°, *c* at 49°, *d* at 52°, and *e* at 55° C., and left for one hour. After this time the amount of sugar in *b* was found to be $\frac{1}{4}$, in *c* and *d* $\frac{3}{10}$ to $\frac{2}{5}$ less than in *a*, while in *e* it was the same as in *a*. This shows that the "sugar-destroying ferment" acts better the higher the temperature, until at about 54° C. its activity is destroyed. If blood withdrawn from an artery be centrifugalized, one obtains a serum which of course contains more sugar than the original blood, because the corpuscles contain scarcely any sugar. If such serum be kept at 39° C. for some time—for example, one hour—there is no diminution in the amount of the sugar, while blood similarly treated loses $\frac{1}{4}$ of its sugar. If the corpuscles which are separated by the centrifugalizing process be washed with saline solution, a filtrate is obtained which, if mixed with grape sugar, causes a part of the latter to disappear when the mixture is kept a 39° C. It would seem, therefore, that the "sugar-destroying ferment" is present in the blood corpuscles.—*Brit. Med. Jour.*

PURULENT PLEURISY.

Courtois-Suffit has made a study of the subject of purulent pleurisy, and presents certain facts of practical importance. Bacteriological research has revealed the existence of several varieties of purulent pleurisy, the etiology, symptoms, course, prognosis, and treatment of which differ with the active infectious agent. Three main groups may be recognized; 1, pleurisy due to the pneumonia-coccus of Fränkel; 2, that due to streptococci; 3, that due to the baccillus tuberculosis. In addition, there may be the following mixed forms: 1, pleurisy due to pneumonia-cocci and streptococci; 2, that due to streptococci and staphylococci; 3, that due to the bacilli of tuberculosis and streptococci; 4, putrid and gangrenous empyemata, caused by the microbes of suppuration associated with certain saprogenic organisms. There are, besides, rare forms of purulent pleurisy due to the bacillus of Friedländer, to the staphylococcus pyogenes, and to the bacillus of Eberth. In the pleurisy due to pneumonia-cocci—metapneumonic pleurisy—the pus is thick, greenish, creamy, without odor; the pleura is covered with false membrane, shreds of which may float in the effusion; the pleurisy has a tendency to become encysted; it often terminates in a vomica, and rarely becomes chronic; it may be primary, associated or not with other pathological conditions due to the pneumonia-coccus, in which case its onset is sudden; or it may appear insidiously in the course of a pneumonia or suddenly during defervescence; the temperature is that of a continued fever, without oscillations or irregularities; the effusion is copious in the acute primary form, moderate in the latent; the pleurisy terminates by absorption or by the formation of an encysted vomica; the prognosis is favorable; the mortality does not exceed five or ten per cent.; in this form, especially, is simple puncture justifiable. Purulent pleurisy due to streptococci may develop in the course of a constitutional affection caused by the same organisms as puerperal fever; in connection with other pathological conditions arising from infection by streptococci, as broncho-pneumonia and peritonitis, and

secondarily to remote affections, as an otitis or a phlegmon: the pus is thin, yellowish, without odor, flocculent, and shows no tendency to become encysted. Occurring in the course of another affection the pleurisy is latent and insidious; appearing at the termination it may be acute, frank, and painful; its evolution is slower than in the case of pleurisy due to pneumonia-cocci; the temperature is that of suppuration due to streptococci, with decided remissions and exacerbations; the effusion, usually moderate in degree, never yields to simple puncture; it shows no tendency to absorption or spontaneous evacuation, and only exceptionally gives rise to vomicæ; death may occur from septicæmia or purulent infection; the duration is long; the mortality about twenty-five per cent.; early and radical operative interference is necessary. The bacillus tuberculosis alone may occasion a purulent pleurisy, comparable to a cold abscess; the pus is thin, yellowish, opaque, without odor and flakes of fibrin; the pleura is thickened by many layers of superimposed plastic exudate, containing tuberculous nodules; the pleurisy may set in frankly and acutely, or may be insidious and latent, the patient sometimes remaining unconscious of the presence of the effusion, though this be abundant; during the active stage the general health may be preserved, febrile reaction may be absent, and the fluid slowly but persistently reaccumulates; a fatal result occurs sooner or later, according to the course of the pulmonary disease; repeated puncture is necessary. In the purulent pleurisies due to mixed infection the condition assumes the gravity occasioned by the most virulent microbe. The association of streptococci and staphylococci gives rise to a pleurisy of grave type, insidious onset, irregular course, with the signs of pyæmia and wide range of temperature; early and energetic treatment by means of incision and lavage is required. Pleurisy from streptococci may be a complication of pulmonary tuberculosis; although curable it may prove a serious complication, necessitating, perhaps, the operation for empyema. The pleurisy occasioned by the microbes of suppuration is especially grave when pulmonary cavities exist; the prognosis is then almost fatal. The putrid and gangrenous pleurisy rapidly gives rise to the grave general manifestations of sapræmia, it necessitates speedy and energetic intervention.—*Gazette Méd. de Paris*, No. 12, 1891.—*Amer. Jour. Med. Sci.*

DEFECTIVE INTER-VENTRICULAR SEPTUM WITHOUT CYANOSIS.

Wilbouschewitch (*Bulletin de la Soc. Anat. de Paris*, 1891, No. 2) reports the case of a seamstress, twenty-five years of age, with a tuberculous family history. The patient had been uninterruptedly at work, when suddenly a copious hæmoptysis took place. She was pale and thin. The chest was small and flat; the vertebral column kyphotic. The percussion note was dull and the respiratory murmur feeble over the upper third of the left lung. Râles and friction-sounds were heard, in greater number on the right. There was a little cough and expectoration. At the apex of the heart both a presystolic and a systolic murmur were heard and a purring tremor felt. Duplication of the second sound was heard at the base. A second copious hæmoptysis in the course of a few days, was followed by death. At the autopsy pleural adhesions were found, and the lungs contained many tubercles and some cavities. The heart was relatively large; the vessels were given off normally; the mitral orifice admitted two fingers. The inter-ventricular septum was defective at its upper part, and by the foramen thus formed the ventricles communicated; the opening was oval, slightly elongated transversely, and about as large as a two-franc piece; the lower portion of the septum was thickened, its upper free border was smooth; a thin band of muscular tissue intervened between the abnormal opening and the aorta; the mitral and tricuspid leaflets came in contact; a tendon of a leaflet of the tricuspid valve was inserted into the free border of the opening, before which the left tricuspid leaflet was stretched like a curtain. The pulmonary artery was dilated; the vessel bifurcated just above the valve, its branches in the lung were also dilated. Upon the endocardium of the right side of the heart and of the branches of the pulmonary artery were numerous patches and lines, probably the evidences of a fœtal endocarditis. During the ventricular systole the defect in the septum had apparently been partially closed by the tricuspid valve, preventing the admixture of venous and arterial blood and the production of cyanosis.—*Amer. Jour. Med. Sci.*

Quinine has been found to possess strongly pronounced cardio-tonic properties and hence will retard and strengthen the heart's action during pyresis.

SURGERY.

EXTIRPATION OF THE GALL-BLADDER, WITH THE ESTABLISHMENT OF A COMMUNICATION BETWEEN THE DUODENUM AND THE COMMON CHOLEDOCH DUCT.

In operating upon a woman forty years old, with calcular obstruction of the cyst duct, Sprengel (*Deutsche Medicin. Wochenschr.*, Sept. 3, 1891) mistook the cystic duct, and the common duct for the intestine. By expression the calculus was forced from the cystic into the common duct, and it was thought that the biliary passages were free. The symptoms continuing, however, the abdomen was again opened, and two calculi were found, one in the cystic duct, and the other at the transverse fissure of the liver. On account of the former the gall-bladder was removed, and the cystic duct was ligated; the second calculus was crushed. To overcome the obstruction in the common duct an artificial communication was established with the duodedum. Three months later the patient had recovered, and was free from symptoms.

TREATMENT OF CONGENITAL PTOSIS BY MEANS OF NAPHTHOLATED CATGUT.

Dransart has devised an operation for the relief of congenital ptosis, in which an artificial tendon, created from the frontal muscle, takes the place of the absent or atrophied levator palpebræ. The new tendon is made by means of subcutaneous sutures uniting the superior border of the tarsal cartilage with the superciliary muscle. The success of the operation depends upon the asepsis of the sutures and placing them in the deep, connective tissue layer of the skin. Sterilized catgut has answered admirably, except that it is absorbed in the course of two or three days, while twelve to fifteen are required to obtain a suitable artificial tendon.

Dehenne has found that by preparation with a solution of napthol the rapidity of absorption of cat-gut may be sufficiently retarded so as not to jeopardize the success of the operation. He reports a case in which the result obtained was excellent.—*Jour. de Med. de Paris.*

THE TREATMENT OF VARICOSE ULCERS.

Dr. J. Hartman recommends ichthyol in the treatment of varicose ulcers of the leg. After cleansing the sore with soap and warm water he applies pure ichthyol to the ulcerated surfaces and covers them with a thick layer of cotton, which is secured by an unstarched gauze bandage. The application produces an intense burning pain which usually lasts only for a short time. During the following days the patient experiences great relief, but as soon as the sore again gives rise to pain or discomfort, the dressing must be changed. Even at the first change of dressings, the ulcer will be found to present a better appearance, it will look cleaner and, unless, very chronic, will show signs of granulations at the margin.—*Correspondenz Blatt f. Schweitzer Aerzte.*

BRANCHIAL FISTULA CURED BY EXCISION.

G. Cavazzani relates (*Rif. Med.*, October 7th, 1891) a case of congenital fistula of the neck which he cured by excision. The patient was a girl, aged 13, who came under his care at the end of November, 1888. She had, just internally to the sternal insertion of the sterno-mastoid of the right side, a tiny pimple, which was said to become larger from time to time and to burst, giving issue to a discharge usually mucus, but occasionally milky, and sometimes containing fragments of food. The discharge generally continued for a few days and then ceased, when the opening closed and a pimple gradually formed over it as before. A small cord could be felt running upwards in the neck from the aperture to the right cornu of the hyoid bone, where it was lost. By a little manipulation it was possible to pass a slender probe along the fistula into the pharynx, where it could be seen at the edge of the posterior pillar of the fauces beside the tonsil. On December 21st the patient was placed under chloroform, and the strictest antiseptic precautions being used, two very small semi-elliptical incisions were made, enclosing the aperture of the fistula in the neck. The cervical end of the fistula was next drawn out and its walls isolated to as great a depth as possible. A probe was then introduced into the fistula, and the latter cut down upon by a vertical incision extending from the cornu of the hyoid bone downwards for two centimetres. The fistula was detached at the lower part, and drawn out of the wound with forceps. An attempt was then made to dissect it out towards the pharyngeal aperture. In the course of this proceeding, however, the lower end of the fistula was torn away. A small incision was therefore made around the pharyngeal opening, and the fistula was drawn into the

mouth, the stump being ligatured with a long thread, which was fastened to the patient's right ear. The small wound in the pharyngeal wall was closed with two points of suture; the edges of the upper part of the external wound were approximated, and a small drain tube was placed in the lower. The temperature was somewhat raised for a day or two, but no further complication occurred. The upper part of the wound in the neck healed by first intention, and the lower after suppurating a little during a few days closed firmly. The pharyngeal end of the fistula which had been ligatured came away entire on the third day without any trouble. The patient was discharged completely cured on January 16th, 1889.—*Brit. Med. Jour.*

TREATMENT OF HYPERTROPHIED TONSILS BY MEANS OF IGNIPUNCTURE.

Dr. Gilbert I. Cullen says in the *Cincinnatti Med. Journal* that the main indications for reduction of tonsils by galvano-cautery might be summarized as follows:

I. When tonsils have ceased to perform their function by reason of interstitial thickening and occlusion of the lacunæ of the glands, in which condition the mouths of the crypts becoming blocked with the accumulation of sebaceous matter, which rapidly decomposes, they form an excellent culture medium for various pathogenic germs which may ultimately be absorbed into the lymphatic system.

II. That when a tonsil shows itself competent at short intervals to become inflamed and give rise to peritonsillar abscess.

III. Where the tonsil is so situated that it is a matter of great difficulty as well as danger to use the tonsillotome, and from extensive adhesion of the pillars, likely to cause severe hæmorrhage by their being cut.

IV. In all cases where the patient is of a hæmorrhagic diathesis or in other cases in which alarming hæmorrhage is feared.

V. Where patients will not consent to the use of the knife and yet the demand for the removal of the gland is imperative.

DRESSINGS USED IN BILLROTH'S CLINIQUE.

1. Iodoform gauze: this is first sterilized, and then it is soaked in the following mixture—Iodoform, 50 grains; glycerine, 100; alcohol, 400; then squeezed and dried with sterilized cloth.

2. Klebende iodoform gauze (colophonium used in its preparation).

3. Tannin iodoform gauze.

Silk: This is almost the only thing used for sutures, etc. It is disinfected as follows: Boiled in 5 per cent. carbolic lotion for an hour, then wrung out with disinfected hands, and boiled for another hour in 5 per cent. carbolic, then left for 14 days in carbolic lotion, when it is ready to be used.

Cat-gut: First washed with *potash* soap, then laid twice for 12 hours in ethylic ether; then dried and sterilized in a dry chamber by raising the temperature to 120 degrees C., then laid in 1 to 1,000 sublimate for 24 hours, and finally kept for use in *absolute* alcohol.

Instruments before the laparotomy to be boiled for one hour in 5 per cent. carbolic lotion.

Silk, cat-gut, and instruments during the operation placed in 2½ per cent. carbolic lotion, not in 5 per cent., as was previously done.

Needles, clamps, saws, lie always in 15 per cent. carbolic glycerin.

Hypodermic needles and syringes kept in 15 per cent. carbolic oil.

Drains kept at least 14 days in carbolic lotion before use, and always remain therein.

Sponges not used, hydrophile gauze being employed instead. Pieces are folded (10 fold), sterilized in the hot oven, and then boiled for one hour in carbolic lotion, 5 per cent.; then kept in carbolic acid or in sublimate, 10 per cent., and just before the operation placed in 1 to 3,000 of a sublimate solution.

During the operation the wound is washed in a 1 to 3,000–5,000 sublimate solution, which is also used for the hands, tartaric acid being added to lotion as well as fuchsin to color it.—*Med. Press.*

CHLORPHENOL—A VOLATILE ANTISEPTIC.

This is another effort directed to destroy the tubercular microbe which Dr. Passerini has proved to be a success! The same experimenter has long endeavored to modify the *Trichlorphenol*, but the odor and irritation to the mucous membrane is always a serious objection to its use. Dr. Tacchini, of Pavia, has now obtained a preparation of *Chlorphenol* which has as much antiseptic power as trichlorphenol, and is free of all the objections against the latter. Chlorphenol is a very volatile fluid, whose vapor is heavier than air. When applied to

wounds, ulcers, and discharging glands the improvement is marked.

Ozæna, laryngitis, bronchitis, and more particularly tubercular affections are beneficially affected. Passerini has treated five of the latter cases with the vapor, which being heavier than air, presumably reaches the bronchioles if not the alveoli of the lung itself, and he finds that the bacilli rapidly disappear after commencing the inhalations. All the five cases have quite recovered, varying from two to six months from beginning of the treatment, and are apparently well at the present time.

The claims put forth are:

1. The inhalation of chlorphenol is easily borne in advanced phthisis, and is convenient in application.

2. No injurious effects arise from its continuous use.

3. Changes in the quality and quantity of expectoration till pus and bacilli disappear; cough is diminished; fever is reduced; appetite and sleep soon return; the weight of the body increases rapidly and the local improvement is speedily performed.

Hence the three conditions, applicability, innocuity, and efficacy are the dominant recommendations of the drug.—*Med. Press.*

GYNÆCOLOGY.

UTERINE FIBROIDS: HYSTERECTOMY OR ENUCLEATION?

Dr. Chevrier (*Nouvelles Arch. d'Obstét. et de Gynéc.*, July, 1891) writes on the advantages of enucleation of fibro-myomata through the abdomen over supravaginal hysterectomy. He bases his observations on cases observed in Professor Doléris's wards. Hysterectomy will, he thinks, long be practiced, being the only known resource against slow-growing, painless tumors where no hæmorrhages occur. Early diagnosis will lessen the indications for hysterectomy; but this will not greatly increase the indications for enucleation, for very early diagnosis needs great skill and experience, and then the symptoms are as yet so mild that active surgical steps of any kind are hardly justifiable. Bulky hyperplastic and cystic fibromata fused to the uterine muscular tissue usually demand hysterectomy. Enucleation through an abdominal incision is preferable in small or median submucus or interstitial fibromata. The mortality is about 16 per cent.; recurrence occurs in 2 per cent. of the cases. The advantages of enucleation over the more radical operation are distinct. Enucleation saves the woman from a series of harrassing and painful phenomena, often protracted. It diminishes the chances of immediate dangers, such as sepsis and hæmorrhage and distant complications like hernia and fistula. Lastly, it leaves to the patient her reproductive functions unimpaired.—*Brit. Med. Jour.*

THE TREATMENT OF PELVIC SUPPURATION AND INFLAMMATORY LESIONS OF THE APPENDAGES BY VAGINAL HYSTERECTOMY.

Pozzi (*Gaz. Heb. Med. Chir.*) felt a distrust of M. Péan's method at the outset, because it seemed not to be founded upon true physiological principles. Realizing, however, that empiricism sometimes leads to valuable results, he put aside prejudice and carefully followed the discussion upon the subject, studied the published reports, witnessed Ségond's opèration, and twice performed it successfully himself. His opinion is unaltered; he considers hysterectomy inferior to laparotomy in the treatment of pyo-salpinx. He believes, moreover, that its use will lead to mischievous practice in the surgical treatment of diseased appendages.

M. Ségond's paper is entitled "Treatment of Pelvic Suppuration by Vaginal Hysterectomy," but both he and Péan in actual practice apply the operation to *all inflammatory lesions* of the ovaries and tubes. How could it be otherwise when by clinical examination it is so often impossible to diagnose between pyo-salpinx, hemato-salpinx, hydro-salpinx, parenchymatous salpingitis, polycystic degeneration of the ovary, and a small cyst of the broad ligament?

The question is really this: Is vaginal hysterectomy preferable to laparotomy in the treatment of inflammatory lesions of the appendages, whether suppurative or not?

The three principal arguments adduced in its favor are: (1) greater efficacy; (2) lessened danger; (3) absence of cicatrix.

As to the first, it is not to be denied that this indirect method gives good results, but are they better or even so good as those obtained by direct removal of the diseased organs?

(*a*) *Efficacy of hysterectomy for pyo-salpinx and pelvic abscess.*—These cases may be subdivided into those where—

1. The sac is free.

2. Sac is adherent, but can be enucleated (with or without fistulæ).

3. Sac adherent; cannot be enucleatad; fistulæ present or absent (true pelvic abscess).

In the first and second cases, laparotomy would permit a complete removal of the diseased parts. By hysterectomy even the slightest adherent or perfectly free sacs cannot always be removed, and pathological tissues are necessarily left in the pelvis, where, to be sure, they may be absorbed or tolerated, but where there is a good chance of their causing immediate or subsequent infection. These cases are by far the most frequent in occurrence.

A few cases there are, to be sure, of pelvic abscess where extirpation of the sac is an impossibility even by laparotomy, but these are rare. The author found three out of thirty-nine cases, and Bouilly three out of thirty, making a proportion of one in ten. These patients were completely cured after laparotomy, cleansing of the cavity, washing, and insertion of a tampon of iodoform gauze according to Mikuliez's method, which proves that even difficult cases may be cured by laparotomy.

Much stress has been laid upon the incurable lesions resulting from fistulous openings, transforming the pelvic floor into a "purulent sponge," which is an exaggerated figure of speech. Open fistulæ, whether in the rectum, vagina, or abdomen, are assuredly a complication, but less grave than might at first be supposed. They invariably close after a laparotomy, provided that the diseased parts are removed, or the cavity thoroughly cleaned and antiseptically tamponed. Iodoform gauze forms a perfect medium of capillary drainage. Any fistulæ persisting after such treatment can only be old fistulæ from incomplete operation, or of recent formation from infected sutures.

Hysterectomy certainly permits of free drainage. Pozzi gives it credit for this, and considers it valuable as a *secondary* resource, should laparotomy be incomplete.

(*b*) *Efficacy of hysterectomy for non-purulent inflammatory lesions of the appendages.*—So many lesions of the tubes and ovaries may simulate suppuration of the tubes that this operation is most likely to be widely applied, if used at all. The dangers of its general use are manifold, the principal ones being removal of the uterus of a patient in whom the appendages of one side only are affected beyond help, and leaving in place diseased ovaries or tubes adherent to the pelvic walls. The advocates of the method claim that it is undertaken only when the lesion is bilateral; but errors of diagnosis are too easy to make this precaution very valuable. Both sides may apparently be affected, but in reality only one be seriously diseased, the tumefaction of the other being caused by a small cyst of the broad ligament, or serous infiltration due to catarrhal salpingitis. As to the after-results of ovariotomy, pain rarely persists, except when the organs removed are but slightly diseased, and even then often disappears ultimately. Metritis may exist for a while, but usually ceases because of the uterine atrophy following removal of the ovaries. Curetting will remedy this trouble in any case, and its severity and importance have been greatly exaggerated. The relative *gravity* of the two operations is the most important point in the discussion, as well as the most difficult to decide.

From a theoretical point of view even, the author gives the preference to laparotomy. In those cases where the uterus is immovable, the abdominal opening gives free access to the diseased parts, and touch can supplement sight. The vaginal opening necessitates groping at the end of a deep and narrow cavity, hemostasis depends upon a lucky application of the forceps, and the lesions, if too high or too far forward, may be inaccessible.

The statistics so far obtained are also in favor of laparotomy. Bouilly and Ségond are of equal rank as surgeons. The first, out of thirty-three laparotomies for *pyo-salpinx*, had four deaths; the second, out of twenty-three hysterectomies for *pyo-salpinx* and *other tubal lesions*, had four deaths.

Pozzi himself, from February 1st, 1889, to March 10th, 1891, operated upon thirty-nine cases of pyo-salpinx and pelvic abscess, several of them being cases of the "purulent pelvic sponge" spoken of by Messrs. Ségond and Réclus as species of *noli me tangere*. There were in all three deaths, thirty-six complete cures. This list in itself shows better proportionate results than the list of hysterectomies: he further strengthens it by the addition of cases operated upon, during the same period of time, for non-suppurative lesions of the tubes and ovaries, which is as follows:

Parenchymatous salpingitis	19
Hydro-salpinx	3
Hemato-salpinx	3
Sclerocystic ovaritis	12

This he supplements by eight cases operated upon during the previous month: three of pyo-salpinx; two of hæmato-salpinx, of which one was complicated by suppuration and the other by an enormous hæma-

tocele; two of large polycystic ovaritis, and one sclerocystic ovaritis. All the cases but one were followed by cure; this one was hæmato-salpinx consecutive to tubal pregnancy and complicated by hæmatocele. The uterus was friable, and the operation had to be terminated by abdominal hysterectomy.

The total result, then, is eighty-four operations: eighty cures, four deaths. Hysterectomy has no such results to show, and, while its list of cures is on the increase, science must consider acquired results rather than results hoped for.

Hysterectomy presupposes infallibility of diagnosis. The first incision causes sterility. Laparotomy, on the other hand, permits of a rectification of an error of diagnosis before any decided step has been taken. As to the third argument, the absence of deforming cicatrix, it will have less weight with surgeons than with their patients, and it has been much exaggerated. The incision is rarely larger than two and one-half to three and one-half inches, and never larger than four and one-half. Moreover, a suture in layers will reduce the abdominal cicatrix to a mere line, and give it sufficient strength to obviate all necessity for wearing a belt.

TREATMENT OF PELVIC EXUDATES.

Fritch, in the *Gazetta degli Ospitalia*, No. 47, advises the immediate evacuation of the abscesses through the vagina, he then is in the habit of suturing the wall of the abscess to the vaginal wall in order to avoid infiltration of the cellular tissue, after having made an injection into the cavity of the abscess. He uses neither packing with iodoform gauze nor drainage; he recommends, instead, frequent injections. He has found streptococci in the majority of the abscesses.

OBSTETRICS.

KNOTS IN THE UMBILICAL CORD.

Dr. Lyncker (*Deut. med. Zeit.*, No. 57, 1891) has observed three cases where a true knot was found in the cord, the child in each case being alive. He believes that the knot is formed by the fœtus shaking about in the liquor amnii and slipping through a loop in the cord accidently formed by its own evolutions. In 100 births it is rare to detect more than 1 case of true knotted cord. This curious condition appears to have no influence on the child's development; probably there is not sufficient force at hand to pull the cord tightly enough to cause obstruction of its vessels.—*Brit. Med. Jour.*

ANTIPYRIN AS AN ANTIGALACTAGOGUE.

Le Practician states that M. H. Guibert, interne at the encouchment clinic of Professor Grinfelt, at Montpellier, has fully confirmed the value of antipyrin as an antigalactagogue. M. Guibert administered antipyrin in doses of 25 cgm., repeated up to 2 gm. daily, the patient taking a dose every two hours, the interval being somewhat longer after the two principal meals of the day. The lacteal secretion was completely suppressed at the end of a time varying from two to six days, and this too, without changing a single detail of alimentation, even of those newly accouched. No accidents have supervened, although some of the patient's had taken as high as 14 and even 16 gms. in the course of five or six days. M. Guibert concludes from these observations (nineteen in number) that antipyrin renders real service in those cases where it is desirable to suppress the secretion of milk, and that the medication is harmless.

CURE OF ECLAMPSIA BY LARGE DOSES OF CALOMEL.

Dr. Josef Smits (*Der Frauenarzt*, September, 1891) publishes clinical notes of a very severe case of convulsions coming on in the ninth month of pregnancy. The patient was 19 and well nourished. Anasarca was very marked; the urine was albuminous and full of casts. After severe headache and vomiting violent convulsions set in, followed by coma and stertorous breathing. No labor pains had occurred. A quantity of urine was drawn off. The skin was dry, and though the patient was wrapped in warm, moist sheets, diaphoresis did not take place. Dr. Smits feared to give pilocarpin, as Bricon had recently noted unfavorable results under the circumstances. Chloroform and morphine were both considered inadvisable; the heart's action was irregular; the pulse slow, small in volume, and very compressible; and the pupils were contracted. Dr. Smits determined to counteract the uræmic symptoms by free purgation. This occurred after "heroic" doses of calomel (400 milligrammes, or over 61 grains). Thin stools began to pass, and at the same time the convulsions began to be weaker and less frequent. After twenty motions, in which uric acid crystals could be distinguished with the

microscope, the fits ceased altogether, and the sensorium became clearer; but the skin would not act, and the œdema continued. Dr. Smits feared to induce labor, least the eclampsia should return. On the sixth day after the fits had ceased the patient gave birth to a macerated fœtus. The perineum was slightly ruptured. No fits occurred after delivery, and by the sixth day the œdema had disappeared. The specific gravity of the urine fell during the severe attacks from 1032 to 1012.—*Brit. Med. Jour.*

PÆDIATRICS.

IODOFORM AS A PROPHYLACTIC OF OPHTHALMIA NEONATORUM.

Valude (*Ann. d' Oculistique*, August, 1891) publishes results obtained in the clinics of Dr. Bar and Professor Tarnier in Paris by the systematic application of finely powdered iodoform to the eyes of newly-born infants. The figures compare favorably with those obtained in the same wards and under similar conditions by Crédé's treatment by nitrate of silver. Valude thinks that iodoform will prove more useful than nitrate of silver in the hands of midwives, because it is more easily applied and does not decompose in the way that solutions of the silver salt do when kept for any length of time, in spite of precautions such as dark glass bottles, etc. He recommends that immediately the child is born, and before the cord has been divided, the eyelids should be carefully cleansed, and powdered iodoform dusted into the conjunctival sac. One advantage claimed is that the powder, or some of it at least, remains in the folds of the conjunctiva for a considerable time after its application, whereas solutions of all kinds at once drain away.—*Brit. Med. Jour.*

INFANTILE PALSIES OF OBSTETRIC ORIGIN.

Dauchez (*Annales de Gynécologie*, September, 1891) has contributed the first part of an article on the subject of infantile palsies of obstetric origin. This paper is devoted to a classification of the forms of paralysis, both as to their origin and as to the nerve-trunks which are affected.

The writer distinguishes between spontaneous and traumatic palsies. The former are those produced, first, by pressure in contracted pelves; second, by the effects of face-presentation; third, during protracted labors. The discussion of palsies of traumatic origin is reserved for the latter half of the paper. The termination of spontaneous palsies in sixteen cases observed by the writer is noted as follows:

Recovery in	9 cases.
Persistence of loss of power in	3 "
Death in	2 "
Result not observed in	2 "

This form of paralysis appears, often to the astonishment of the accoucheur, after a spontaneous labor. It is sometimes apparent after a labor in which the face has presented with the neck forcibly extended, or in which a nerve-trunk has been compressed by a loop of the cord. In writing of these spontaneous palsies the author devotes his attention principally to the peripheral origin of the lesions. For instance, in alluding to facial paralysis, he asserts that the simple inclination of the vertex is sufficient to produce this form, often attributed to pressure of the head against the walls of a contracted pelvis.

He classifies the order in which the lesions occur as follows: Facial paralysis, either peripheral, central or cortical.

Paralysis of the brachial plexus and of the circumflex nerve, resulting either from pressure during prolonged labor, or, in the first case, from forcible extension of the neck in face-presentations.

Paralysis of the inferior extremities, arising from efforts at traction by means of the blunt hook, etc., in breech-presentations, or from compression exerted by the cord tightly wound about one of the extremities.

The list of cases presented offers a very interesting summary of the results of these various forms of paralysis. Case No. 10 is especially interesting, inasmuch as the cause and the effect are both of unusual occurrence. The description of this case is taken from an article by Roulland. It refers to an infant, born with the vertex presenting in the L. O. A. position, and whose neck was tightly compressed by the cord. On the second day complete paralysis of both upper extremities was noticed; the lower extremities were not implicated, illustrating clearly an instance of paralysis due to compression of the cord pure and simple.—*Univ. Med. Mag.*

HYGIENE.

MICROBES AND CARPETS.

In our endeavor to be comfortable in this vale of tears, there is a tendency to overlook the elementary laws of hygiene, and in no respect, perhaps, more so than in the superabundance of curtains and carpets—these

non-patented contrivances for hindering the free circulation of fresh air and for stultifying Nature's automatic arrangements for the deodorization and disinfection of our homes. Carpets are always objectionable when they are not designed to permit of easy removal for cleansing purposes without the necessity of turning a room topsy-turvy. In most houses the carpet only comes up once a year, by which time it is as full of microbes and accumulated filth as its interstices will allow. No wonder, then, if our rooms preserve a musty smell in spite of periodical opening of windows and vigorous sweepings, which only displace a portion of the dust to settle promptly elsewhere in some less accessible spot. Fixed carpets are even more objectionable and unwholesome in bed rooms, for there they absorb the fœtid emanations of the night, and soak up various decomposable materials for future use. The ideal would be a polished wooden floor garnished with rugs in sufficient number to give an aspect and feeling of comfort, while admitting of easy exposure to the salutary influence of air and light. Rugs, carpets, and curtains ought to be frequently shaken and hung up in the fresh air if they are to remain sweet, not once a month or year, but twice or thrice a week, if not oftener. At this price only can we hope to deprive confined spaces of their native unwholesomeness, and the sooner housewives lay this maxim to their hearts and act upon it, the better.—*Hospital Gazette.*

GLYCOSURIA DUE TO FOOD SUBSTANCES.

In a paper read before the Academy of Medicine of Rome, March 22nd, 1891, M. Colasanti discussed the question whether in cases of circulatory disturbances of the liver, especially in cirrhosis, the elimination of saccharine substances takes place by way of the kidneys. The divergence of opinion on this point has led him to again investigate the action of carbohydrates in cases of cirrhosis of the liver. After numerous examinations continued for a time he was able to demonstrate that the sugars are not excreted by the kidneys, but occur in the serous exudations in the pleural and abdominal cavities.—*Deutsche Medizinal Zeitung.*

DRINKING WATER AND ENTERIC FEVER.

Legrain (*Ann. de la Policlin. de Paris*, October, 1891) says that the problem of the origin and propagation of enteric fever is probably solved by the discovery of Eberth's bacillus and by the finding of this micro-organism in the water suspected of conveying the disease. Three theories have been put forward (1) autotyphisation—and the identity of the B. coli communis with Eberth's bacillus lent some strength to this idea—(2) direct contagion, and (3) the presence of the germ in external media, especially in water, and its transmission in that way. This latter is the most generally accepted theory. Brouardel in 1887 admitted that though the disease could be propagated by water, air, the patient's linen, or the hands of those looking after him, yet in 99 out of 100 cases it was through the medium of water. The author then gives the details of an epidemic occurring in a home for idiots and the weak-minded. After describing the insanitary condition of the river, M. Legrain draws attention to the increasing prevalence of gastro-intestinal affections in the home. Thus among an average of 170 treated yearly, there were 25 such cases in 1887, 57 in 1889, and 84 in 1890, the epidemic taking place from January to May of that year. Two conclusions are drawn (1) that the highest figure representing the gastro-intestinal disturbance and that representing enteric fever corresponded, and (2) that the epidemic was the climax of a preparatory period of gastro-intestinal disorders. The author agrees with Chantemesse that gastric disturbance with fever, apart from simple indigestion, may be abortive enteric fever. Thus the epidemic was the progressive and (at length) momentary aggravation of an evil increasing from day to day. This is borne out not only by the prevalence of gastro-intestinal catarrh and its steady increase, but also by the sporadic cases of enteric fever in the community and the occurrence of cases of gastric disturbance clearly infective, such, for instance, as happened in one newly arrived and which disappeared with the discontinued use of the water. Occurrences suggesting direct contagion were few. Most attacked had drunk the water straight from the river. Again nine individuals who had also drank the water were seized with diarrhœa. The river water was the first if not the only source of the disease. Outside the home there were cases of gastric disturbance with diarrhœa, fever, and enlarged spleen. The epidemic lasted long, as if the cause was quasi-permanent. It hardly affected the other part of the institution situated at a little distance from the first-named home, for the inmates drank water which had at least been filtered. The most robust boys were mostly attacked because they worked in the fields near the

river, and thus the water was directly accessible to them. When the weaker ones suffered, it must have been through the medium of the table water. They would no doubt be less resistant that the stronger.—*Brit. Med. Jour.*

MEDICAL CHEMISTRY.

GALLACETOPHENON.

Pyrogallol, or pyrogallic acid, much used in the treatment of psoriasis, having been found to produce grave disturbances (sometimes mortal) with great ease, dermatologists have of late largely renounced its employment. These facts led Nencki to experimentation with pyrogallol, and he found that by replacement of the three hydroxyl molecules with methylketon he obtained a comparatively harmless compound, to which he has given the name gallacetophenon. It is obtained as a yellow powder, soluble in hot water, alcohol, ether, and glycerin. It is sparingly soluble in cold water, but its solubility is greatly increased in the presence of sodium acetate. The following is recommended as a formula for a hot solution, which does not deposit on cooling:

℞

Gallacetophenon	parts iv.
Sodium acetate	" xxx.
Hot water	" c.

This substance, according to Von Ino and others, has greater efficacy in psoriasis and other parasitic skin diseases than pyrogallol, and does not have any of the inconveniences of the latter, not even staining the clothing of the patient.

DETECTION OF QUININE IN THE PRESENCE OF PHENACETIN.

Sestini and Campani, in the *Pharmaceutische Zeitung* (quoted by *American Journal of Pharmacy*), state that phenacetin prevents the fluorescence of quinine sulphate, especially in dilute solutions; with chlorine water and ammonia phenacetin produces a yellowish-violet coloration, a mixture of quinine and phenacetin with these reagents produces a fine blue color. To obtain the thalleioquin test, best results are obtained with bromine vapor. Bromine vapor is allowed to act upon the solution until a faint turbidity results, then ammonia is added, drop by drop; proceeding in this manner, the green coloration appears, although darker and inclined towards a violet; if the test be now agitated with ether and allowed to stand awhile, the ethereal layer will be colored yellowish-violet and the aqueous layer green.

PENTAL, OR TRIMETHYL-ETHYLENE.

Another anæsthetic has made its appearance, viz., "pental." This is the name given by Dr. von Mering, of Halle—who had also introduced the hypnotic amylene hydrate, $(CH_3)_3COH$, into therapeutic practice—to a new derivative of amylene, viz., the trimethyl-ethylene: $(CH_3)_2.C:CH.CH_3$. It is to be regretted that a commercial name has been coined for this; or at least that no better name than "pental" has been chosen, for the presence of 5 carbon atoms should not have been taken as a characteristic feature.

According to present reports, pental is safe anæsthetic, and acts promptly, only about 20 c.c. of it being required to produce anæsthesia, which supervenes generally after four or five minutes. Insensibility is neither very deep nor very long, but it is sufficient to permit, under its influence, the performance of minor operations, such as extraction of teeth, etc. In most cases insensibility to pain appears before complete unconsciousness. Pental in said not to produce any disagreeable after-effects, and no untoward symptoms during its use.

Trimethyl-ethylene boils, according to E. Schmidt, at 35° C. (95° F.); according to Le Bel, at 36°–38° C. (96.8°–100.4° F.). Its spec. grav., according to R. Schiff, is 0.6783 at 0° C. (32° F.), and 0.6353 at 36.8° C. (98.3 F.).

NEWS AND MISCELLANY.

PITTING OF SMALL-POX.

The pitting of small-pox has been entirely prevented by Dr. Lewintaner, of Constantinople (*Wien. Klin. Woch.*) by antiseptic treatment as follows: The entire head and face, except eyes, and the neck are covered with plaster consisting of three parts carbolic acid and fifty parts each of olive oil and starch. The body is covered over with a mixture of three parts salicylic acid, thirty parts starch, and seventy parts olive oil. The internal treatment consists in giving quinine in acid solution.

OREGON OPIUM LAW.

From the *Pacific Drug Review* of October we publish the following synopsis of a law passed in 1887 which relates to the sale of

opium, morphine, eng-she or cooked opium, hydrate of chloral or cocaine. In the publication referred to the law is printed in full. No persons can have in their possession or offer for sale either of the above articles unless they have a license from the county clerk of the county in which they reside. The license is good for one year and costs $1. Such licenses can only be granted to regularly qualified physicians and druggists. The party selling must only deliver the quantity ordered in the prescription. These articles can only be prescribed for medicinal use, and in such quantities as are recognized by proper medical authorities as suitable. A record must be kept and this be open for public inspection. The punishment for violation of the law is from $50 to $250 fine, or 30 to 90 days imprisonment, or both.

THE GOOD OLD REMEDY.

When everything goes wrong, boys,
When you're sick or tired.
When you visit your best girl,
And by her pa get fired,
There's nothing in the world, boys,
Will bring you such relief.
As a real good hearty laugh, boys,
'Twill soon allay your grief.
So for each pain what e'er the cause,
Just try the laughing plan.
Laughter's an institution, boys,
Then let's laugh all we can.

Let preachers rate frivolity,
We very well do know
The greatest prosers use it,
But oppose it just for show;
They find it such a help, boys,
As all poor sinners do,
And they need its consolation, boys,
As much as I or you.
Of all the remedies on earth
Within the reach of man,
Laughter's the best and cheapest, boys,
Then let's laugh all we can.

Pharmaceutical Era.

FOR THE CURE OF SNAKE-BITE.

Dinshah Ardeshir Taleyarkhan, the municipal commissioner of Baroda, India, has published a pamphlet in which he offers some suggestions concerning the cure of snake-bite by means of inoculations of the blood-serum of immune animals. The common weasel is, he says, proof against snake-bites, and it will attack and kill any snake that it may come across, never suffering in the slightest from the serpent venom. He suggests therefore that the blood-serum of this weasel (or mongoose) be injected in case of snake-bite, and believes that experience will show that this is an effective antidote against the poison.

ALLOY IMITATING GOLD.

An alloy closely imitating gold has been discovered by Held (*Chem. Centralbl.*) It is formed by fusing copper, heating it to a certain temperature, and combining it with six parts of antimony; when the latter has also melted, magnesium, calc-spar and charcoal ashes are added. This compound is not oxidized by ammoniacal or acid vapors, and does not lose its color. It can be rolled, hammered and soldered like the genuine metal, but it is harder.

FATAL ELECTRICAL CURRENTS.

Prof. Elihu Thomson finds in his experiments on the physiological effects of alternate currents that the danger of the current diminishes as the number of alternations per second is increased. Thus it took twenty times as strong a current to kill a dog when the alternations were 4,500 per second than when they were 120 per second. When the alternations were 300 per second, the current was only half as dangerous to life as when the alternations were 120.

ARE HOSPITALS NUISANCES NECESSARILY?

There seems to be a growing tendency to regard Hospitals as nuisances, or at least as undesirable neighbors. The Trustees of the Free Hospital for Women not long ago purchased a lot of land in Brookline, with the intention of building a Hospital to be devoted entirely to gynæcological work. It would seem as if such a building could hardly affect the value of adjacent real estate very unfavorably, but apparently the owners of land and houses in the neighborhood thought otherwise. Some of the objections urged against the granting of a permission to build were unique, others far-fetched and absurd, but they seem to have had weight with the selectmen of the town. The remonstrants forced the friends of the Hospitals to admit that when patients were re-

covering from ether, there was sometimes more or less screaming, and that in warm weather it might be necessary to leave the windows open at that time. The counsel of one of the objectors remarked that the erection of such a Hospital would certainly be a detriment to his client's home. There is a prejudice against hospitals, and when it is known that it is a charity hospital the prejudice is still stronger. Another important point is its influence on school-children. They will imagine a great many things, and it is just as bad to have their imagination aroused as it is to see the very worst of sights.

This surely is carrying even sentimental objections pretty far, but the real state of the case seemed to be that such an institution is a hindrance to suburban land that is being "improved for residential purposes."

A somewhat similar case occurred in Winthrop some months ago, except that in this case the hospital had already been built, and had been doing good work for a number of years, and the private houses had grown up around it. Since 1878 the Sea Shore Home had received during the summer months a large number of infants suffering from intestinal diseases, with their mothers. The number of children treated by the institution had amounted to 2,483. Within a few years extensive additions had been made to the buildings. Last winter the citizens of the town, at the annual town meeting voted that the institution was a nuisance and that a renewed occupancy of the buildings would be opposed with the assistance of a legal injunction. With this evident intention to make the position an undesirable one, the managers felt that it would be best to remain inactive during the present season, not yielding their position, but retaining the right to carry on a home for sick children when the proper time comes.

Is it well that the unselfish efforts of those who are devoting time and money and skill to the amelioration of the lot of the unfortunate and impecunious sick should be hampered by the opposition of this narrow, selfish character?—*Boston Med. Surg. Jour.*

FRENCH LAWS REGARDING PROFESSIONAL SECRECY.

In France, the laws regarding the abuse of professional secrecy, the secrets between a physician and his patient, the pharmacist and the physician or the patient, are very severe, and enforced with great vigor and impartiality. The prefect of police is the officer who usually is the complainant in criminal proceedings against violators of these laws. A great commotion has recently been caused at Lyons by the discovery of the fact that the prefect of police had been the direct cause of what might be called a wholesale violation of the statutes. It appears that this officer had recently sold a lot of old paper, among which was a bundle of physicians' reports relative to deaths occurring in the city for twenty years past. These reports gave the name, residences, etc., of the deceased, the nature of the maladies, and other information forbidden to be made public. The papers had been sold by the purchaser to grocers, spicers, and other retailers, as wrapping paper, and were thus as widely distributed as possible in the community. Upon bringing the matter to the notice of the officials, the latter could only offer excuses and promise not to let such an accident happen again.

STAMPING OUT SMALL-POX.

Dr. J. M. Boyles, City Health Officer of Houston, Tex., relates in the *Abstract of Sanitary Report*, of January 26, 1891, an instructive history of an epidemic of small-pox in that city. On December 4, 1890, a circus arrived in Houston with a case of small-pox which was kept concealed until after the circus had left several days. On December 21st, small-pox made its appearance in several parts of the city simultaneously—in hotels, boarding-houses, etc. In less than five days there were 41 cases, mostly white. How many persons had been exposed at this time could not be estimated. At the suggestion of the Health Officer the City Council made vaccination compulsory. The house-to-house plan was adopted. Of the 21,000 persons vaccinated there was no bad effects—no amputations or deaths. Some suffered several weeks with sore arms. In forty days Dr. Boyles succeeded in getting the disease under control. Of the 359 cases no one contracted the disease that had been vaccinated under eleven years. Some vaccinated forty-nine years ago had varioloid, but of such a mild type it was not necessary to go to bed. There were 120 in the quarantine hospital that had been vaccinated and were exposed who did not take the disease.

THE PRICES OF QUININE FOR SIXTY-NINE YEARS.

The *Oil, Paint and Drug Reporter* has recently published the following table of the highest and lowest prices at which quinine has been quoted during each year since and including 1823. The prices given in the latter portion of the table are for foreign quinine in bulk:

PRICE PER OUNCE.

	Highest.	Lowest.		Highest.	Lowest.
1823	$20.00	$16.00	1858	$1.40	$1.25
1824	14.00	12.00	1859	1.50	1.25
1825	8.00	8.00	1860	1.80	1.20
1826	7.00	5.25	1861	2.10	1.80
1827	7.50	6.00	1862	2.90	2.25
1828	6.00	3.25	1863	3.25	2.70
1829	2.90	2.25	1864	3.75	2.60
1830	2.50	1.75	1865	2.40	2.20
1831	1.50	1.35	1866	2.60	2.35
1832	2.00	1.75	1867	2.20	1.95
1833	1.87	1.70	1868	2.35	1.90
1834	1.80	1.25	1869	2.30	2.00
1835	1.65	1.60	1870	3.30	2.10
1836	1.58	1.45	1871	2.45	2.20
1837	1.40	1.40	1872	2.45	2.40
1838	1.90	1.60	1873	2.55	2.45
1839	3.30	2.75	1874	2.50	2.20
1840	3.12	2.87	1875	2.30	2.15
1841	2.62	2.50	1876	2.70	2.20
1842	2.00	1.60	1877	4.50	2.70
1843	1.80	1.55	1878	3.60	3.40
1844	3.00	2.00	1879	3.60	2.60
1845	2.40	2.35	1880	3.25	2.25
1846	2.40	2.20	1881	3.25	1.90
1847	2.40	2.30	1882	2.50	1.80
1848	2.70	2.60	1883	1.80	1.60
1849	3.65	2.95	1884	1.80	90
1850	3.70	3.70	1885	1.05	75
1851	3.25	3.25	1886	80	65
1852	3.00	2.70	1887	70	46
1853	3.20	2.70	1888	50	30
1854	2.50	2.60	1889	30	22½
1855	3.00	2.00	1890	32	23½
1856	2.60	2.40	1891	24	18½
1857	2.00	140			

From some explanatory comments made on this table by our contemporary we take the following:

"The marked decline observable in 1857 was largely attributable to the abolition of the 15 per cent. duty on cinchona barks. The rise in price from 1861 to 1866 was due, primarily, of course, to the changed conditions arising from the civil war, including increased consumption, diminished supplies due to the perils of navigation incidental to the war, and an increased cost arising from these combined causes, and from the imposition of a high rate of duty, ranging up to 45 per cent. for quinine itself, and 20 per cent. for the bark. The high range of prices continued to rule for some years, reaching the maximum of $4.50 per ounce in 1877, since which time there has been a gradual decline to the present low values of 19 cents for foreign bulk. At this juncture the influence of the East India barks began to be felt. In 1876 only 1,777 bales of this bark were imported into London, but the quantity rapidly increased to 6,260 in 1877, 13,460 in 1880, and 20,692 in 1881. In 1879 the alkaloid was also placed on the free list. It is this last downward movement that has caused tremendous losses, and in many cases ruin, to those who have maintained faith in the market price of the article. The large deals, the excitement, and final failures occurring when a price of $3 was predicted as the bottom figure in 1880 and thereabouts, will no doubt be vividly remembered by many members of the trade."

PHYSIOLOGY OF GASTRIC DIGESTION.

The foundations of our knowledge of the physiology of gastric digestion were undoubtedly laid by the careful study of the historical case of gastric fistula by Dr. Beaumont—the case of Alexis St. Martin. Animal experimentation and the test-tube reactions of the laboratory cannot be compared in accuracy to observations made directly upon the living human organism, when these rare opportunity arise which permit of such a study. Then, too, it may happen that a considerable rectification of current physiological doctrine has to be made, and the laboriously gathered results of many observers have to be replaced by those made upon a single case. Much depends, then, upon the skill and thoroughness with which the study of the processes in the human subject are undertaken. It must be admitted that these qualities are conspicuous in the recently published records of a study of the chemical processes of the small intestine by Drs. McFadden, Nencki, and Sieber. The subject of their researches was a female patient under the care of Prof. Kocher, in whom an intestinal fistula had resulted from excision of a portion of gangrenous intestine due to strangulated hernia. The false anus was situated in the ileum just above the ileocæcal valve, so that the materials escaping thereby were wholly composed of the chyme which had passed through the whole length

of the small intestine. For a period of nearly six months the woman lived under these conditions, permitting of a long series of observations relative to the time and character of intestinal digestion under varying forms of diet, etc. At the end of that time Prof. Kocher re-established the natural channel by means of an operation which proved perfectly successful. It may be remarked at once that during the whole period when there was practically no large intestine the patient gained in weight, and, as the urinary analysis showed, eliminated a fairly normal quantity of urea.

The procedure consisted in adapting a flexible tube to the fistulous outlet, so as to collect all the material that escaped, and to note its characters under varying circumstances. In consistency this "chyme"—if it may be so termed—was more fluid and diarrhœal when the diet was albuminous than when it was mainly of a vegetable nature. It was seen that the flow of chyme from the small into the large intestine is steadily continuous, being least marked during the night, owing to no food being then taken; and by some ingenious experiments (e. g., the addition of hard beans to the food, or of salol, which allowed of the detection of salicylic acid in the matters escaping) it was shown that the passage of foods from mouth to cæcum occupies at the least two hours; but all traces of the substances introduced did not disappear for from nine to fourteen or even twenty-three hours. The rate of flow, of course, bears much relation to the consistency of the intestinal contents. As regards the nature and properties of the evacuated materials, it is noticeable that they were almost free from odor, containing hardly any products of albuminous disintegration, such as indol and sulphuretted hydrogen; they were slightly acid in reaction, tinged yellow by bilirubin, and, according to the predominance of flesh or starchy matter in the food, showed muscle fibre, albuminous granules, vegetable fibres, starch granules, etc. and invariably a large number of various forms of bacteria. The filtrate yielded albumen, mucin, peptone, dextrose, the two forms of lactic acid, acetic acid, and the biliary acids and bilirubin. The authors enter very fully into the characters of the bacteria they find, many forms being special to the small intestine, others existing also in the mouth; but, passing over these, which would entail a full description to be intelligible, we may glance at the main results of their researches, which somewhat modify accepted physiological teachings. One point of interest is the fact that albumen is hardly, if at all, decomposed in the small intestine. Even the action of the tyrosin of the pancreatic juice is small, for leucin and tyrosin were not to be found. Probably, in health, albuminous disintegration takes place chiefly in the large intestine, and it is only in disease that it occurs in the stomach or small intestine. Amongst the products of such decomposition are iodol, skatol, phenol, sulphuretted hydrogen, carbonic acid, methylmercaptan, etc., all of which may be regained from the large intestine. The bacteria of the small intestine are concerned in the disintegration of the carbo-hydrates into lactic, acetic, and succinic acids, and also into ethylic alcohol. The authors, in noting this last-named fact, cannot avoid a thrust at the total abstainers. It is generally believed that the chyme is rendered alkaline by the secretion of the small intestine, but they find that, owing probably to the reinforcement of gastric acidity by the organic acid resulting from sugar, the total quantity of acid is more than can be neutralized by the bile, pancreatic, and intestinal juices. If, however, the alkalinity of these fluids be diminished, the intestinal contents are hyper-acid, and mucin is precipitated instead of being intermingled with the chyme. This explained the diarrhœal quality of the evacuations noted to be associated with a large amount of sugar and organic acid in the chyme. On the other hand, an excess of alkalinity favors putrefactive decomposition, the acids apparently holding in check the bacteria concerned in albuminous disintegration. A marked contrast in this respect was exhibited between the small and large intestine. Putrefactive bacteria could hardly be at all isolated from the former, whilst they abounded in the latter; but this is not owing to the influence of bile, which Nencki showed to have no real antiseptic property. The part played by bacteria in intestinal digestion is limited probably to the fermentation of sugar and carbo-hydrates generally, the excess of acid resulting from this fermentation being neutralized by the alkaline intestinal juice. But, much as bacterial life abounds in the intestinal canals, varying according to the kind and quality of the ingesta, it does not appear that the processes initiated by these organisms are of such value or importance in nutrition as the chemical ferments. Certainly the patient who was the subject of these observations gained in flesh, although for six months she was deprived of all the bacterial processes that go on in the large intestine.—*Lancet.*

Clinical Lecture.

CHRONIC NEPHRITIS—CARCINOMA OF THE ŒSOPHAGUS—DIABETES MELLITUS.

BY FRANCIS DELAFIELD, M. D.,

PROFESSOR OF PATHOLOGY AND PRACTICAL MEDICINE OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Gentlemen:—The first patient that I will present to you to-day, is a man 60 years of age, who has been in his ordinary health and able to do his usual work until within two or three months ago. During this very recent period, he has the symptoms of a constant dyspnœa which is made worse on exertion, and from time to time he has attacks of what he calls "smothering," that is, attacks of dyspnœa of a spasmodic character added to his constant dyspnœa. Besides this, he has a cough which is unattended by expectoration. He has lost his appetite as well as flesh and strength. He also has had some dropsy of the hands and feet, but this is now somewhat less marked than when he first came under our observation a couple of weeks ago. He looks poorly nourished, and has the physical signs of emphysema over both lungs. The heart is also somewhat enlarged. It works feebly, and has a murmur indicative of a mitral stenosis. The arteries are somewhat overfilled with blood and of high tension. His urine has a specific gravity of 1007 and contains albumen.

We have then in this man's case an illustration of an ordinary instance of disease of the lungs, the heart, and the kidneys, all of the same character and all examples of an inflammatory condition, and added to that, we get evidence of the contraction of the arteries, a condition which is often found associated with these pathological states, taken either separately or together. This man has had, first of all, a lesion for some time which gave him no subjective symptoms, and then he has had other conditions added to that which brought on this pathological train of symptoms. Now, to what part of this man's system are we to look for the original cause of his present troubles. To the kidneys our suspicions are at once directed, and we find this man had first of all a chronic nephritis. He has had this trouble for a considerable length of time, and yet, as so often happens, he has been able to do his ordinary work and was not conscious of the existence of any pathological lesion in these organs. But, probably, if his urine had been examined a year or so ago, it would have been then found to be of low specific gravity, though, perhaps, containing no albumen.

Now, the kidney lesion being the first to manifest itself in this man's case, what other pathological condition followed this one? The next lesion that followed that of the kidney was hypertrophy of the left ventricle of the heart, and that hypertrophy has probably existed for some time without giving rise to any other subjective symptoms. The patient did not in fact feel he was in any way unwell. What was the next lesion that came after this hypertrophy? Two or three months ago when he began to get suddenly worse, what pathological condition was it that caused him to feel so? It was brought about in this way: His heart became feeble, and contraction of the arteries developed at the same time, and with these two pathological factors, dyspnœa and dropsy developed, and he lost flesh and strength as a result. We know from clinical experience that patients may have disease of the kidneys and hypertrophy of the left ventricle, and yet be able to do their ordinary work, but not until these two last named pathological conditions are superadded, viz: feeble heart and arterial contraction, do they begin to feel sick and have to stop work. If you can get rid of this feeble heart action and of the contraction of the arteries, this man may be able

to return to his work for a time at least. It is, however, an easier matter to treat successfully either one of those conditions separately than both together. If a man has only contracted arteries, and the heart's action is all right, the problem is very much simplified, and, if he has feeble heart without arterial contraction the same holds true, but with a combination of feeble heart and contracted arteries, such as this man exhibits, then it becomes extremely uncertain whether we can relieve these conditions or not.

The first practical point that suggests itself to our minds in a case like this, is whether such a man should be kept quiet or given regulated exercises and allowed to go about. Taking this man, as he now presents himself to us, I should advise that he be kept in doors and not allowed to go about at all. Exercise would only tend to make him become worse. The next thing is to increase the force of his heart's action. To that end, he should be put on the use of iodide of potash, giving him ten grains of this drug four times a day, and with the relaxation of the arteries secured by this means, note the condition of the heart's action. It would be possible, if the heart's action were increased in force, that the arteries would continue to be contracted, and it would be also possible that if the arteries were dilated, the heart would continue to be feeble. Such a condition of affairs as that would mean that this man should have digitalis in addition to the iodide of potash.

In such a case as this, we can safely make a bad prognosis, for this man is not very apt to be relieved to any great extent by the therapeutic measures at our command. His heart and arteries are in such a bad condition that I do not think he will be able to go back to work, though he may get rid of his emphysema and dropsy; so long as he is allowed to remain quiet, he will feel comfortable enough.

CARCINOMA OF THE ŒSOPHAGUS.

The next patient I show you is a man 53 years of age, and a cabinet-maker by occupation. On January 5th, of this year, he noticed that he had some difficulty in swallowing solids, and this difficulty became gradually more intense, until finally he began to regurgitate his food.

He has lost since that time about 20 pounds in flesh, and, as you see, looks quite emaciated. His urine has a specific gravity of 1015 and contains no albumen. He complains of pain in the back and over the sternum when he attempts to swallow. I will now try the stomach pump in his case. As I pass the stomach pump down to a certain point in the œsophagus he experiences great discomfort when the tube reaches that point. This is not the discomfort that ordinarily attends the passage of a stomach tube, for when it has passed the pharynx, there is, generally, no more disagreeable feeling experienced on the part of the patient. As I withdraw the tube some mucus and blood regurgitates. This is the usual behavior of the patients suffering from a pathological condition like this man when you pass a stomach tube, as I have done here. By determining this condition with a soft tube you can do no possible harm to your patient.

This man then has a plain case of carcinoma of the œsophagus, which is already beginning to produce its starvation effects upon his system to a very considerable extent. He can still get down fluid food and he will have to continue with the use of that form of food. Pain is a symptom of this condition with some patients, though not with others, and this pain is excited by mechanical contact with the new growth in the œsophagus. It is for that reason he suffered so intensely as I passed down the tube, touching the neoplasm with its end. Other patients develop no pain at all when you attempt this manœuvre and I know of no grounds upon which I can explain this curious phenomenon. All we can do in the way of treatment for this man is to advise him to continue with the use of fluid diet as before.

DIABETES MELLITUS.

The next patient furnishes us an example of a very marked case of diabetes mellitus which has produced within a very moderately brief space of time a most profound effect on his general health. He is a man 30 years of age, and has noticed the symptoms he complains of for the past two or three months, though they have, probably, existed to a modified extent for a much longer period of time. Within the past two months he has lost considerably in flesh and strength and not only has he passed an increased quantity of urine which contains a good deal of sugar, but he has also a hunger that seems almost insatiable. He is no longer fit to do any work on account of his great debility.

This man has now been under treatment for this trouble over a month and has been kept during that time on a restricted diet and a solution of bromide of arsenic. The result of this treatment has been a marked

diminution in the quantity of urine voided, and, to some extent, in the quantity of sugar, though there is apparently no improvement in his weight or in his general health. This case is evidently one of a diabetes that is likely to present some difficulties in the way of treatment. For my own part, I think a great deal more of the effect on the patient's general health by the disease than I do of the quantity of urine or sugar that has been passed. For this reason in the treatment of patients I think more of the improvement in their general health than in the diminution of the quantity of urine or sugar passed. The nutrition of these patients gives us a cue to the severity of the disease and to the treatment.

The best thing we can do for this man then is to send him to the country and have him stay out of doors without doing work of any kind. It is a matter of great moment to him to pass as much of the day as he can in the open air and sunlight. He does not need exercise, he does not want to move about, but sit out in the open air under the light of the sun. Now, in regard to the kind of food he should take, I would advise him to take fat in some form or other, either in the shape of codliver oil or cream. If he is to take codliver oil he is to begin with small doses and run them up until he is able to take and digest ten or twelve tablespoonfuls a day of the oil. If, instead of codliver oil, he prefers to take cream, he can take this in a variety of ways. He should take as much as a pint of cream in the 24 hours. Then, with regard to the rest of his dietary, these are the ordinary rules governing the diet of diabetic persons, and that is to avoid the use of sugar and starches altogether. There are a good many diabetic patients to whom I would allow the use of wheaten bread as an article of food, but this man is too sick for that. We must get him down to the most restricted diet possible.

If this patient were one whom you could watch, a great deal might be gained by getting up bills of fare for him, yourself, suited to his condition. If you tell a patient he must not eat such and such articles of food, and he then goes away from your office and eats very little of anything, such a man as that will not do well at all. You must find out what articles of diet they like to eat and what things they do not like to eat. Bear in mind that the diabetic, as well as other patients, are people whom it is very necessary to feed properly and they have an appetite only for the articles of diet that they like best. This is a matter of a great deal of importance in the management of your patients and is a subject you should study in detail. There are people whom you can feed very well if you give them the right things to eat; and who would sooner starve them eat what they do not like.

Now, as regards the use of medicine for this man. There are a number of different medicines that we give for diabetes, and we give them all in a very empirical and uncertain sort of way. We do not know why any of them does good, and we are not sure that any of them will do good in a given case, but we know, on the other hand, that each of them is capable of doing some good in certain cases. The solution of the bromide of arsenic is a preparation that has been given a good deal, and with some success, in a considerable number of cases. In other cases, it does no good whatever. The same is true of the other preparations of arsenic, and according to the experience of different physicians, there are some who think that arsenic is of service in diabetes, while there are others who think it is of no use whatever. Then, beside arsenic and its preparations, opium is given either in the form of opium or of morphine or codeine. Codeine is the favorite preparation for this purpose, and, in my opinion, is the best form in which to give it. The trouble with all the forms of this drug is that it is very easy to begin its use but a very difficult thing to stop it after it has been taken for a considerable length of time. Then sulphide of calcium, given in doses of a quarter of a grain and run up to a half or one grain three or four times a day, is also used. This drug again answers for some patients and not for others. Iodoform has also been given for this condition and there are some who report good results from its use. In fact, I have seen some patients myself benefited by the use of this drug. It is generally given in pills or capsules in the proportion of one to three grains three or four times a day. Antipyrin, which has been given for almost everything, has also been given for diabetes, and good results have been reported from its use. I could go over a large number of drugs that have been given with more or less good results for the cure of diabetes.

The best thing that I can do for this man is to advise him about the proper place for him to live in and the food suitable for his condition. As regards his medicinal treatment, instead of continuing with the use of the bromide of arsenic I will give him arsenious acid, in combination with ipecac

and rhubarb according to the following formula:

℞ Acidi arseniosi.....gr. $\frac{1}{30}$.
Ipecac pulv.....gr. $\frac{1}{30}$.
Rhei pulv.....gr. $\frac{1}{30}$.
M. Sig. To be taken three times a day.

The only reason I give this preparation to bad cases like this man's, is because I have had better results from its use than other remedies which I have tried.

COMMUNICATIONS.

PENETRATING WOUND OF THE BASE OF THE BRAIN THROUGH THE LEFT ORBIT; HEMIPLEGIA; REMOVAL OF CLOTS FROM THE BASE OF THE BRAIN; RECOVERY.*

BY ERNEST LAPLACE, M. D.,
PHILADELPHIA.

R. B., aged 10 years, whilst at play on the lawn of his parents' country residence, fell on a broken fencing foil. The steel penetrated the left orbit between the inferior orbital ridge and the eyeball. The child was found a few moments later in an unconscious condition, with the instrument still in the wound. It was removed by a servant, and the child placed in bed.

I saw the case about five hours after the accident. Dr. Keyser, who was first summoned to the case, declaring, from an ophthalmoscopic examination, that the eyeball proper was uninjured.

There was coma, right hemiplegia, left facial paralysis, complete aphonia, respiration 30, pulse 140, temperature 104½°. Immediately above and about the centre of the left orbital ridge was an incised wound about one-quarter inch wide, from which oozed a little blood. Having but very meagre details of how the accident occurred, an exploration of the wound was determined upon. The patient being etherized, the cutaneous wound was slightly enlarged, and the handle of a Graefe cataract knife was inserted into the wound, and sank almost by its own weight to a length of three and one-quarter inches into the wound, taking a superior and internal direction.

Inasmuch as no spiculæ of detached bone could be detected, the probability was that the instrument passed through the sphenoided fissure, thence entering the base of the brain. The eye was apparently uninjured. There was, however, complete anæsthesia. Pupil dilated; insensible to light.

Having consulted with Drs. Keyser, Anders, and Shelly, it was determined to adopt the expectant plan of treatment; six ounces of blood was, however, extracted from the left median basilic vein.

May 17 (night of accident). Great jactitation of uninjured side of body. Quieted with ⅛ gr. morphia sulph. hypodermically, repeated in two hours. Temp. 103°, pulse 120. 5 grs. quinine suppositories; peptonized milk 2 oz. every three hours.

20th. Temp. 105⅗°, pulse 110, resp. 30. Sponged every fifteen minutes. 5 grs. quinine suppositories; ⅛ gr. calomel three times daily; peptonized milk. Jactitation continues; coma continues.

23d. Temp. 99.6, pulse 100, resp. 26. General condition unchanged.

25th. Temp. 98.6, pulse 72. Collapse. Cold extremities; cold sweat. Teaspoonful of brandy every half hour.

27th. Collapse. Temp. 96.8°, pulse 72. Brandy; $\frac{1}{60}$ gr. strychnine sulph. hypodermically every two hours.

During the intervals of collapse there was great restlessness. Great emaciation had taken place, and there was not the slightest improvement in the general condition of the patient. Judging that at least a part of the symptoms were the result of compression from a clot at the base of the brain, and wishing to offer a surface for the relief of tension within the cranium, trephining was resorted to on May 30th, thirteen days after the accident.

Operation. From the direction taken by the instrument it was evident that it had penetrated the middle fossa, and that hæmorrhagic clots should be sought for in that locality. Accordingly, the patient being etherized, a horseshoe incision three inches long was made in the temporal region, down to the level of the zygomatic arch, and the tissues were lifted *en masse* from the bone. The trephine was rested on the middle of the zygomatic arch, and a three-quarter inch piece removed, consisting of the temporal bone and a small fragment of the sphenoid; the dura mater appeared very congested.

To reach the centre of the base of the brain for the removal of the suspected clot, a miniature egg-beater, consisting of four loops of platinum wire, had been improvised; this was perfectly malleable, and could be insinuated between the dura mater and skull

*Read before the Philadelphia County Medical Society, November 25th, 1891.

without wounding the structures. Having reached the cavernous groove the instrument could be pushed no further; it was then turned on its axis for the purpose of catching the coagula in its loops. This was effectually done, and about a teaspoonful of clotted blood was removed piecemeal.

Whilst dragging more out, considerable venous hæmorrhage took place, most probably as the result of the removal of the clot that occluded the injured cavernous sinus.

The trephined opening was immediately plugged with iodoform gauze, and a graduated compress applied over it, secured by a tight bandage about the head.

May 31. Patient reacted well after the operation. Temp. 100°, pulse 72, rep. 22. Very restless.

June 3. Temp. 98.2°, pulse 80, resp. 24. Vomiting. Milk enemata every two hours. Dressings saturated with blood and serum. Slight return of consciousness; patient notices sounds.

8th. Temp. 97.6°. On dressing the wound the patient makes signs with uninjured hand, recognizing things about him.

11th. Temp. 97.8°. After an apparently great effort patient articulated a few words. Dressing completely saturated with serum. Motion has gradually returned in affected limbs. Hypodermic injection of strychnine sulph. $\frac{1}{30}$ gr. twice daily. Patient greatly emaciated.

15th. Temp. 97.3°, pulse 64. Speaks more distinctly. Memory remarkably clear; reason perfect. Dressings daily saturated with serum.

July 1. Patient's condition has steadily improved; voracious appetite. Massage, electricity, and general inunctions with cod-liver oil to increase nutrition.

10th. Secretion has ceased from the wound. A plastic operation was performed under ether by which the wound was closed. Union by first intention, except at the most dependent portion where a sinus remained about one month, giving exit to slight serous exudate.

September 1. Patient sits at table. Wound completely healed. Has gained 15 pounds. Remarkably bright and cheerful.

November 15. Has apparently equal use of both inferior extremities. Can stand and make a few steps without support. Pupil of left eye somewhat contracted. There remains anæsthesia of the eye and internal strabismus, showing in injury to the ophthalmic division of the fifth pair which supplies sensation to the eye, and an injury to the sixth pair which supplies the external rectus, giving a paralysis of this muscle, hence internal squint, thus corroborating our suspicion that the foil penetrated through the sphenoidal fissure. The improvement continues so steadily that everything points to an ultimate complete recovery.

I must here render thanks to Dr. James M. Anders, of Philadelphia, and to Dr. Shelly, of Ambler, Pa., for their unremitting aid in carrying out the medical treatment of the case.

Remarks.—1. From the direction taken by the instrument producing the injury, it is probable that it passed through the sphenoidal fissure, wounded the cavernous sinus, the crus cerebri and entered the left lateral ventricle.

2. The hemiplegia was due to venous hæmorrhage and laceration of the crus cerebri and other structures, no spiculæ of bone being detected.

3. The coma, hemiplegia, aphonia, and progressively unfavorable course of the patient were relieved after trephining, low in the temporal fossa, lifting the brain and removing blood-clots from the seat of hæmorrhage.

4. The vast amount of oozing and secretion from the opening, was evidence of the intra-cranial tension and of the absolute necessity of drainage.

5. Consciousness returned shortly after the relief of the intra-cranial tension. Phonation and articulation soon followed.

6. The brain is situated in an unyielding box of the cranium, and therefore when exposed to a great irritant, little allowance has been made by nature for the resulting expansion (congestion, swelling in other parts), following upon the irritant. With a view of remedying this condition, the brain if not in a position to expand freely as a result of the irritation, should by trephining be given an opportunity of drainage, which meets the same object by offering a spot of least resistance to relieve the tension within the brain.

The principle applies to many cerebral conditions where symptoms of general compression are the result of a local or a general irritant, within the cranial cavity. That this principle found a happy application in the present case, is evidenced by the great serous effusion which daily permeated the dressings.

7. We wish to exphasize, the safety of trephining near the base of the skull, the ease of arresting violent hæmorrhage from

the sinuses of the dura mater, and the importance of drainage in all cases of cerebral injury.

8. To our knowledge there is no recorded case of trephining as low in the temporal region, and removal of clots from the base of the brain.

OVARIOTOMY FOLLOWED BY VENTRAL HERNIA; OPERATION; RECOVERY.

BY D. BENJAMIN, M. D.,

SURGEON TO THE COOPER HOSPITAL, CAMDEN, N. J.

Mrs. S., aged 28, having had a fall a few months after she had been operated upon for an ovarian tumor, felt pain in the region of the incision, which had extended nearly from the umbilicus to the pubes.

In a few days an enlargement was noticed by her in the median line below the umbilicus, several inches in diameter, whereupon my attention was called to the case. I found a ventral hernia about three and a half inches in its longest axis, occupying the site of the former incision. A suitable support was applied and the patient was told that an operation would be necessary to cure the condition. Feeling more comfortable she delayed the operation for three weeks, at which time her consent was obtained to proceed; accordingly, she was placed under ether on the 27th day of March, 1890.

The question arose whether it is better in such cases to make the incision through the old cicatrix, or alongside of it. In this instance I decided to make the incision one-quarter of an inch to the left of the old incision—to the left, because if I had to proceed above the navel I could go to the left side, which is preferable. On opening the peritoneum I found the bowel had grown fast for a distance of three inches along the line of the old incision, and if the opening had been made in the cicatrix the bowel would have been in great danger of being opened. This fact has satisfied my mind as to the impropriety of reopening the abdominal cavity in the cicatrix of a former section, if it can be avoided.

The bowel was with great difficulty dissected from its close and strong adhesions along the old incision. It was found that the conjoined tendon and dense fibrous tissue along the linea alba had been separated, stretched and thinned out, and that a hernia had occurred alongside the adherent bowel, and had pressed before it the skin and superficial fascia. In order to obtain a strong and solid basis of union, the thinned out fibrous tissue was pared away until the thick tendinous structures underlying the anterior borders of the recti muscles was reached. Each of the muscles was exposed by the dissection.

This, of course, slightly reduced the parietal circumference, and would necessitate increased tension to bring the edges of the wound together.

On passing the hand into the abdominal cavity a fatty tumor three inches in diameter was found in the omentum, which tumor was responsible to some extent, for the undue internal abdominal pressure found to exist at the time of the operation.

I determined at once upon the removal of this mass. Double ligatures were passed through the omentum near its attachment to the stomach and colon, and the *entire omentum* and tumor were cut away and removed.

All the bleeding points having been secured and the toilette of the abdominal cavity carefully made, a row of deep sutures consisting of No. 14 Chinese silk was passed from within outward through the peritoneum and tendinous structures, taking in the sheathes of the recti muscles. These were placed about an inch apart. Before being tied an additional row of heavy silk sutures were passed from within outward, through all the tissues, including the skin and superficial fascia.

Deep sutures which included only the tendinous structures were drawn and tied tightly, beginning with the lower one and the suture next adjoining, which included all the tissues, was drawn up so as to prevent the catching of any portion of the bowel left untied. Proceeding in this manner, each of the deep sutures was tied and cut short, being therefore buried deeply in the abdominal parietes. This having been accomplished, the dense tissues were drawn strongly together, and the other sutures including all the tissues, were tied.

No unpleasant results followed leaving the heavy silk ligatures upon the omentum or buried in the abdominal walls, and sufficient time has now elapsed to enable us to say that the operation was entirely successful in curing what, at the time appeared to be a large and dangerous ventral hernia.

209 Cooper St., Camden, N. J.

THIOL is said to act well in constipation, one pill of 1½ grains daily for ten days.

ELEMENTS OF THOROUGH DIAGNOSIS.*

BY E. N. CAMPBELL, M. D.,
GOOD HOPE, ILL.

One of our American humorists has said that it is better not to know so much than to know so many things that are not true. Early errors accepted in the practice of medicine, as well as in other branches of business, are not easily gotten rid of. No subject (not the minutest thing) can be so exhausted that further thought and the insight of genius may not discover still deeper meanings, and more subtile relations. And thus the mighty labor becomes progressive, each generation receives its inheritance of knowledge, makes its own additions, and bequeaths the whole to its successor. So that we of the present stand as heirs of all the ages, in the foremost files of time. Life is too short, and humanity too frail, for one to undertake to solve all the great principles that arise before him. If there is one thing more than another that should give the heart cheer, it is to know we are dealing with facts, and that our time is not lost or wasted by unfounded and unproved theories. If a person would become proficient in the practice of medicine, he must early bend his energies towards that difficult problem of separating truth from error. In no profession do we find such heroic tendencies to error, than in this one of ours—the practice of medicine. And why? Remembering that medicine is not an exact science, and to be able to deduce truth from error, requires trained and well cultivated minds, as well as long and continued research, which at once indicate that the proficient practitioner unqualifiedly must become a life student and a diligent searcher for truth.

In the practice of medicine, as well as in other professions, we find persons who are not so constituted as to undergo the ordeal of much mental exertion, and in consequence of which they soon take up the line of empiricism, under the reputation of the profession, and gain for themselves a livelihood in accordance with their own ambition. The first prerequisite of a good diagnostician, is a clear head and an honest heart. If a person is in possession of these elementary qualifications, then is he fitly prepared to study and learn morbid signs and separate truth from error. The truth is, that the detection of disease is the product of close investigation and observation of symptoms, and of correct deduction from those symptoms. This art of observation implies close thought and practice. No one aspiring to become a skilful observer depends exclusively upon the writings of others. It must be by his own persistent and careful investigation, reflected from his own enlightenment, that he is enabled to elucidate the truth. The knowledge to be gained by reading is, of course, serviceable in this way; it helps in overcoming the main difficulties at first experienced, (*i. e.*) to know where to look, and what to look for. Of course, there are in almost every affection some symptoms which can be detected by the merest beginner, but others again which do not appear on the surface, and which will tax the most experienced physician to find. And it is in this search for hidden signs, that medical information as well as cultivated tact is demanded. In earlier days we could not go further than our eyes could see, ears could hear, and the sense of smell and touch could carry us. Science has lent her aid and furnished us means by the help of which we can clearly detect that of which before we only got a glimpse. We now possess instruments by which we can ascertain with accuracy the size of organs. Thermometers tell us of the fraction of a degree of heat. Specific gravity bottles give us the relative values of fluids.

The microscope unveils to our view the hidden mysteries of past generations. The laryngoscope demonstrates the appearance and the movements of that wonderful organ of speech. The ophthalmoscope informs us of the state of the vessels of the brain. And chemistry with its unparalleled teachings, is bringing to our minds amazing truths that belong to the morbid state. The effect of all these improved methods of study has been to give immense impetus to clinical research, and thus to lead to the establishment of solid ground work of experience, which certainly is in striking contrast with the looseness of former times. The advance in diagnosis thus attained, to me forms one of the most pleasing portions of medical history.

Now we will suppose the symptoms of a certain malady have been discovered, our next step in diagnosis would certainly be a proper appreciation of their significance, and relation toward each other. Knowledge, and above all, the exercise of the reasoning faculties are now indispensable. The daily habit of discovering disease, the skilful use of the microscope, and the searching analy-

*Read before the Military Tract Medical Association, October, 1891.

sis of chemistry would be of little use, unless we could place side by side the morbid signs they expose, and be able to consider their individual and respective value, otherwise the science of diagnosis would be simply a matter of memory. There are few symptoms in themselves distinctive, and often a symptom may be due to several causes. Semeiology informs us of their different causes, but to find out the precise meaning of the abnormal manifestation in a given case, we have to draw our inference from all the signs encountered, to compare them with one another, to seek out those that are in the background.

To accomplish all this effectually the physician has need of much and varied knowledge. He must be master of something more than the information supplied to him by semeiology. He must be an anatomist, a physiologist, and above all a pathologist in the full sense of the term.

From what has already been represented, he must be a correct *reasoner*, for, a good observer will, by bad reasoning, arrive at a faulty diagnosis, just as sometimes a bad observer by some process blunders into the truth.

There is indeed no end to the extent of knowledge which may be brought to bear in working out a conclusion regarding the character and seat of a malady.

Having thus indicated the elements of a thorough diagnosis, we may next inquire in what way this is the most easily arrived at, when at the bed-side. In the first place, we will say, the main facts of the case on which the deductions are to be based, must first be ascertained. Now, take these main facts, especially those which have the most direct sign or bearing on morbid action, then these morbid signs are coupled together, and we start a chain of inquiry as to what organ they point as the seat of the disease. This often has been already settled in your mind by the very mode of examination. Now right here is the place that so many practitioners switch off into mistakes, and I desire to call your especial attention to this point. Instead of jumping at once to a conclusion or being satisfied that the diagnosis is complete, we should proceed to investigate the precise nature of the disorder, by analyzing the symptoms, and the previous history. We must go back and compare the facts ascertained, giving each its individual bearing as compared with the peculiar history of the case.

As stated above, there are few signs in themselves pathognomonic, therefore special pathology is brought to bear on the accumulated symptoms, in order to establish a correct opinion.

Let us cite a case. A patient consults us for a cough brought on by exposure. He says he has been ill for four or five days, his health having been previously good. We notice that his breathing is hurried; he has fever; the lower portion of one side of the chest is dull on percussion, and the respiration there is wanting; the action and sounds of the heart are normal. The facts point to the lung or its coverings as the seat of disease. We also know from the history of the case that we have to deal with an acute disease. Now, are you about to say pneumonia? Right here, we must remember, comes in that particular time not to be in a hurry to conclude your diagnosis. It is much easier to take a little more time now, than to take back an opinion once given. We should first ask: What are the acute pulmonary affections? We say—acute bronchitis, acute phthisis, acute pleurisy, and acute pneumonia. In all these we have fever, cough, and impaired breathing. Now, do you say pneumonia? No, for notwithstanding there is in this complaint, in addition to the general symptoms mentioned, dulness on percussion, the dulness is associated with a blowing respiration. Whereas in the case before us, no respiration is heard. Look at the sputum, see if it is tenacious or rusty. Let us see if acute pleurisy will explain all these signs. The patient says that he had at the start, sharp pain in his side, and this we are aware takes place in pleurisy. Then take the local vibrations, they are noticed to be absent on the affected side of the chest, which when measured, is found to be enlarged. The disease is, therefore, pleurisy in the stage of effusion. This process of arriving at an opinion is the simplest, and it is astonishing how rapid it may be performed, by habit. This method aims so far as the symptoms permit at a direct diagnosis, which in truth is differential. To prove what a thing is, by proving *all* that it is not, is a very tedious process. Yet, there are many close observers who depend upon the process of exclusion to clearly establish diagnosis, but owing to the many drawbacks diagnosis by exclusion is not on ordinary occasions to be encouraged. The most serious obstacle to a precise diagnosis, lies in the fact, that frequently lesions coexist. We know that disease is a very complex state and when one portion of the economy gets out of order, another is apt to follow. One great advantage, indeed, of attending carefully to diagnosis, is, that it enables us to use

remedies knowingly, and with decision, and appreciate what they are effecting. It is sometimes urged that the accurate detection of disease, makes timid practitioners, and deprives them of confidence in medicines. Nay, verily, but it does show, unfortunately, that our skill to detect disease is far in advance of our power to cure it. Therefore, gentlemen, the medical man who is able to clearly and intelligently diagnose his case is also able to give a correct prognosis regarding it, and in any event that follows, if these two elements have been correct, it forms one of the strongest bulwarks the practitioner can possess, and puts him in position to face the ever present conflict of a criticising public, and justly crown him with an abiding confidence that truth and merit will always prevail.

MODIFIED JUNKER INHALER, WITH POINTS FOR DISCUSSION ON ETHER AND CHLOROFORM NARCOSIS.*

BY MARIE B. WERNER, M. D.

My object in presenting this inhaler before the Society is not alone because I consider it the best of its kind ever brought to my notice, and therefore concluded it might be of interest to some of the members here to-night, but also to learn something about the pros and cons regarding the use of ether and chloroform as anæsthetics.

This inhaler has the respiration indicator approved of by the Hyderabad Chloroform Commission, and in addition has a graduated stopcock which will, if properly adjusted, control the volume of air forced through the bottle containing the anæsthetic, thus giving a continuous current.

The bottle should be but partially filled—4 to 7 drachms—thus allowing the contents to pass over through the tube to the face-piece in the form of vapor. If chloroform is used, with one compression of the bulb 5.19 cubic inches of air are forced through the liquid, and will evaporate, in a temperature of 68° F., about one minim; a trifle more than one cubic inch of the vapor passes through the short tube into the face-piece.

The noteworthy points are that the patient does not inspire much, if any, of the expired air; the apparatus is clean and can be kept so with little trouble; the quantity of the anæsthetic used is comparatively small; and last, but not least perhaps, the character of the respiration is always indicated to the operator as well as the anæsthetizer.

The character of the respiration seems to be of vast importance if we accept the report of the Hyderabad Commission, based upon an almost unbroken series of 45,000 cases of chloroform administrations extending over 40 years, in which the anæsthetizers were guided entirely by the respiration, and there was not a death. In strict accordance with these clinical facts the experimental data of the Hyderabad Commission prove —[1]

"1. That the administration of chloroform is free from risk if the breathing is perfectly regular throughout and the inhaler is stopped as soon as the animal is fully under its influence.

"2. That chloroform never causes death by sudden stoppage of the heart.

"3. That death from chloroform is always the result of an overdose.

"4. That the danger of overdosing is enormously increased by holding the breath, struggling, asphyxia, or anything which causes the patient or animal to take gasping inspirations.

"5. That the inhibitory action of the vagus nerve, which is called into play in threatened and actual posioning with chloroform, is a safeguard."

I do not wish to give the impression that I advocate chloroform in all cases, but think many will admit that there are cases where it has advantages over ether, provided it can be given with safety to the patient. For instance, in cases of bronchorrhœa it is less stimulating to the mucous membrane; in certain pathological conditions of the kidneys it can be relied on with greater safety. Last and perhaps not least to be considered is the small quantity necessary for a large operation, thereby possibly obviating some of the unpleasant after-effects of ether, notably the nausea, vomiting, and depression which sometimes follow a prolonged operation.

There is one point I have not yet been able to develop, and that is the utility of this apparatus in giving ether. Although I have been assured it would behave satisfactorily, I have not had sufficient opportunities to demonstrate in with any degree of certainty to myself; but feel sure, however, if it could be utilized it would mean economy of ether and greater comfort to the patient.

*Read before the Philadelphia County Medical Society, November 25th, 1891.

[1] Lancet, November 29th, 1890.

This inhaler may be obtained from Messrs. Krohne & Senseman, London. (For discussion, see Society Reports).

Society Reports.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 25th, 1891.

Papers were read by Dr. Ernest La Place (see p. 1004), by Dr. John B. Roberts (to be published in the Reporter, Jan. 2nd) and by Marie B. Werner. Dr. Werner's paper was entitled, "Modified Junker Inhaler, with Points for Discussion on Ether and Chloroform Narcosis." (See p. 1009.)

DISCUSSION.

Dr. Joseph Hoffman:—I have used this instrument quite a great deal, and its utility for chloroform inhalation is unquestioned. The quantity of chloroform required is much diminished by its use; for an extended abdominal operation I have more than once had a drachm of chloroform suffice. Nor have I seen any bad effects from chloroform when this instrument was used, although I do not believe that the bad effects are completely obviated. In two or three cases I have found that ether had to be abandoned and chloroform substituted.

So far as the report of the Hyderabad Commission is concerned, I do not think that in this country it will be accepted as final. The results of experiments on animals are not always applicable to man. In the sudden deaths in man, fatal result is brought about by action of the anæsthetic on the heart, and not on the respiratory apparatus. Chloroform paralyzes reflex action, while ether stimulates it. In children there is little danger from chloroform, and in children too the reflexes are stronger than in adults.

So far as the application of this apparatus to the administration of ether is concerned, I do not think that it will work, as it is not possible to obtain a dense vapor of ether in sufficient quantity. If the apparatus were modified so that a larger quantity of vapor might be produced, the effect might be better. Finally, too, it is to be insisted, that to obtain good results and to escape the dangers of anæsthesia, we must depend rather on the anæsthetizer than on any apparatus he uses.

Dr. James Collins:—I recall very well the time when we had no ether. It was chloroform. Chloroform was found in all the medical chests and was given with impunity. We never thought of danger, provided the man was sufficiently recovered from shock. I saw only one accident from chloroform, and that was after the battle of the Wilderness. We had been giving chloroform all day, when a man came in with a wound of the hand; he took a few whiffs of ether, and expired. In his case the rule had not been observed—that is, not to give the anæsthetic when the man was under the influence of shock. The shock from gunshot wounds often acted strangely. Men with severe wounds would walk long distances to the hospital with no signs of shock, and yet, when placed in bed would, in a few minutes, present marked evidences of shock. It was with some regret that I saw the reaction against chloroform that came later. Chloroform is certainly more pleasant than ether, and I think that if properly given it is as safe as ether. I have seen death from ether. It was a case of pistol-shot wound; ether was given and the shock came on while the man was under the influence of the anæsthetic, and he died. Many years ago, at the University, we gave a mixture of ether and chloroform. From that, I saw no accidents.

Dr. Joseph Leidy:—The only death that I have seen from an anæsthetic occurred while chloroform was being administered with this apparatus. The chloroform was administered by a gentleman who had been in the habit of using this instrument almost daily for months. I think, however, the death would have occurred whether the instrument had been used or not.

Dr. John B. Roberts:—I have seen six deaths attributed, and probably justly, to anæsthetics. Fortunately, in none of these was I the administrator of the anæsthetic. I never have a patient etherized without feeling a great deal of discomfort, especially if the ether is given by the ordinary individual that administers ether. The majority of them do not know how to give ether unless they have seen a death, or nearly killed someone by ether. If ether or chloroform is given 100,000 times without a death, it is no proof that there is no danger in the administration of ether or chloroform. Although the Hyderabad Commission decided that chloroform is better than ether, yet I think that Dr. Wood echoes the senti-

ment of this portion of the country, at least, when he says that ether is the safer.

It seems to me that the difficulty is that the anæsthetic is placed in the hands of incompetent people, who do not know how to give it and do not pay attention to their work. In several of the cases of death from anæsthesia which I have seen, I believe that the result was due to the carelessness of the administrator. A short time ago I saw a patient nearly die from ether, and he was only kept alive by about an hour and a quarter's artificial respiration. The trouble in this instance was due to the fact that I, the operator, called the attention of the anæsthetizer from his work. I have scarcely used chloroform, and have seen very little of its use, but if the evidence of literature is worth anything, it is in favor of ether. I do not believe that it is the shock of injury; I believe that it is the chloroform that kills. Chloroform is certainly the more powerful and more dangerous agent. In spite of the objections to ether, it seems to me that the opinion of the Philadelphia profession in favor of ether is correct, and is borne out by the literary evidence.

Dr. T. S. K. Morton:—I have had an opportunity of examining this apparatus, and so far as apparatus' go, it seems superior to any that I have seen. But I do not see that any method for administering chloroform can be better than the little wire frame, invented, I think, by Esmarch. So far as ether is concerned, I dispense with all apparatus; especially do I dislike the Clover apparatus, where the patient respires the same air over and over. In most cases ether is given badly. Just as I have learned to give ether in less condensed form, so have my results been more satisfactory. The cone, as usually employed, is extremely objectionable; and towels as found at patient's houses are usually impregnated with starch and will not absorb the ether or allow air to pass freely through. Unless you obtain very old towels or napkins, it is either difficult to etherize the patient, or you have to give the ether in too concentrated form. Some two or three years ago it struck me that it would be well to use cheese-cloth for this purpose, and since then I have used nothing else. I use small squares, about six by seven inches, consisting of ten or twelve thicknesses of the gauze. This is placed over the patient's face and the center raised up by puckering the lateral edges. This offers no obstruction to the passage of air. The ether is dropped upon the centre of the gauze from above. I have etherized a child by this method, and kept it under the influence of the anæsthetic for ten minutes, with but one drachm of ether.

Dr. Werner:—In presenting this apparatus, I do not wish to be understood as advocating the general use of chloroform. It seems that there are some cases in which it can be used with better advantage than ether, and, therefore, it is well to know the best method of administering it. I think that the trial alluded to by Dr. Hoffman with this apparatus for ether was not a fair test. The patient was difficult to etherize at best, and seeing that, I used the towel. I had occasion to try it again for a smaller operation, and it answered admirably. In answer to Dr. Morton's remark about the unequal supply of vapor and air, I would like to call attention to the fact that this stopcock, if adjusted properly, will give a continuous current of air. I think Dr. Morton's plan of giving ether better than the towel. I heartily endorse Dr. Robert's statement that there is often not sufficient care and attention given by the anæsthetizer to the work in question, and feel certain the operator can work with greater freedom when the mind is at rest in that direction. I think there is room for improvement in the methods of administering both ether and chloroform.

Selected Formulæ.

RHEUMATIC ENDOCARDITIS.

Prof. DaCosta prescribed the following for a boy ten years of age:

℞ Tinct. strophanti.....m ij.
Tinct. cardamom. comp.....f 5 j. M.
Sig. Three times daily.

—*Coll. Clin. Rec.*

RHEUM IN ROUND WORMS.

Dr. Martin (*Les Nouveaux Remédes*, No. 3, 1891), praises the following in round worms:

℞ Tinct. rhei.....gtt. xxx.
Magn. carb.....gr. iij.
Tinct. zingib.....gtt j.
Aq. destillat.....f 3 ij.
Sufficient for one dose.

To be taken three or four times daily.

NUTMEGS IN HÆMORRHOIDS.

The common nutmeg employed in the form of an ointment is said to give prompt and permanent relief in itching and painful piles. It may be employed as follows:

℞ Pulv. nuc. moschat.....3ij.
Acid. tannic.....3j.
Petrolat.....3j.

SCHENK'S PULMONIC SYRUP.

The following formula for Schenk's Pulmonic Syrup was given to me by an old lady several years ago, who professed to know all about the late Dr. Schenk when he commenced:

℞
Wormwood.
Catnip.
Tansy.
Hyssop.
Hoarhound.
Hops
Chamomile.
Comfrey.
Senega.
Elecampane, aa.....ʒ ss.

Boil with sufficient water to make, after straining, one quart, add—

Gum arabic.
Licorice, aa.....ʒ jss.

Then one good-sized Indian turnip, and finally add—

Sugar.....lb. ʒ.
Brandy.....pt. ½.
Juice of two lemons.

—H. M. Wilder, in *Pharm. Journ.*

BECKER'S EYE SALVE.

℞
Calamine.....ʒ jss.
Tutty.....ʒ jss.
Red oxide of mercury.....ʒ vj.
Camphor in powder.....ʒ j.
Almond oil.....ʒ j.
White wax.....ʒ jss.
Fresh butter.....ʒ viij.

Reduce the mineral substances to a very fine powder and incorporate with the oil, in which the camphor has been dissolved with the wax and butter, previously melted together.—*Kilner's Modern Pharmacy.*

INTERTRIGO.

R. L. Paterson recommends for severe chafing or intertrigo the following:

℞
Camphoræ.....ʒ ij.
Acid carbolici.....gtt. xv.
Cretæ precip. (English).....ʒ ij.
Zinci oxidi pulv.....ʒ ij.
Ol. nerolii.....gtt. v.
Ol. rosæ.....gtt. ij. M.

Sig. Rub the camphor to a fine powder, using alcohol to reduce it, and mix the other components thoroughly.

This powder is invaluable for healing raw and excoriated surfaces, and for sunburn. Mixed in the proportion of one part to three of ung. petrolatum or ung. aquæ rosæ, it forms a most useful salve.—*Med. Summary*, Sept., 1891.

WICHERSCHEIMER'S FLUID.

For the preservation of anatomical and pathological preparations, Dr. F. J. Lutz, 105 South Broadway, has kindly furnished the formula taken from *Nu Yorker Medicinische Wochenschrift*, Sept., 1891, copied from No. 23 of the *Polytechnisches Centralblatt:*

℞
Alum.....gr. c.
Sodium chloride.....gr. xxv.
Potassium nitrate.....gr. xij.
Potash caustic.....gr. lx.
Arsenious acid.....gr. x.

Dissolve in 3,000 g. of boiling water. The solution is allowed to cool and is then filtered.

To each 10 litres of this neutral, odorless and colorless fluid are added four litres of glycerin and one litre of methyl-alcohol.

If the preparations are to be preserved in a dry state they are kept in the fluid for from six to twelve days, according to size, and then exposed to the atmosphere.

It is claimed that specimens treated by immersion in the fluid can be used for scientific demonstrations and in medico-legal inquiries after many years. They do not decompose and are odorless.

RHACHITIS.

Kassowitz, after an experience with 25,000 cases, discards the theory that rickets is due to a want of calcareous salts in the food, and believes it results from an inflammatory hyperæmia of the osteo-genetic tissues. He, therefore, considers the administration of the salts of lime useless, and does not forbid the use of starchy foods. He recommends the use of phosphorus in cod-liver oil $\frac{1}{120}$ grain of the former in a teaspoonful of the latter. If there is any reason for not giving the oil he uses lipanine, as in the following:

℞
Phosphori.....gr. ⅙.
Lipanine.....ʒ j.
Sacch. alb.
Gum. Arabic, aa.....ʒ ss.
Aq. destil.....f ʒ j.
Ft. Emulsionem.
Sig. ʒ j, daily.

LEADING ARTICLE.

GONORRHŒA IN WOMEN.

The more exact studies of the present have expanded very greatly our knowledge of gonorrhœa in women. It is but a little while since this disease in women was considered as trivial; as being only a vulva-vaginitis which would recover even without treatment in six weeks; and as meriting attention, not so much because of the evil it might do the woman, as because of the possibility of the disease being conveyed to men. Enlarged experience has shown this conception of the affection to be not only inadequate, but even partly erroneous. The error is with reference to the usual seat, which has been shown to be the cervix uteri and not the vagina. It is now well established also, that far from the disease terminating spontaneously it tends to persist in a chronic form for a very long time—almost indefinitely. The disease tends to invade the entire genital tract. Not only the vulva-vaginal glands but the endometrium, tubes, ovaries and the peritoneum—even distant organs and tissues as the knee or ligaments of the spine may be affected. Thus, incurable or even fatal conditions may and frequently do arise from this disease heretofore considered so trivial; not to consider the extension of the disease to the urinary organs, where it may produce the same serious conditions which it does in men.

The cause of the disease is still disputed, but the evidence is certainly satisfactory that it is the gonococcus of Neisser. The studies of Neisser, Bumm, Menge, Saenger, Wertheim and others seem to be conclusive on this point. Wertheim, in a paper read before the German Gynæcological Association at its last meeting reports the demonstration of the presence of the gonococcus and the absence of other germs in the pus from numerous cases of pyosalpinx, and in two cases of abscess of the ovary, suspected to be gonorrhœal in origin. In three cases gonococci taken from cultures obtained from germs contained in tubo-ovarian pus, and

inoculated in the human urethra produced a typical gonorrhœa, showing not only the presence of the gonococci in the pus but also that in these cases the germs had retained their virulence.

It has been shown that the internal os uteri is a fairly effectual bar to the further progress of the disease toward the peritoneum. Hence, it is of interest to know under what conditions the corporeal endometrium and the tubes become affected. It is assumed by some writers that menstruation and coition favor the spread of the disease from the cervix to the uterus, but no very strong evidence in support of this is available. But the evidence is demonstrative that the infection can be and is carried on the examining finger during abortion or labor from the vagina or cervix to the corporeal endometrium, and that it is also carried in the same way when the uterine sound or applicator is introduced into the uterus in cases of gonorrhœal vaginitis and endocervicitis. The practical deduction from these facts is, that the condition of the genitalia of puerpera should be investigated when they come under our care, and if purulent or irritating leucorrhœa is present, vigorous germicidal and astringent treatment should be instituted to guard against possible, and even probable, gonorrhœal puerperal inflammation in the mother and ophthalmia in the child. A further argument is here found against the indiscriminate use of the sound, especially when passed through the vaginal and cervical secretions without the aid of the speculum, and without the previous cleansing of the parts.

Bacteriologists differ as to whether intraperitoneal abscesses and other deeply seated inflammations are due to the gonococcus or to some other germ also present and constituting mixed infection. The solution of this question will be of importance, but what interests the clinician far more is, that gonorrhœa unless cured promptly, before it invades the endometrium, may induce incurable tubal inflammation, ovarian abscess or purulent peritonitis, and necessitate abdominal section and removal of the diseased organs to save life, or to rescue the sufferer from chronic invalidism.

Every practitioner must learn the important lesson that gonorrhœa is a serious disease, which may even destroy life immediately or remotely. Also, that it is a most intractable disease since the cocci can retain their vitality when lodged in the folds of the vagina, or in the cervix uteri or in the urethra, where it is difficult to reach and destroy them. Gonorrhœa should be treated actively by sublimate douches, the application of silver nitrate solutions, tannin packing, etc., until all signs of the disease disappear. Then the patient should be told of the tendency of the disease to recur by reason of its spread from some concealed nidus, and she should be instructed to present herself for examination at monthly intervals for at least six months after the disease is apparently cured. A candid description of the not improbable consequences of neglecting this advice—gonorrhœal salpingitis with recurring attacks of peritonitis, with invalidism or death—is usually a sufficient incentive to the patient to induce her to follow the instructions. Were these principles of treatment more faithfully carried out with men as well as women, the number of sterile women, and of invalids from pelvic inflammatory mischief, would be greatly lessened, and the field of usefulness of the abdominal surgeon, thereby, greatly curtailed.

Book Reviews.

THE PHYSICIAN AS A BUSINESS MAN; OR HOW TO OBTAIN THE BEST FINANCIAL RESULTS IN THE PRACTICE OF MEDICINE. By J. J. Taylor, M. D., Philadelphia. The Medical World. Price, $1.00.

The author of this little book, to use his own words, has endeavored to outline a practical business policy for the physician, while living and practicing under the present economic system. In its compilation he has made liberal use of clippings both from the medical and secular press, and freely interspersed his individual views. The subject is one which seems to be all but utterly neglected, and there can be no question about the enormous amount of good that would accrue to

the profession if many of the suggestions offered were earnestly carried out. The physician, considering the nature of his work, is the worst paid man in existence, and the reason for it is largely due to his seeming indifference to business methods.

This book can be read with profit, especially by those who have just entered, or are about to enter, the profession.

SAUNDERS' POCKET MEDICAL FORMULARY: WITH AN APPENDIX. By WILLIAM M. POWELL, M. D., Philadelphia: W. B. Saunders, 261 pp. Price, cloth, $1.50; tucks, $1.75.

Dr. Powell has brought together in this handy little formulary 1734 prescriptions from authors of repute, and covering almost the entire field of pharmaceutical therapeutics. Its value is very much enhanced by a thumb index, so that one is enabled to turn at once to any disease and find a number of prescriptions from which to select. Besides the above valuable formulæ there is a dose table, formulæ and doses for hypodermatic medication, poisons and antidotes, cuts of the female pelvis and fœtal head with diameters, a diet table, table for calculating the period of gestation, and drugs and materials used in antiseptic surgery.

The practitioner will find this formulary of great usefulness, not so much for the prescriptions themselves as for the many suggestions of pharmaceutical combinations and the excellent memoranda.

PERISCOPE.

THERAPEUTICS.

CHLORALAMID IN EPILEPSY.

At the October meeting of the New York Academy of Medicine, Dr. Chas. L. Dana, Professor of Diseases of the Mind and Nervous System, New York Postgraduate Medical School, in speaking of symptomatic treatment of epilepsy refers to chloralamid as follows: "The most valuable adjuvant was hydrate of chloral, but I have found a new drug in chloralamid, which does all the good ascribed to the former drug, without affecting the heart or circulation."

TREATMENT OF DIABETIC COMA.

Reynolds, after referring to the recent papers by Dickinson advocating Fagge's method of treating diabetic coma by intravenous injection of saline solutions, recommends (*Med. Chronicle*, August) the administration of a large amount of saline solution by the mouth. In the case of a man with rapidly approaching symptoms of diabetic coma he ordered an aperient, telling the patient to drink during the night at least a gallon of fluid, together with an ounce every hour of a mixture containing 60 grains of citrate of potash to the ounce. Next morning the man was slightly better, and the treatment was continued for another twelve hours, the citrate of potash being lessened in quantity. In three days all symptoms of coma had passed away, the sugar had again increased in quantity, the acetone had disappeared from the breath and urine, and the albuminuria had entirely ceased. In a second case a similar plan of treatment was followed by a like happy result. Dr. Reynolds emphasizes the importance of recognizing the earliest warning of impending coma, and lays stress on the following points: A distinct sense and appearance of increased weakness, slight drowsiness, pain in the left hypochondrium, labored respiration, the expiration being especially prolonged, an acetone-like smell in the breath and urine, lessened excretion of sugar, so-called acetone reaction (port wine coloration with perchloride of iron) in the urine, and albuminuria. When such symptoms are present the patient is in the greatest danger. The treatment is absolute rest in bed, moderate purgation, a slight relaxation of the diabetic diet, large doses of citrate of potash, and very large quantities of fluids taken internally; these fluids may consist of milk, lemonade, tea, water, or barley water; the quantity should amount to nearly a gallon in the twelve hours.—*Brit. Med. Jour.*

TREATMENT OF ASTHMA.

Prof. Dieulafoy (*Gaceta médica catalana*, Tomo XIV, No. 1) treats asthma as follows:

1. If the attack is just coming on, he applies the following to the interior of the nasal cavity:

℞ Cocain. muriat.....gr. xv.
Aquæ destillat.....f℥ v.

Or this solution may be applied to the nasal cavity or throat by means of a spray, a teaspoonful being thrown in in four or five minutes. If this does not suffice six to twelve drops of pyridin may be inhaled from a handkerchief, or three to four grammes (1 fl ʒ) may be poured upon a cloth and kept near the patient's chair. Stramonium leaves and nitrated paper may be stuffed into a large pipe in alternate layers and smoked if the attack is well under way.

If the attack is at its height, then one may inject half a hypodermic syringeful of:

℞ Morphin. mur.....gr. jss.
Aquæ destillat.....f3 ijss.

This usually has a sedative influence. Repeat in a quarter of an hour, if necessary.

2. In the intervals administer the iodide of potash, 1.50 to 2 grammes (22–30 grains) daily, commencing with 2.6 decigrammes (4 grains) a day, and increasing the dose to one, one and a half, and even two grammes (15, 22 and 30 grains), if the asthma be of long duration.

3. If the disease be of diasthetic origin give during fifteen days one to two grammes (15 to 30 grains) of the iodide of potash, to follow with fifteen days belladonna:

℞ Pulv. folior. belladonnæ.
Extract belladonnæ, aa.....gr. iij.
Sufficient for twenty pills. Commence with one-half a pill, increasing to one pill a day.

At the same time prescribe:

℞ Sodii arseniat.....gr. j.
Aquæ destillat.....f3 ijss.

This treatment should be continued three to six months.

4. If there be emphysema, inhalations of compressed air.

Residence in mountainous and elevated countries should be avoided. Strong odors are among the exciting causes.

RULES FOR THE ADMINISTRATION OF COCAINE.

Dr. Magitot, in the *Repertoire de Pharmacie* for August 10th, 1891, formulates the following rules which should govern the employment of cocaine as an anæsthetic:

1. The dose of cocaine injected should be appropriate to the extent of the surface desired to render insensitive. It should not exceed in any case 1 grain to 1¾ grains. Each dose should be restricted in large surfaces.

2. Cocaine should never be employed in cases of heart disease, in chronic affections of the respiratory apparatus, or in nervous subjects; and this exclusion applies also to other anæsthetics.

3. Cocaine should be injected into the interior and not under the derm of the mucous membrane of the skin. This is the intradermic method of Reclus, which should be substitututed for the hypodermic method. By this means the introduction of a substance into the vein is avoided and the risk of accidents therefore minimized.

4. The injections should always be practiced upon the subject in a recumbent position, and he should only be raised when the operation is to be performed upon the head and mouth, and then only after anæsthesia is complete.

5. The cocaine should be absolutely pure, since, as pointed out by Laborde, its mixture with other alkalies forms highly poisonous compounds.

6. Cocaine should be injected in divided doses, with a few minutes' intervals.

7. Suspension of administration, or, as the author terms the method, "fractional injection," renders it possible to guard against the production of sudden symptoms of poisoning.—*Therapeutic Gazette.*

IODOFORM INJECTIONS IN GOITRE.

Dr. Kapper, an Austrian military surgeon, has employed in fifteen cases, with invariable success, Mosetig's plan of injecting iodoform emulsion into soft thyroid tumors. In every instance there was a diminution in the circumference of the neck amounting to from 8 to 10 cm. Antiseptic precautions were employed, and in some cases where the tumor was of considerable dimensions several syringefuls were injected into different parts of the parenchyoma. In order to ascertain whether the needle has entered the gland the patient is asked to swallow, when, if it has so entered, the downward movement of the syringe shows that the needle has been carried upwards. In some cases the injections were repeated daily for several days, in others at intervals of a few days. In no cases were any untoward symptoms produced.—*Lancet.*

INTERSTITIAL INJECTIONS OF CAMPHORATED NAPHTHOL IN TUBERCULOUS ADENITIS.

Dr. Reboul, whose treatment of tuberculous glands by interstitial injections of camphorated naphthol has already been referred to, has recently made a further communication on the subject (*Sem. Méd.*, September 23rd, 1891). Since his first communication to the Paris Société de Chirurgie, in 1890, which was based on 27 cases, he has had 5 more, which added to 15 unpublished cases reported in an inaugural thesis by David, make a total of 47 cases. In 43 of these the cervical, in 1 the axillary, and in 3 the inguinal glands were affected. In 18 cases the glands were hard, in 24 they were softened, and in 5 they were ulcerated. Of the 47 cases 28 were cured and 19 improved. Of the 32 cases observed by Reboul himself, 19 were cured and 13 improved. The cure,

however, was not complete, that is to say, the tuberculous adenitis did not entirely disappear in all cases, but there could be no doubt as to the remarkable improvement and the favorable modification of the morbid process. The treatment is absolutely harmless, and seems to act beneficially both on the local and on the general condition.

Dr. Reboul, (*ibid.*) has treated in the same way three cases of tuberculosis of the testis. In one of them he injected some drops of camphorated naphthol through a fistula; in the two others the substance was injected interstitially into the tuberculous nodules on the epididymis and testis. The result was very marked, induration taking place with progressive diminution of the neoplastic formation, and closure of the fistulæ. More recently M. Reboul has treated two further cases in the same way, injecting four to five drops every eight or ten days. Whilst admitting that these cases are too few to warrant definitive conclusions being drawn therefrom, he thinks himself justified in affirming that as the result of the treatment the evolution of the disease was checked, the tuberculous nodules diminishing in size and the diseased parts becoming manifestly hardened, showing that a process of sclerosis had become which it might be hoped would lead to complete cure.—*Brit. Med. Jour.*

MEDICINE.

SPONTANEOUS LUXATION OF THE HIP AS A RESULT OF GONORRHŒAL COXITIS.

The *Centralblatt für Chirurgie*, No. 38, contains the record of a case in which Dr. Karewski, of Berlin, removed the head of the femur after disorganization of the hip-joint originating in gonorrhœal arthritis. In most instances of gonorrhœal affections of joints the effusion is speedily absorbed and all traces of disorder are removed, but occasionally very serious articular changes result. The acute inflammatory stage may be followed by fibrous ankylosis of the articular extremities of the bones, or it may lead to suppuration of the joint, and consequent disorganization. The subject of the case reported in this paper was a woman, aged 41, who shortly after an attack of gonorrhœa had been seized with very intense pain in the left hip. The patient was treated by rest, and the lower limb was placed with the thigh flexed, and the knee rotated outwards and abducted. When the case was first seen by Dr. Karewski after an interval of six months, the left lower limb was two inches shorter than the opposite limb, the trochanter was much elevated, and the soft parts of the extremity were much wasted. The hip-joint was very stiff, and the patient was unable to perform any active movement, and could not tolerate the least passive movement. On examination of the hip, whilst the patient was under the influence of anæsthetic, Dr. Karewski found that the head of the femur had been displaced, and no longer occupied the cavity of the acetabulum. The case was diagnosed as one of spontaneous luxation resulting from acute gonorrhœal monarthritis, and due to excessive effusion into the joint, and a faulty position of the lower limb. As reposition of the head was impracticable, and no improvement could be anticipated from extension of the limb, the head of the bone was excised. It was found dislocated beyond the upper margin of the acetabulum: the round ligament had been destroyed, and almost all the articular cartilage absorbed. The acetabular cavity was occupied by a large mass of succulent connective tissue. The patient made a good recovery.—*Brit. Med. Jour.*

THE VIRULENCE OF PNEUMONIC SPUTUM

Bordoni-Uffreduzzi (*Centralblatt f. u. Parasitenk.*, September 18th, 1891) has sought to determine the length of time during which pneumonic sputum, when dried by exposure to the air, retains its pathogenic activity. His procedure was as follows: The sputum was collected and dried in a room at the ordinary temperature, some of the sputum being exposed to diffused daylight for a number of days, the rest to direct sunshine for twelve hours. At intervals a little of the sputum was mixed with water and injected subcutaneously into a rabbit. Experiments made with the sputum treated as first described showed that the virulence continued for at least nineteen days, every inoculated rabbit dying within a few days. Indeed, some additional experiments prolonged the period of potency to fifty-five days. Sputum, on the other hand, that had been exposed to direct sunlight for even as long as twelve hours remained equally potent, a fatal result in each case following upon its injection. Clearly pneumonic sputum possesses considerable power of resisting both desiccation and sunlight. Bor-

doni-Uffreduzzi concludes that not only is it important to destroy the sputa of pneumonic patients, but that the sick-room should be disinfected as after other infectious diseases. —*Brit. Med. Jour.*

SUBCUTANEOUS EMPHYSEMA FOLLOWING BRONCHO-PNEUMONIA.

Dr. Damsch, of Göottingen, points out that the occurrence of subcutaneous emphysema in association with disease of internal organs is extremely rare. It is generally produced during some act of respiratory effort, such as straining, prolonged crying, violent vomiting, etc., but is commonly found to be limited within the alveolar or subpleural tissue of the lung itself—the so-called interlobular emphysema. This condition is not always productive of diagnostic signs, unless it spreads to the mediastinal tissues. Children are on all hands admitted to be more liable to rupture of the pulmonary alveoli than adults, but almost all writers agree that simple whooping-cough, unless accompanied by tuberculous or inflammatory disease, is hardly ever productive of subcutaneous emphysema. The latter has been produced by phthisis, especially where tuberculous ulcers are present in trachea or bronchi, and by other forms of disease tending to weaken the bronchial walls. The air, as a rule, passes from the mediastinum to the surface along the course of the great vessels. A case is recorded in which a gradually progressive condition of subcutaneous emphysema affecting the left half of the head, face, and body, showed itself in an infant, aged fifteen months, in the course of broncho-pneumonia of both bases. The emphysema attained a degree described as monstrous, but the child did not appear to suffer from it, becoming quietly somnolent until its death. On examination, it was found that extensive interstitial emphysema was present over the upper lobes of both lungs, forming several rows of tiny subpleural bubbles, some of them as large as a bean. The rest of the lungs, except where consolidated by the broncho-pneumonia, were somewhat dry and anæmic. The tissues of the mediastinum were emphysematous, but the pericardium was free, and the air was found to have reached the surface by the usual route.—*Deutsche Medicinishe Wochenschrift.*

ALBUMINATURIA.

In a communication presented to the Société de Biologie, Gaube (*La Médecine Moderne*, 1881, No. 23) described as albuminaturia a condition characterized by the presence in the urine of a small quantity of albumin in association with carbonates, or especially with earthy phosphates. Albuminaturia may be physiological, pathological, or experimental. Physiological albuminaturia is transitory; it accompanies pregnancy; in both sexes it follows coitus; in the female it follows menstruation. Pathological albuminaturia is protracted in duration and of grave prognosis; it appears in the course of extensive suppuration, or associated with changes in the nervous system. Experimental albuminaturia is a result of the stomachal ingestion of an excess of phosphates soluble in the urine, of which the excess is eliminated as albumino-phosphates. Calcic albumino-phosphate, the most abundant in the urine during the existence of albuminaturia, is a combination of albumin with the bibasic calcium phosphate, and has a rotatory constant of —92°. The urine of albuminaturia is scanty; it contains but a small proportion of urea, of mineral matters, and of phosphoric acid; it is scarcely acid; filtered, not acidulated and heated, a precipitate of the bibasic calcium phosphate is thrown down, soluble by the addition of one or two drops of acetic acid; the solution of the precipitate is followed by a cloudiness of the urine, dependent upon precipitation of albumin, insoluble by heat or acids, but soluble in alkalies. Albuminaturia is distinguished from ordinary albuminuria or serumuria, in addition to other physico-chemical characteristics, by the preponderance in the urine of the mineral over the proteid matters; in serumuria proteids predominate over mineral constituents.—*Amer. Jour. Med. Sci.*

SURGERY.

SURGICAL TREATMENT OF GRANULAR CONJUNCTIVITIS.

M. Darier, in a paper on this subject, gives the operative details of the treatment of trachoma in Abadie's clinic:

1. Anæsthesia by chloroform or ether.
2. The conjunctival surface being thoroughly exposed, the granulations are scarified and emptied of their contents.
3. By means of a brush, and sometimes of a curette when the tissue is hardened, the morbid tissue is completely removed.

Very thorough and energetic lavage sublimate solution (1–500).—*Bulletin Général de Thérapeutique*, July 30, 1891, p. 80.

FOUR HUNDRED AND FIFTY SIMPLE EXTRACTIONS OF SENILE CATARACT.

Greef (*Knapp's Archives of Ophthalmology*, vol. xx., part 3.) reports these cases, all done at Sweigger's Public Hospital, which give, as regards losses and secondary cataracts, very similar results to a series of 371 cases done with iridectomy, showing there is no more risk in the simple operation. The method of asepsis is the following: on the evening before the operation the skin around the eye to be operated upon is well washed with ether, and then with a 1 in 5,000 watery solution of sublimate, after which the eye is closed by a pad of borated cotton wrung out of a sublimate solution, which is removed just before the operation, then the eye is again irrigated with the sublimate solution. The instruments are kept in a 4 per cent. solution of carbolic acid, but before use are dipped in boiling water. The dressing is kept in a Koch's steam sterilizer, and placed directly on the eye from this. Since the employment of these precautions not a single case of suppuration has occurred in his private clinic, but in his public clinic these cases still occur occasionally.

TREPHINING FOR CONVULSIONS.

To the St. Bartholomew's Hospital Reports for the last year Dr. Calvert and Dr. Berry have contributed a case of some interest. The patient was a child of nine years, who had been rendered unconscious by a fall which bruised her head in the left parietal region, in June, 1888. Consciousness was recovered in half an hour, and with the exception of a little giddiness her condition was quite normal. On the next day she seemed quite well, but early on the following morning she had a fit, and fits continued to recur frequently, but they were slight, unattended with loss of consciousness, and limited to the right leg. In August, 1888, the right upper limb began to be involved in the convulsions, and about a year after the accident the face as well was affected. Rarely, however, did the convulsion spread to the left side of the body. On admission in March, 1890, nothing abnormal was discovered in the head; the fits were frequent, as many as 172 occurring in twenty-four hours, but varying in severity. The spasm usually began in the right index finger, spreading to the arm and leg of the same side. After several trials with bromine, which could only stop the fits at the expense of greatly depressing the patient, it was resolved to trephine, first over the arm centre. Nothing abnormal was discovered, except an unusual tendency of the brain to bulge. A similar negative result followed the removal of a second disc of bone over the leg area. That the correct areas were exposed was verified by the application of a weak faradaic current. After the operation the patient continued to have slight seizures, but with less frequency. On these threatening to become again very frequent small doses of bromide were exhibited, and these were continued, three grains thrice daily being given, with the result that no depression was produced, and the fits were so much reduced in number that during the three months from July to October she had had only ten slight fits in all. Although the patient cannot be described as cured by the operation, there seems little reason to doubt that she was materially benefited—as much, perhaps, as was to be expected considering the lapse of time between the accident and the operation.—*Lancet.*

ANTISEPSIS OF THE URETHRA.

The experiments of Petit and Wasserman confirm anew the fact that even thorough and prolonged antiseptic irrigation of the urethra is incapable of producing perfect antisepsis of the canal. The authors made their investigations on eleven patients suffering from various urethral diseases (prostatic hypertrophy, stricture, gleet, cystitis, vesical tumors). After careful disinfection of the glands and external meatus, the urethra was irrigated for from twenty to thirty minutes with boiled water, four per cent. boric acid solution, and a 1 to 1000 solution of silver nitrate. From one to two litres of each fluid were used. Notwithstanding these measures, however, bacteriological examination of the urethral secretions before and after the irrigations showed no material difference as regards the variety and number of bacteria.—*Centralbl. f. Chirurg.* No. 44, 1891.

OPERATIVE TREATMENT OF A CYST OF THE PANCREAS.

Albert (*Wiener Medizin. Presse*, No. 43, 1891) recently presented to the Royal Society of Physicians of Vienna a man upon whom seventeen months previously he had operated for a tumor of the pancreas. Clinically, there was a tumor, as large as the uterus at the end of pregnancy, situated in the epigastrium and sending a process into

the pelvis, the percussion-dulness of which posteriorly was indistinguishable from that of the liver and which was taken for an echinococcus of the liver. As, however, the stomach could be detected anteriorly to the tumor, a diagnosis of tumor of the pancreas was made and operation advised. When the abdomen was opened by a median incision and the transverse fascia divided, no translucent membrane was found; so that to enter the free peritoneal cavity, a second incision was made in the right hypogastric region, the tumor reached and punctured. After the cyst was evacuated, it was drawn forward, and a portion that appeared to protrude from the foramen of Winslow was removed. It did not seem advisable to remove the entire tumor, on account of the high mortality (50 per cent.) of such operations. For some time after the operation, a saccharifying and peptonizing fluid was discharged through the wound, progressively diminishing in quantity. The case was the third of tumor of the pancreas operated on by Albert.

GALVANO TREATMENT OF ENLARGED PROSTATE.

Morotti (*British Medical Journal*, May, 1891) describes the method of Bottini in the treatment of enlarged prostate. The "incisor" apparatus is constructed like a small lithotrite in which the male blade has been substituted by a platinum wire loop. The female blade is hollow to allow the passage of two streams of water, by means of which the apparatus is cooled off. An accumulator battery is used with the instrument. Chloroform is only occasionally required. Unless the bladder is quite empty no water need be injected. The instrument is introduced into the bladder, its beak reversed so as to press against the enlarged prostate and the current turned on. When the sound of burning is distinctly heard the point should be gently moved backward and forward until the lobe is divided. Contact for one minute made a scar one centimetre thick, and for two minutes double the size. The instrument should be allowed to remain *in situ* for two or three minutes, so as to allow it to become cool before it is withdrawn. After the operation Nelaton's catheter may be used. Bottini has operated on fifty-seven cases with two deaths. In thirty-two cases a perfect cure was effected, in eleven there was improvement, and in twelve the results were nil. Operation is contraindicated when kidney disease is present or even suspected.—*Univ. Med. Mag.*

GYNÆCOLOGY.

THE EARLY DIAGNOSIS OF CARCINOMA UTERI.

G. Winter (*Berlin klin. Wochenschr.*, August 17th, 1891) draws attention to the great importance of diagnosing cancer of the uterus at an early stage, in view of the success that now attends the operation of total extirpation. Out of 474 such operations performed for cancer in Germany, only 40 (=8.4 per cent.) have been fatal, while since 1884, 64 supravaginal removals of the cervix have been performed in Berlin without a single death. The primary results thus attained are highly satisfactory. In regard to permanent recovery, our knowledge is not so accurate as might be desired; but there are the reasons for thinking that about 25 per cent. of women operated on remain in good health five years after the operation. In view of these facts it is lamentable that only 28 per cent.—that is, about one quarter—of the cases of uterine cancer are operated on, and if of this number only a quarter survive for five years, not more than about 7 per cent. of patients suffering from uterine cancer are permanently cured. The chief reason for this is that women do not apply for hospital treatment sufficiently early. Sometimes the medical man who is consulted in the first instance fails to examine, and consequently does not arrive at the diagnosis. In other cases the unwillingness or dread of the patient prevents her applying for relief sufficiently early for operation. In a few cases the symptoms are so slow and insidious in showing themselves that the disease has progressed too far for operation when they do so. If only medical men were fully alive to the importance of an early diagnosis, if they were more familiar with the first signs and symptoms, many patients who now apply for help when it is too late to operate would present themselves at an earlier stage, and consequently many more lives would be saved.—*Brit. Med. Jour.*

IS A PESSARY OR A TAMPON NATURALLY INDICATED AS A SUPPORT?

This question is the outcome of remarks made by Dr. G. Betton Massey, of Philadelphia, before the New York Obstetrical Society, in which he advocated the abandonment of pessaries. He believes their extensive use by the profession is based on an unnatural theory. It was in contradiction of nature to place a skeleton in a woman's

vagina. Nature never placed a skeleton there, and he could not conceive of our improving upon nature in that one point. Nor had he ever been able to trace any distinct advantage to the use of the tampon as a support. He had found that a woman at all sensitive objected to the irritation of the tampon. Practically he had been able to reduce his use of pessaries to bad and chronic cases of movable retroflexions and very bad cases of prolapsus, which were hopeless from any other method of treatment. He thinks we should get rid of the ultra-mechanical view when discussing the subject of displacements. What some others called displacement he has classed under the head of metritis or endometritis, or of inflammatory conditions, with displacements complicating or attending upon them. He regards displacements as secondary, and thinks the cases may be divided into two classes—first, displacements with movable uteri; second, displacements with fixed uteri.

The electrical treatment in these conditions would so frequently effect a cure that we had no need to resort to a pessary. That which is at the bottom of nearly all such conditions was metritis. That cured, the displacement would take care of itself, whether it was anteflexion, retroflexion, version or prolapsus. He has seen numerous instances in which the uterus had ascended and taken its proper place simply because the over size had been reduced by galvanic or faradic treatment.—*Practice.*

CONTRIBUTION TO THE STUDY OF OVULATION AND MENSTRUATION.

Cohnstein (*Deutsche Med. Woch.*) undertakes in this article to determine whether an artificial irritation of the ovaries is capable of producing the vaso-motor reflex necessary for menstruation, and also what role special conditions, as, for example, irritation of the external genitals, play in the causation of the menstrual flow. In his investigations he employed women whose ovaries could be easily palpated, the object of his investigations being to determine whether menstruation could be brought on by manual compression of the ovaries.

His results are as follows: (1) There exists a periodical and causal connection between the ovarian and the catamenial functions. The ovarian changes precede the uterine, and determine them. (2) If the ovarian activity is suspended, neither menstruation nor any of the accompanying changes in the uterus occur. (3) Ovarian activity may occur without menstruation, as, for instance, during lactation. The functional activity of an ovary can be inferred from its reaction to irritation. (4) Menstruation can be brought on before its regular time, but it is always preceded by changes in the ovary, induced, for example, by irritation from pressure. (5) The ovaries seem to alternate in the production of follicles ready to burst. (6) That Graafian follicles can ripen at any time is not proven, nor can menstrual bleeding or uterine changes occur at any given time in the intermenstrual period.

OBSTETRICS.

LEUKÆMIA AND PREGNANCY.

Dr. C. E. Laubenburg, of Oppeln (*Arch. f. Gynäk.*, vol. xl, pt. 3, 1891) relates a case where a woman died of œdema of the lungs forty hours, after giving birth to a macerated fœtus in the twentieth week of development. She was 32 years of age, and had been pregnant ten times. She had aborted on the last three occasions, and for six or seven years her health began to grow bad, always getting worse at each pregnancy. During her last gestation she had all the signs of leukæmia. She lost but little blood during the labor, which lasted over twelve hours, the breech presenting. The uterus contracted well after the expulsion of the fœtus, although the mother was comatose during the last three hours of labor, and rapidly grew worse afterwards. Great enlargement of the spleen was discovered after death. On the evidence of a large number of cases, Dr. Laubenburg concludes that leukæmia may directly originate in disturbances associated with pregnancy, delivery, or childbed. Leukæmia is liable to cause abortion. It always appears to grow worse during pregnancy. The prognosis of a case of leukæmia is especially bad if the patient becomes pregnant. As many cases grow progressively worse as pregnancy advances, it is sometimes justifiable to induce abortion or premature labor after due consideration of the relative dangers of the disease and the operation.—*Brit. Med. Jour.*

WHITE OF EGG FOR CRACKED NIPPLES.

Dr. Frank Van Allen, of India, in a letter to the *New York Medical Journal*, says he has found white of egg to be the best remedy for sore nipples he has ever tried. The

nipple should be painted several times a day. The albumin may best be applied just after nursing, while the nipple is still moist from the baby's mouth. As somewhat of a thick film is formed, it is well for the nipple to be moistened with a soft cloth dipped in water just before the baby is again put to the breast. The efficiency of the albumin is heightened by allowing it to dry on thoroughly before drawing the clothes again over the breast. This soothing albuminous covering forms a delicate film over the abraded nipple, and the surface is soon—within a few hours, except in severe cases—entirely healed.

TETANUS AFTER ABORTION: ALLEGED INFECTION FROM CASE OF TRISMUS NASCENTIUM.

Professor G. Henricius (*Centralbl. f. Gynäk.*, August 15, 1891) had under his care at the Helsinfors Lying-in Hospital last winter a woman, aged 25. She was admitted on January 9th, with marked symptoms of tetanus, risus sardonicus, trismus, spasm of the muscles at the back of the neck, and retracted abdominal parietes. She had been married for one year. She aborted at the second month in July, 1890. Her last period was in October, 1890. In the first week of January she aborted; on January 1st a physician had hastily examined her, and entrusted her thenceforward to a midwife. It transpired that on December 20th, 1890, the same physician was called in to a case of trismus nascentium in a child aged six days; its umbilicus had ulcerated. The same nurse who attended Dr. Henricius' case dressed the infant's wound. It died on the day that it was first seen, December 20th. This nurse took charge of the case of abortion, and detected the ovum distending the os on January 3rd and 4th. On January 5th she was absent, and the ovum apparently came away. On the morning of January 8th the patient's lower jaw became stiff, the other symptoms of tetanus developed, and the case was sent into the hospital on the next day. The patient rapidly became worse. Chloroform inhalations, subcutaneous injections of morphine, etc., gave temporary relief. On January 10th an attempt was made to explore the uterus thoroughly; it succeeded, but no trace of the ovum was found, though some membrane came away. Nutrient enemata and chloral injections were given, but œdema of the lungs set in. The patient died on January 11th; the temperature was then 39.6° C.; it rose as high as 40.2° C. within three-quarters of an hour after death. The brain and cord were freely speckled with hæmorrhagic foci, the grey matter of the cord being of an almost uniform chocolate color. A polypus was found in the uterine cavity; it contained traces of decidua and chorionic villi. Professor Henricius concludes that "in all probability the tetanic virus was transferred from the child to the woman."—*Brit. Med. Jour.*

PÆDIATRICS.

TREATMENT OF DIPHTHERIA BY ICE.

Sevestre (*Soc. Med. des Hospitaux, Jan.*, 1891; *Revue Obstét. et Gynécology*), reports in behalf of a committee that diphtheria may be treated by the use of ice alone. Small pieces are inserted into the mouth of the child every ten minutes, day and night. This can be done without annoying the child, even though it be sleeping. The ice should be continued for some time after the membrane has disappeared. Sevestre does not recommend, however, that this be the sole treatment, but that it may be made a powerful adjuvant to the ordinary antiseptic medication of diphtheria.

PUNCTURE IN CHRONIC HYDROCEPHALUS.

Karnitzky (*Arch. für Ped.*, August and October, 1891) reports five cases of chronic hydrocephalus treated by puncture. In none of the cases did any complication follow the operation, which was performed with aseptic instruments. In two cases the child died; in one the head was tapped twice, in the other five times; in the latter death was due to diarrhœa, and considerable improvement followed the first tapping. In another case, tapped five times, the child was growing rapidly worse when last seen; one case was only under observation five days; in the fifth case—a female child, 11 months old, with a very large head, with extremely thin bones—six punctures were made during the course of a month; the circumference of the head was reduced from 70 to 62 centimetres, and when at the end of this time the child ceased to be brought for treatment, it appeared to be doing well.—*Brit. Med. Jour.*

SIMPLE TREATMENT OF RANULA.

The *Lancet* states that Dr. B. Hernandez Briz, of the General hospital, Madrid, writ-

ing in *La Andalucia Médica* on ranula in children, mentions a case of one of these tumors which was as large as a hen's egg, and which he cured in a very simple way. Intending to empty it, he inserted a needle of common hypodermic syringe into it in order to employ aspiration. The contents were, however, evidently too thick to come through such a fine tube. He then filled the syringe with a mixture of 10 parts each of tincture of iodine and water, with one part of iodide of potassium, and injected 15 min. of this mixture. Three days later the tumor was decidedly smaller. A second similar injection was given, and when the child was next seen, three days afterward, the ranula had almost disappeared. Several months have now elapsed, and there is no sign of the return of the tumor.

A CURE OF SANTONIN-POISONING.

J. A. Smith (*British Medical Journal*, June 6, 1891,) gives the case of a girl, three and a half years old, who had taken three grains of santonin in one dose. She had vomited once. There was no diarrhœa, no prostration, no rash; the pupils were slightly dilated, the temperature normal, the pulse 80. There was no true delirium, the chief symptom being the apparent change in the color of all objects, mostly to green. White appeared yellow, red and blue were changed to green. No object appeared its proper color. The urine was an intense saffron color. The symptoms disappeared after twelve hours.

HYGIENE.

WASH FRUITS BEFORE EATING THEM.

The following curious instance is reported in a French journal by M. Schnirer of the ease with which tubercle bacilli may be disseminated. While at work one day in the laboratory of Weichselbaum he sent for some grapes to refresh himself with. The fruit had been kept up for some time in a basket outside the laboratory, and was covered thickly with dust, so that the water in which it was washed was absolutely black. On examining the water he reflected that, inasmuch as the neighboring street was traversed frequently by consumptive patients going to the clinic, the dust probably contained the desiccated sputa of these patients, charged with tubercle bacilli. To settle this point M. Schnirer injected into three guinea pigs 10 cub. centim. of the water in which the grapes had been washed. One animal died in two days from peritonitis, the two others died on the forty-eighth and fifty-eighth days respectively, presenting marked tuberculous lesions, especially at the place of injection. The water in which the grapes had been washed was taken directly from the faucet, and the glass containing it had been sterilized; neither the boy who had brought the grapes, nor the merchant who had sold them, was tuberculous. Hence the cause of infection was beyond doubt the dust on the grapes. This experiment illustrates the danger arising from the dissemination of desiccated tuberculous sputa in the air. The conclusion is obvious: Wash grapes before they are eaten.—*Jour. State Med. Soc., of Arkansas.*

VACCINE MATERIAL FORMED BY STAPHYLOCOCCUS PYOGENES.

In a communication presented to the Académie des Sciences of Paris on October 5th, 1891, A. Rodet and J. Courmont (*Revue Scient.*, October 17th, 1891) give the following conclusions based on a series of experiments carried out by them with the staphylococcus pyogenes. Certain pathogenic microbes are able to produce simultaneously, in the same culture medium, both vaccine substances and predisposing substances, which, however, are perfectly distinct. The staphylococcus pyogenes is one of these in question. The vaccine material formed by this organism is precipitated by alcohol, whilst the predisposing substance is soluble in alcohol. In filtered cultures the action of the vaccine material is completely masked by the effect of the predisposing material. On heating for twenty-four hours to 55° C., however, this vaccine substance makes its appearance, so that it is possible that one may have to look for a vaccine from the soluble products of a pathogenic microbe which may not be formed under normal conditions, but which may be artificially forced.—*Brit. Med. Jour.*

MEDICAL CHEMISTRY.

DETECTION OF TRACES OF COPPER IN DISTILLED WATER.

According to H. Thoms, distilled water often contains traces of copper which escape detection by the usual reagents, such as ammonia or potassium ferrocyanide.

Such traces may be detected by dissolving in the water some potassium iodide. The water will acquire a yellowish color if only

1 part of copper in 200,000 parts is present. Of course, the water must contain no other substance capable of decomposing the iodide or liberating iodine.—After *Pharm. Centralh.*

NEWS AND MISCELLANY.

JOULE'S LAW DEMONSTRATED.

An experimental demonstration of Joule's law has been furnished by Professor Robert Spice, of Brooklyn. The method employed is to send a current through a known resistance, immersed in a known quantity of liquid, and also to immerse in the same liquid one set of junctions of a small thermo battery connected with a galvanometer. The other set of junctions are immersed in another vessel in a known volume of the same liquid, in which is another known resistance. If both quantities of liquid are heated by the current to the same temperature, the galvanometer will remain at zero, but not otherwise. The results of the experiments show that the rise of temperature of the liquids is proportional to the electrical energy expended.

SHALL DOCTORS DISPENSE THEIR OWN MEDICINES?

Slowly, but surely, the time seems drawing near when doctors will dispense their own drugs, and not run the risk of substitution, adulteration or repetition at the apothecary's shop.

The New York *Medical Journal*, of June 13, 1891, contains a letter on this subject written by Dr. A. W. Herzog, of Hoboken, N. J. He says: "If the druggist would content himself with the compounding of medicines according to physician's prescriptions, it would be useless to argue this question, as it would be more handy and time-saving for the physician to prescribe than to dispense. But it is different; not only does the druggist dispense the doctor's prescriptions, but he sells patent medicines and does counter prescribing as well."

He then takes the case of a young doctor just starting out, and gives his experience, which will be recognized as truthful by all who have started in large towns or cities in the last decade. How all the druggists in the neighborhood send nicely printed pads of prescription blanks with their trade mark on the back. "Have this put up at Blank's pharmacy." How they send a patient to the doctor when they can't sell a bottle of patent medicine or put up something themselves. How this state of affairs continues till some other doctor comes into the vicinity, when the same course is gone through with him also. How "all the doctors in the neighborhood will notice that their prescriptions not only get repeated for the same patient, but even for patients that they never saw. They will find that even the words *non repete* written at the top of the prescription will not remedy the evil."

Doctor Herzog closes his communication in the following words:

"As I said before, if the druggist would do no more or less than dispense our prescriptions, we doctors could and would be satisfied; but as it is now, when the druggist will not only sell and recommend patent medicines, distribute almanacs recommending the use of the same, sell his own rheumatic and gout cure, his own cough medicine; prescription No. 77,777, which will surely cure hæmorrhoids, and give all sorts of syrups and other things over the counter, not only when people ask for them, but also when they ask what is good for this or that; when they will stanch bleeding wounds, and use the stethoscope, and do other things utterly outside of their domain; when they will persuade patients to change doctors, sometimes by telling them so outright, sometimes by remarking that it is wonderful that just at present so many patients die on that doctor's hands, or by making some other remark of this kind. And then the question is laid before us: Shall doctors dispense their own medicine?"

The same journal in its issue of August 22nd, 1891, contains another letter on this subject from Dr. J. A. Wessinger, of Howell, Mich., who answers the question in the affirmative, and says further:

"Dispensing one's own medicine is a sure protection against the cupidity and (often) incompetence of the druggist. I am free to say that all druggists are not alike in this matter, but from personal experience I *know* some of them do practice the grossest violation of honor in the case of a physician's prescription. During the past three years I have dispensed my own medicines, and shall continue to do so."—*The Alkaloid.*

Hypnotism and crime seem to be becoming closely united, as in at least a dozen recent criminal cases the defendants have claimed to have acted under hypnotic influence.
